In order to throw more light on these relationships, test data were taken on pulverizers in a number of plants. In each case the principal data obtained were:

Rate of pulverization in pounds of coal per hour
Percentage moisture in raw coal entering the pulverizer
Percentage moisture in pulverized coal leaving the pulverizer
Temperature of air entering the pulverizer
Temperature of air leaving the pulverizer
Inlet and discharge pressures.

This information was obtained on sixteen pulverizers scattered over seven different states. Nominal capacity of the pulverizers varied from 2500 to 12,000 lb of coal per hr. More than 100 sets of determinations were made.

To indicate the primary relations in all of these tests, the temperatures of discharge from pulverizers and the temperature drops through the pulverizers were plotted against the temperatures of air supplied to the pulverizers as primary air, as shown in Figs. 2 and 3. Obviously the ordinates in Fig. 3 are the temperatures of air supplied to the pulverizers minus the ordinates in Fig. 2. In both these cases, points were plotted, giving no consideration to the size of the pulverizer, the amount of coal being pulverized, or the moisture content of the coal. The actual quantities of coal pulverized, as represented by the various points, varied from 500 to 12,000 lb per hr, and the moisture content of coal fed varied from 2 to 10 per cent. It is interesting to note that, regardless of all these variations, points in Fig. 2 representing the temperatures of air leaving the pulverizers, nearly all fell within a band having a width of about 65 deg. Also most of the points in Fig. 3 fell within a band of the same width. The writer does not attempt to explain this. It is known that those points falling largely outside this band were for conditions in which the coal was unusually wet. In Fig. 2 a line is drawn through the center of the band, representing the average discharge temperatures corresponding to the temperatures of air admitted to the pulverizers. This curve is nearly flat, changing only about 40 deg in discharge temperature over a range from 100 to 600 F in temperature of air admitted to the pulverizers. In Fig. 3 an average curve is also shown representing the average temperature drop of air in passing through the pulverizers in relation to the temperature of air supplied to the pulverizers. Because of the flatness of the curve in Fig. 2 the curve in Fig. 3 is necessarily steep.

In most of the plants in which data were taken, sufficient information was not obtained to calculate heat balances. In two plants, however, sufficient information was obtained; in one plant at six rates of coal grinding, and in the other plant at twelve rates of coal grinding. The heat balance was calculated for each rate of coal grinding in both plants, as shown in Tables 1 and 2. In principle, the calculation of the heat balance for a pulverizer is the same as that for a boiler. Primary air supplies a certain amount of heat which is determined from the weight of air, the temperature drop of the air in passing through the pulverizer, and its specific heat. A portion of the power used to drive the pulverizer is converted into heat within the pulverizer. The sum of these two quantities represents the total heat input. Heat is absorbed in raising the temperature of the coal, in evaporating and superheating the moisture, in heating leakage or tempering air, and in dissipation by radiation.

In both plants in which data were taken as a basis of these heat-balance calculations, hot air was supplied to the pulverizers from air preheaters. In neither case was tempering room air admitted to the pulverizers intentionally. Any such air entering the pulverizers occurred as leakage. In first making the heat-balance calculations, leakage was ignored, consequently the two sides of the heat balance did not check. It was obvious that the discrepancy was due to heat absorbed by air which leaked into the pulverizers. The amount of this air and the heat absorbed by it were then determined by differences. The determination of leakage then included the resultant of all errors in obtaining data. This accounts for the erratic figures in connection with leakage air. The curves in Fig. 4 give a picture of the amount of leakage

air. On the average, primary air varied from about 30 per cent of total air required for combustion at 3500 lb of coal per hr to 12 per cent at 8500 lb of coal per hr. Throughout this same range, leakage air varied from about 13 to about 11 per cent of the total primary air through the pulverizer and from about 3.5 to 1.5 per cent of total air of combustion. The average leakage was only slightly above 2 per cent of the total air of combustion. Generally in the cases of those boiler installations which have air pre-

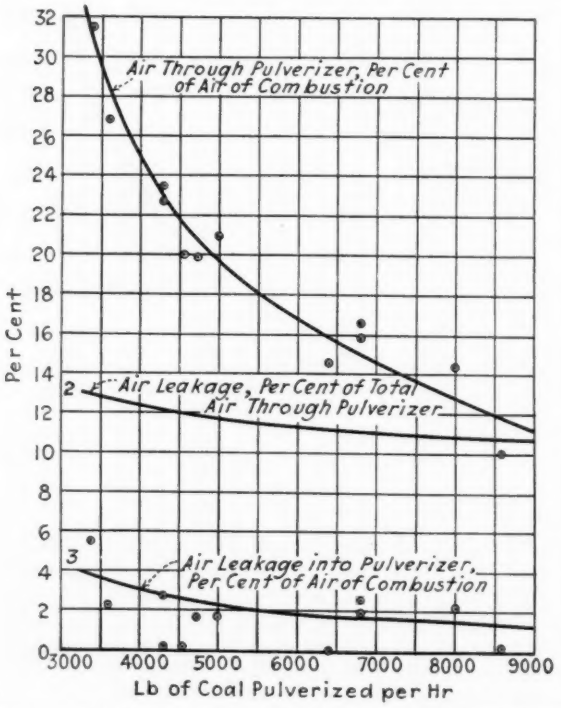

FIG. 4 AIR LEAKAGE AND TOTAL AIR THROUGH PULVERIZERS
(Data from Table 2.)

heaters, the amount of air passing through the air preheater will be from 80 to 85 per cent of the total air of combustion. From 15 to 20 per cent of the total air of combustion enters the furnace by other means. This leakage represents air which is not controllable in operation and which reduces the effectiveness of the air preheater. It is then desirable to reduce to a minimum the amount of combustion air which does not go through the air preheater. It is to be noted from Fig. 4 that the average amount of air leaking into the pulverizer is only about 2 per cent of the total air of combustion as compared to the total leakages from all causes of from 15 to 20 per cent in the ordinary installation.

It is indicated in the heat balances in Tables 1 and 2 that by far the greater portion of heat supplied to the pulverizer is absorbed by coal and by evaporating and superheating moisture. The coal used during the tests covered by Table 2 had somewhat more than the usual amount of moisture, from 5.8 to 9.6 per cent.

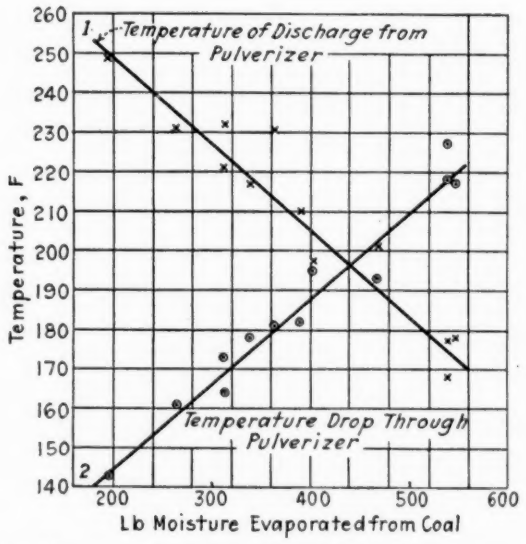

FIG. 5 MOISTURE EVAPORATED VERSUS DISCHARGE TEMPERATURE AND TEMPERATURE DROP
(Data from Table 2.)

The total weight of water evaporated from the coal varied from 392 to 643 lb per hr and the amount of heat absorbed by this moisture varied from 225,000 to 600,000 Btu per hr. Heat absorbed by moisture varied from 45 to 73 per cent of the total heat used and averaged 64 per cent. The temperature of air admitted to the pulverizer during all of the tests represented in Table 2 varied from 391 to 396 F and averaged 394 F. Since the temperature of air entering the pulverizer was so nearly constant and since the heat absorbed by the moisture was an unusually large percentage of the total heat absorbed, it would seem that in this case there was a fair relation between the amount of water evaporated, the temperature of discharge from the pulverizer, and the temperature drop through the pulverizer. Fig. 5 shows these relationships. It is to be noted that the range in temperature of discharge from the pulverizer is about 80 F although the temperature of air to the pulverizer is practically constant. A portion of the corresponding points in Fig. 2 are those which lie without the band. The reason for this peculiar arrangement of points is of course due to the large amount of heat absorbed by moisture and the large variation in total moisture evaporated.

The writer realizes that the amount of information presented in this paper is relatively meager and that no broad conclusions can be drawn from the results. It is expected however that these data will produce some interest, particularly on account of their relationship to air-preheater and boiler performance. The results indicate the need for additional tests in a larger number of plants burning a wider range of coals. The present tests were all made on pulverizers of a single make and similar information in connection with other makes would be desirable.

Atomization of Oil by Small Pressure-Atomizing Nozzles

By E. B. GLENDENNING,[1] A. R. BLACK,[2] L. H. VENTRES,[3] and W. A. SULLIVAN[4]

This paper develops the importance of atomization, carburetion, and oil characteristics for efficient combustion, and demonstrates the effect of pump pressure, oil viscosity, variation in oil temperature, and nozzle design on the rate of efflux and spray characteristics. It includes a study of hollow- and center-spray nozzles with relation to oil viscosity, aerodynamic design of the oil burner, and combustion efficiency.

THE DOMESTIC oil burner is expected to supply just the correct amount of heat to maintain constant room temperatures regardless of the outside temperature. It must do this without overloading the boiler or building too high boiler pressures. It must do this safely, economically, and with the minimum amount of attention. Economy is the feature with which this paper is concerned. Of the many factors affecting operating economy, one of the most important is atomization.

To offset physical limitations of the domestic heating plant which influence combustion, atomization and carburetion in the burner must approach perfection. In order to establish the definite relationship between viscosity and atomization and the combustion characteristics of fuel oils in domestic-oil-burner nozzles, an investigation was undertaken, the results of which are reported in this paper. All features of oil-burner design which might promote economy and efficiency of operation have been studied, particularly the construction of those parts which affect atomization of the oil and carburetion of the oil and air in correct proportions.

Principles of Oil-Burner Operation

The atomization of oil in a domestic high-pressure-atomizing burner involves a small pump, a pressure-regulating valve, and an atomizing nozzle. The nozzle comprises three essential elements, i.e., a stem with tangential slots, a conical swirl chamber, and an orifice. Atomization is the result of centrifugal action and pressure. The slotted stem imparts an initial tangential velocity which produces a rapid rotation of the oil within the conical swirl chamber. The swirl chamber converts as much as possible of the initial pressure into velocity by forcing the oil against the action of centrifugal force toward the center of the chamber. The orifice releases the oil to the atmosphere at a very small radius and at a high speed of rotation, while at the same time governing the quantity of oil delivered at a given pump pressure. Fig. 1 is a cross section through a conventional high-pressure-atomizing nozzle.

Effect of Atomizing Pressure on Spray Characteristics

In the authors' investigation a specially devised spray-testing chamber, Fig. 2, has been used to study the effect of atomizing pressure on spray characteristics. The following sequence will illustrate this effect on the development and evolution of the spray as the pressure is raised from a very low level upward until a stable atomization pressure is reached.

As the pressure is raised slowly from 10 lb per sq in., the oil, as it issues, goes through a fairly regular set of phases, culminating eventually in the fully formed spray.

At low oil pressures, the oil forms a "bubble" or "node" as it emerges from the orifice. As the pressure is raised there is a transition of the "node" into a "cup" or hollow hemisphere. In order to develop the spray fully after the point is reached at which the cup first forms, it is necessary to raise the pressure an additional 20 or 30 lb.

[b] Nozzle capacity.
[c] Spray angle, deg.

Table 1 contains the results of a series of tests on nozzles of various rate capacities in gallons per hour and spray angles in degrees. As a typical example consider the first nozzle, 1.35–60. The node forms at 10 lb per sq in. pressure. The transition from node to cup when the spray opens occurs at 30 lb. In this case the pressure must be raised to 75 lb per sq in. to establish the fully formed, stable-operating spray. It would be inadvisable to employ this nozzle to operate at pressures below 100 lb per sq in., since any increase in viscosity due to a slight fall in oil temperature would result in a reversion from full spray back to cup form.

Table 2 contains results of tests run on the same set of nozzles using 50-sec-viscosity oil. With the heavier oil, the nodes and cups were formed generally at higher pressures. Also, with few exceptions, full spray was developed at higher pressures. These results indicate that, in order to provide a reasonable margin of safety with these nozzles in cold weather, when the temperature of the oil is likely to drop below 50 F, a minimum pressure of 125 lb should be specified if 50-sec oil is used.

It will be noted that the margins between "full spray" and "safe spray" are not equal for all the nozzles in the group. The pressure for safe spray was selected to insure satisfactory operation for the group of nozzles as a whole on the particular grades of oil used, rather than for any individual nozzle.

Effect of Atomizing Pressure on Rate of Efflux

From the foregoing spray-chamber tests, it will be understood how pressure affects the nature and degree of atomization. It is natural to expect that pressure exerts a governing influence on the rate of efflux from an atomizing nozzle. Tests were run on a type-DR 2½ gal per hr nozzle having a 60-deg spray angle, to establish the relation between pressure and rate of efflux for oils of various viscosities. The results are given in Table 3.

[a] Viscosity, Saybolt Universal at 100 F.

The theoretical rate of discharge through a simple orifice varies with the square root of the pressure head. Experimental results on the nozzle fall short of the theoretical rates, the difference between the theoretical discharge from a simple orifice and

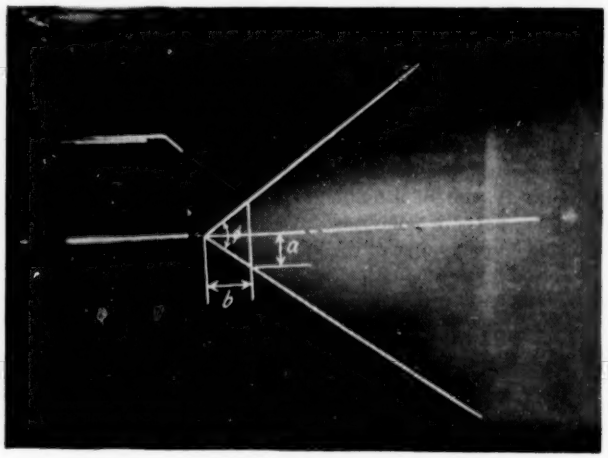

Fig. 3 Diagram for Measuring Spray Angle

the actual rate of efflux from the nozzle being more pronounced with the lower-viscosity oils.

Accuracy of Nozzle Calibration

Tests were run on several sets of nozzles in the spray chamber for the purpose of determining the accuracy of their calibration, as regards capacity and angle of spray. Table 4 shows results of

[a] Saybolt Universal at 100 F.

spray-chamber tests using an oil of 50 sec viscosity, Saybolt Universal at 100 F. The angle of spray ϕ is determined by measuring the distance a from center line to the outside of the spray cone at a distance b from the orifice, Fig. 3.

Table 5 gives the results of spray-chamber tests using an oil of 34 sec Saybolt Universal viscosity at 100 F.

The type-A nozzles ranged from 10 to 25 per cent over rated capacity on the 50-sec oil and 0 to 20 per cent over rated capacity on the 34-sec oil.

The type-NR nozzles ranged from 0 to 23 per cent over rating on the 50-sec oil and 8 per cent under to 3 per cent over rating on the 34-sec oil.

Influence of Oil Viscosity on Nozzle Capacities

From the test results given in Tables 3, 4, and 5, it will be appreciated that the capacity of a nozzle depends to a degree upon the viscosity of the oil which is being atomized. To develop more information along these lines, three different nozzles were calibrated on oils having viscosities ranging from 35 to 118 sec Saybolt Universal at 100 F. Then the slotted stem which fits inside of each nozzle was removed and the rates of flow through each of the straight nozzle orifices were determined. The same oils were used for each nozzle; a constant pressure of 100 lb per sq in. was maintained, and the temperature of the oil was held at 70 F. The resulting data are plotted in Figs. 4, 5, and 6.

The oils which were used were blends containing different proportions of No. 2 and No. 4 fuel oils. This was done for the purpose of obtaining oils of various viscosities without changing the oil temperature, thus making it possible to derive more accurate data regarding both the nozzle capacities and the angles of spray.

From Figs. 4, 5, and 6, it will be seen that the rate of flow through the straight orifices (the nozzles with the slotted stems removed) gradually diminished as the viscosity of the oil increased, which is to be expected in view of the fact that the higher-viscosity oils obviously have higher coefficients of friction and higher internal friction. The effect of viscosity changes on the output of the nozzles containing the slotted stems, however, was entirely different. Instead of dropping off, as the viscosity of the oil was increased, the rate of flow actually began to increase, until a point was reached at which the oil became so heavy that it could no longer be atomized. From this point on, any further increase in the viscosity of the oil reduced the output of the nozzles. It is interesting to note that the downward side of each of the nozzle curves takes on the general slope of the straight-orifice curves, i.e., they seem to drop off at about the same rate.

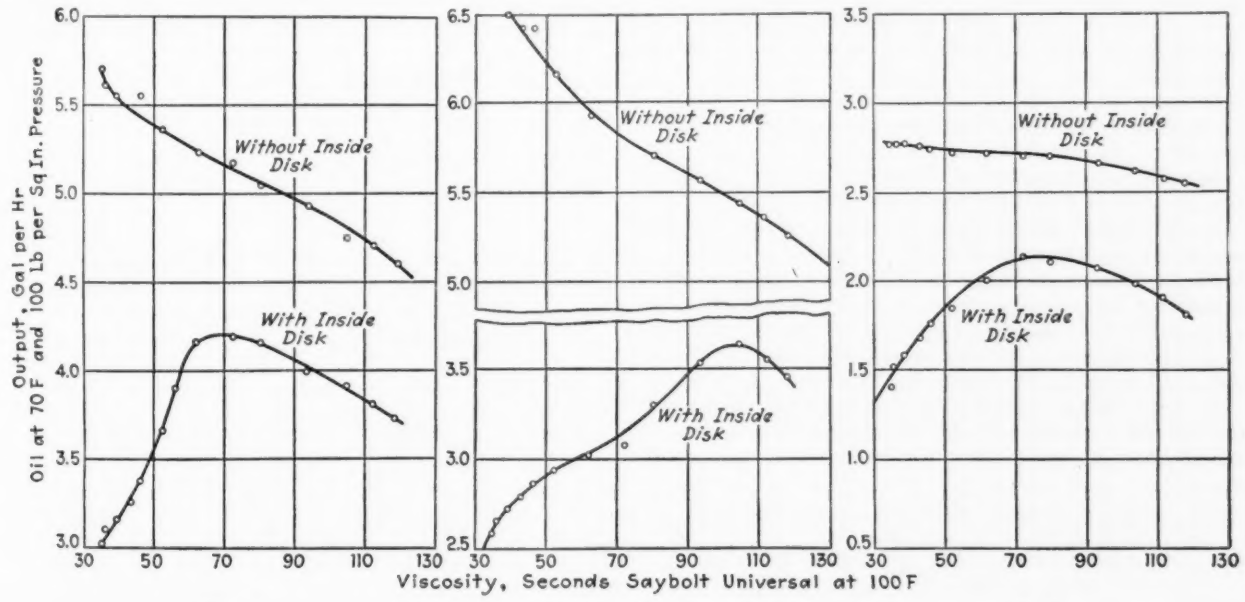

Fig. 4 Fig. 5 Fig. 6

FIG. 4 CURVES SHOWING EFFECT OF VISCOSITY CHANGES ON CAPACITY OF PRESSURE-ATOMIZING NOZZLE NO. 1
(Nozzle No. 1, rated 3 gal, 60-deg face, slotted stem.)

FIG. 5 CURVES SHOWING EFFECT OF VISCOSITY CHANGES ON CAPACITY OF PRESSURE-ATOMIZING NOZZLE NO. 2
(Nozzle No. 2, rated 3 gal, 60-deg flat face, slotted stem.)

FIG. 6 CURVES SHOWING EFFECT OF VISCOSITY CHANGES ON CAPACITY OF PRESSURE-ATOMIZING NOZZLE NO. 3
(Nozzle No. 3, rated 1.65 gal, 80-deg flat face, slotted stem.)

It should also be pointed out that all three of the nozzle curves did not break at the same point. In other words, all of the nozzles did not reach their peak output on the same-viscosity oil. The output of nozzles Nos. 1 and 3 (Figs. 4 and 6, respectively) began to drop off at 72 sec viscosity, but the output of nozzle No. 2 (Fig. 5) continued to increase until 104 sec viscosity was reached.

To understand how an increase in the viscosity of the oil causes this paradoxical increase in the nozzle output, one must consider the design and construction of the nozzle and the action of the oil as it is forced through the slots in the stem into the conical chamber, thence out through the nozzle orifice.

The slots are cut in the head of the stem at a tangent to the wall of the swirl chamber, so that the oil upon entering the chamber at high speed is given a rapid swirling motion which throws it to the sides of the chamber. This is similar to the action of any thin liquid when it is being poured through an ordinary funnel. Of course, the oil in the nozzle, being forced through the tangential slots in the nozzle stem under high pressure, swirls at a very high rate of speed. Thus, even as it leaves the cone-shaped chamber and is being forced through the orifice of the nozzle, it continues to swirl rapidly. Therefore, instead of a straight-flowing stream such as would result with an ordinary orifice, a swirling stream of oil passes through the nozzle orifice.

As soon as the stream is released to the atmosphere and is no longer restricted by the walls of the orifice, it breaks into millions of oil particles, each of which follows a straight line, the direction depending upon the relation of tangential velocity to axial velocity. The ratio of these two velocities determines the angle of the cone-shaped spray.

The lighter oils, due to their lower viscosities, are caused to swirl faster than the heavier oils, i.e., a greater proportion of the initial pressure is converted into rotative velocity. The oil, instead of filling the entire cross-sectional area of the swirl chamber and orifice, forms a hollow whirlpool moving along the walls of the chamber as a thin film, rotating at high velocity. The capacity of the nozzle is reduced due to the presence of the hollow core.

The more viscous oils, on the other hand, swirl at lower speed and more nearly approach solid or full flow in the swirl chamber and orifice. As full flow is approximated, the output curve tends to flatten out and reach a crest. When the viscosity of the oil becomes so high that it ceases to swirl in the nozzle to any appreciable extent, the resistance which the oil encounters in passing through the tangential slots in the nozzle stem and through the orifice determines its rate of flow. The resistance encountered here, of course, increases as the viscosity of the oil increases, which accounts for the fact that the nozzle output drops off with increasing viscosity, as soon as the centrifugal force of the swirling oil ceases to be a determining factor in the rate of flow.

The nozzle output increases as the viscosity of the oil increases until full flow is reached. At this point the rate of flow begins to drop off at the same rate as if it were being forced through a simple orifice.

[a] Oil pressure, 100 lb per sq in.

Swirl-Chamber Pressures

By drilling a small hole through the center of the slotted stem of a 4-gal-capacity nozzle and attaching a pressure gage (by means of a piece of small-diameter copper tubing which was inserted through the hole in the disk and soldered tight), it was found that the pressures inside the swirl chamber of the nozzle varied considerably when oils of different viscosities were used. The highest pressures were obtained with the lightest oils but, as the viscosity of the oil increased and the nozzle output increased, the pressure inside this chamber dropped off. However, when the point was reached at which a further increase in viscosity was attended by a drop in the rate of flow, the pressure in the chamber began to build up again. In Table 6 are given the oil pressures, inside the swirl chamber of the nozzles, which were recorded on different-viscosity oils.

The rapid rotation of the lighter oils inside the swirl chamber more than offsets the effect of the higher pressures, thus making it possible to force more gallons per hour of the 43-sec-viscosity oil through the nozzle orifice under 48 lb per sq in. pressure than the 34-sec-viscosity oil under 58 lb per sq in. pressure; the oil

pressure on the pump side of the nozzle chamber being the same in each case (100 lb per sq in.).

INFLUENCE OF VISCOSITY ON ANGLE OF SPRAY

A further study was made to determine the effect of viscosity of an oil on the angle of spray produced by pressure-atomizing nozzles. Generally these nozzles are constructed so as to produce sprays of any specified angle, from 45 to 90 deg. The angle is usually stamped on the outside of the nozzle along with its capacity.

However, it was found that the size of the spray angles produced by the nozzles tested were influenced largely by the viscosity of the oil used. Some of the nozzles were found to be much more sensitive in this respect than others depending on their design.

Eleven nozzles of different designs were tested on oils varying in viscosity from 34 to 92 sec Saybolt Universal at 100 F, with the oil temperature held at 70 F. Figs. 7 and 8 show graphically the variations in the angle of spray which took place in three of the more important nozzles of the group, as the viscosity of the oil increased. Nozzle A held its original angle of spray on oils up to 46 sec viscosity. From this point on the angle of spray became smaller as the viscosity of the oil increased. Over the entire viscosity range, the angle of spray dropped from 81 to 33 deg. Nozzle B held its original angle of spray on oil up to 36 sec viscosity. At this point there was a break and the angle of spray finally dropped to only 12 deg. Nozzle C was very sensitive. Its angle of spray varied slightly on all of the oils from 34 up to 43 sec viscosity. An increase in viscosity from 43 up to 46 sec narrowed the spray angle 20 deg. This nozzle produced its minimum angle of spray, 13 deg, on oil of only 62 sec viscosity.

It is interesting to note that both nozzles A and C attained their rated angle on 34-sec oil. However, nozzle B which was rated at 60 deg seems to have been improperly marked, since over the entire viscosity range of the oils used, its spray angles fall somewhere between those of the 70- and 80-deg nozzles. It would produce only a 60-deg spray angle when using an oil having a viscosity of approximately 48 sec Saybolt Universal at 100 F.

The explanation for this variation in the angle of spray goes back to the rate of speed at which the oil is swirling inside the nozzle and the relation between tangential velocity and axial velocity as it leaves the orifice. The construction or design of a nozzle makes it more or less sensitive to the viscosity of the oil.

The greater the ratio of tangential to axial velocity, the greater the tendency for the spray to widen, since the resultant velocity is the determining factor. As previously explained, the higher the viscosity of an oil, the lower the swirling speed inside the nozzle. Therefore, it follows that, as the viscosity of the oil increases, the spray angle decreases.

This is shown very effectively by the results obtained with nozzle C, Fig. 8. This particular nozzle is more sensitive to viscosity changes than nozzles A or B, because of the fact that the outside edge of the orifice in this nozzle is not countersunk or tapered to aid in directing the spray. Instead, the angle of spray is determined entirely by the length of the orifice bore. In a nozzle of this type, if a narrower angle of spray is desired, the length of the orifice barrel is increased. This of course, introduces a braking action on the rotation of the oil, thereby decreasing the tangential component of velocity.

The outside edges of the orifices in nozzles A and B are countersunk and tapered according to angle of spray desired. This has a stabilizing influence on the angle of spray which is quite effective when using the lighter grades of oil. But, as the viscosity of

the oil increases appreciably, the countersink becomes less effective, until finally the spray collapses and the oil comes out of the nozzle in almost a straight stream.

Influence of Variations in Oil Temperature on Character of Flame

By varying the oil temperature, similar changes in capacity and spray angle take place. The magnitude of such changes varies considerably with the viscosity-temperature characteristics of the oils used. An oil having a flat viscosity curve will cause

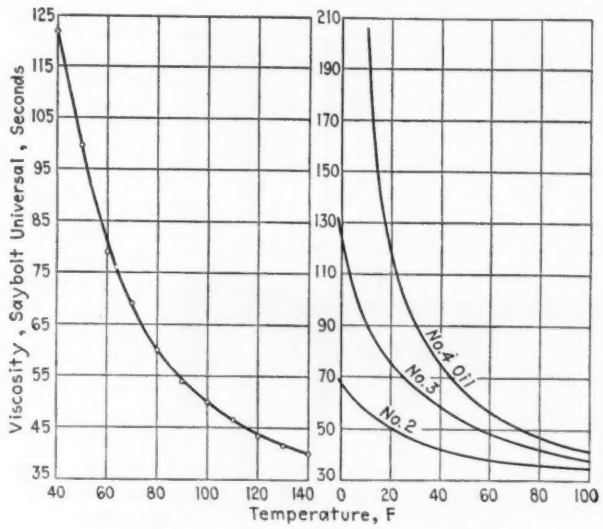

Fig. 10

Fig. 11

Fig. 10 Temperature-Viscosity Curve of Oil Used in Flame Tests

Fig. 11 Typical Temperature-Viscosity Curves for Nos. 2, 3, and Low-Viscosity No. 4 Oils

less change in nozzle capacity and angle of oil spray when the temperature varies than an oil having a steep viscosity curve.

Fig. 9 shows graphically, step by step, the extent to which the character of the flame, produced by a domestic high-pressure-atomizing burner, varies with changes in viscosity due to temperature and how the angle of spray narrows as the oil becomes more viscous. These are actual sketches of the flame, which were drawn as the tests were being conducted.

Fig. 9, sketch No. 1 shows a normal flame with oil temperature at 125 F. No. 2 shows but little change as the temperature is lowered to 116 F. In No. 3 sparks begin to appear, and in No. 4 the flame angle narrows as the flame lengthens. In Nos. 5 and 6 the condition becomes progressively worse as the temperature of the oil drops to 92 and 86 F, respectively. In Nos. 8, 9, and 10 the lengthening of the flame has progressed so far that it exceeds the length of the firebox and tends to curl around to the right. Note that the flame is becoming progressively narrower. No. 11 shows the flame beginning to smoke on the right as the temperature reaches 64 F. In Nos. 12, 13, and 14 sparks predominate. In the last four illustrations Nos. 15, 16, 17, and 18, the final breakdown of the atomization may be noted. The flame ultimately becomes long and stringy, producing clouds of smoke as the cold, poorly atomized oil impinges on the rear wall of the firebox.

The curve in Fig. 10 shows the viscosity of the oil used in this test at different temperatures. At 100 F the oil had a viscosity of 50 sec Saybolt Universal. Fig. 11 shows typical temperature-viscosity curves of three grades of light fuel oil. These curves illustrate the wide variations in viscosity-temperature characteristics of oils of similar viscosities at 100 F, which is the temperature at which light fuel-oil viscosities are generally measured.

Influence of Oil Temperature on Nozzle Capacity

Further tests were run on several nozzles of different types and sizes to determine the variation in rate of flow with oil temperature. Three different grades of oil were used, e.g., kerosene, No. 2 fuel oil, and No. 4 (Commercial Standards 12–35) fuel oil. The results are shown in Table 7.

It will be noted that in all cases the type-N nozzles showed a wider variation in capacity over the full range of temperature than the type-C nozzles. In comparing the different oils,

[c] Viscosity of No. 2 oil, 34-sec Saybolt Universal at 100 F.
[d] Viscosity of kerosene, 30-sec Saybolt Universal at 100 F.

it will be seen that in all instances the widest variations in rate of flow occurred with the No. 4 oil while the smallest variations resulted when kerosene was employed. The reason for this will be understood after considering the temperature-viscosity characteristics of the three oils used in the test. The obviously wider variations in viscosity of the heavier oils with temperature change accounts for the differences in capacity variations previously pointed out.

Effects of Nozzle Design on Combustion

Further work was carried out to determine what effect nozzles of different designs have on combustion efficiency when used in an average-size domestic burner of good design.

One important difference between nozzles used quite generally in pressure-atomizing burners is in the slotted stem which fits inside the tip behind the nozzle orifice. One type of nozzle employs a flat-faced stem, while another employs a stem which has a recessed face, thus enlarging the size of the swirl chamber considerably. The spray produced by the nozzles using the flat-faced stem comes out in the shape of a sharply defined hollow cone, having very little oil spray in the center. The nozzle using the recessed stem produces a spray which is also cone-shaped but, instead of being hollow, it has a considerable quantity of oil spray inside the cone.

In order to get a comparison between the nozzles using the flat-faced stem and those using the recessed stem, combustion tests were conducted on ten of each type, all twenty nozzles being made by the same manufacturer. These nozzles ranged in capacity from 1.35 up to 3 gal per hr, in both 60-deg and 80-deg angles of spray.

These tests were carried out using a well-designed, gun-type burner installed in a cast-iron, sectional, oil-burning boiler. A constant stack draft of 0.06 in. of water was maintained and the atomizing pressure was 100 lb per sq in. in each case. The temperature of the oils used was 70 F. In the case of each nozzle tested under these conditions, the fan shutter was opened just enough to prevent the fire from smoking; then CO_2 readings were taken as evidence of the quality of combustion obtained.

[a] Tests conducted at 100 lb per sq in. pressure.
[b] Saybolt Universal at 100 F.
[c] Fire impinging on sides of firebox.

The results of the tests are given in Table 8. It should be remembered that these figures are only comparative and cannot be taken as a measure of burner performance, especially in the case of the small-size nozzles. Better results could have been obtained with the small nozzles in a smaller boiler under different draft conditions, but these results give the desired comparison between the two types of nozzles.

On an average the figures given in Table 8 show that somewhat better combustion was obtained with the nozzles having recessed stems. These nozzles also produced better appearing fires. The flames produced by the nozzles using the flat-faced stems seemed to have a characteristic tendency to be stringy and lopsided, with long tips, while the nozzles with recessed stems produced shorter, bushier flames, which were more evenly spread over the firebox.

It must be pointed out that these conclusions regarding the performance of flat-faced and recessed-stem nozzles refer only to this particular class of burner. The recessed-stem nozzle producers a heavy center spray and is best adapted to a burner, the air delivery of which is such as to direct a fair proportion of the combustion air into the center of the oil spray.

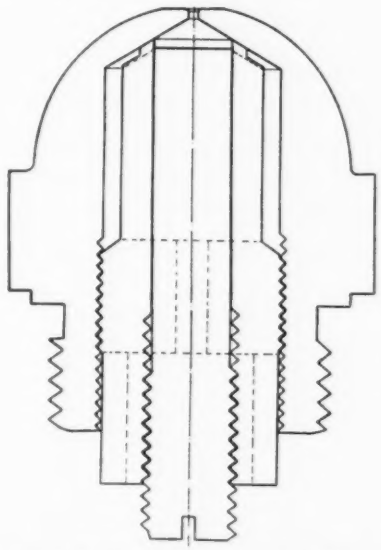

Fig. 12 Special Nozzle With Adjustable Recess in Stem

On the other hand, a nozzle with a flat-faced stem produces a hollow cone of spray which is best suited to a burner with an air tube partially blocked off in such a manner as to shield the nozzle and cause all of the air to envelop the hollow cone of oil spray. These features are now being adopted in building burners of very low capacities. The purpose is to increase air velocity, reduce air delivery, and insure proper carburetion.

The value of increasing the volume of the vortex or swirl chamber by recessing the stem was so marked that it was decided to run further tests to determine if possible the size of vortex chamber for optimum results.

Two type-D atomizers were prepared with special adjustable plungers in the stem, Fig. 12, to permit the depth of the swirl chamber to be varied from zero to 0.187 in. Table 9 shows the nozzle output and the per cent CO_2 in the flue gases for the two nozzles and two grades of oil. The tests were continued from 0.031 in. recess depth past the conditions of peak performance.

In the test of the 80-deg nozzle the recess depth for best results, using the lighter oil (34 sec viscosity, Saybolt Universal at 100 F) was 0.156 in. At this setting, the nozzle output was 3.08 gal per hr and the CO_2 reading 13.6 per cent. When the heavier oil was used (40 sec viscosity, Saybolt Universal at 100 F), the maximum CO_2, 13.8 per cent was reached between 2.96 and 3.15 (average 3.05 gal per hr) which is almost exactly the same burning rate. This would appear to indicate that there is one definite burning rate for a given nozzle which will insure optimum performance regardless of the viscosity of the oil.

As a check on this theory, a series of combustion tests was run on both of the special nozzles, using oils of viscosities ranging from 34 sec to 66 sec Saybolt Universal at 100 F.

Under set conditions of draft and atomizing pressure, the burner was adjusted for best combustion by means of adjusting the depth of the recess in the stem. After conditions of peak performance had been established, the burning rate was checked. In every instance, the rate checked within 3 per cent. Complete results of this series of tests appear in Table 10.

Effect of Atomization and Carburetion on Combustion

Twelve recessed-stem atomizing nozzles were calibrated, examined on the nozzle-testing apparatus to determine their spray characteristics, and tested in a burner under fire to determine the relative combustion efficiency possible of attainment with each nozzle, as indicated by the percentage of CO_2 in the flue gases.

In carrying out these tests, each nozzle was calibrated under 100 lb per sq in. pressure and an examination was made of the spray in the glass testing case, Fig. 2. Then the nozzle was tried out, under actual operating conditions, in an average-size modern burner of good design, which was installed in an oil-burning boiler having a firebox 15 in. wide by 24 in. long.

All tests were carried out on two different grades of oil, one having a Saybolt Universal viscosity of 34 sec at 100 F; the other having a viscosity of 50 sec. These two grades of oil represent the lightest and heaviest, respectively, in the range of fuels ordinarily used in pressure-atomizing domestic burners.

Unusually good results were obtained with this set of nozzles on both the light and heavy oil.

It will be noticed that, although the spray of some of the nozzles appeared to be one-sided when examined in the testing case, this apparently did not affect the fires they produced to any appreciable extent.

In most cases, changing from the 34- to the 50-sec-viscosity oil reduced the spray angle by from 10 to 20 deg, but in no case did this appear to affect the ignition of the oil or the quality of combustion obtained. In fact, not a single case of late ignition or ignition failure was experienced throughout the entire series of tests. The electrodes were set flush with the tip of the nozzle.

Upon studying the test results given in Table 11, it was noted particularly that the low-capacity nozzles, namely, those from 1 to 1.35 gal per hr, did not give as high a combustion efficiency as did the higher-capacity nozzles. However, from the standpoint of the cold tests, conducted in the special glass testing case Fig. 2, it was found that these nozzles had performed very well. Upon considering this matter, it was decided that the rather poor fire test, in the case of the low-capacity nozzles, was not due to any imperfections or to the design of the nozzles but rather to the fact that it was not possible so to adjust the air controls on the large burner as to obtain good carburetion or mixing of the air and atomized oil. Therefore, further tests were undertaken on these small nozzles, installed in a smaller burner especially designed to handle the lower burning rates.

[a] Two nozzles of the same rated capacity of spray were tested.

When a medium- or a large-size burner is used to burn a small quantity of oil it is difficult to secure the proper carburetion of air and oil. This occurs because the oil fog is blown out ahead of the large volume of slowly moving air. For good combustion it is

essential that there be an intimate mixture of atomized oil and air. This condition can be obtained only by providing air of the correct velocity and direction. Good atomization of the oil alone cannot produce the desired results.

From the figures given in Table 12, it is quite apparent that excellent results can be realized with these small nozzles, provided the burner is designed to operate efficiently at low burning rates.

Conclusions

1 One of the most important characteristics of an oil from the standpoint of atomization is viscosity. Viscosity influences nozzle capacity, angle of spray, degree of atomization, character of flame, and efficiency of combustion. Since the viscosity of the oil at atomizing temperature is of first importance, the viscosity-temperature characteristics of an oil must be taken into consideration.

2 Nozzle design has an important bearing on the character of the spray and the sensitivity of the nozzle to variations in the atomizing pressure and the viscosity of the oil. This calls for careful balancing of the sizes of the slots, vortex chamber, and orifice to produce the desired tangential and axial velocities at the exit of the nozzle.

3 Of particular importance for efficient combustion is the placement of the combustion air as it conforms with the shape and nature of the oil spray.

4 Efficiency of combustion and economy of heating with oil in domestic pressure-atomizing burners depends largely upon the selection of a nozzle having the proper atomizing characteristics, the correct aerodynamic design of the burner, and the use of an oil of correct and uniform viscosity.

High-Temperature-Steam Experience at Detroit

By R. M. VAN DUZER, JR.,[1] and ARTHUR McCUTCHAN,[2] DETROIT, MICH.

This paper is a continuation[3] of the one presented in December, 1933, in which the 10,000-kw, 1000-F turbine installed by The Detroit Edison Company, was described in detail together with the results obtained with various materials used in the construction of a small 1100-F superheater and piping system. The turbine installation was dismantled in 1937 after 26,453 hours of service and the 1100 F equipment has been continued in service for the further testing of materials.

The turbine operation has demonstrated the practicability of 1000-F operation. An examination of all principal materials used in the construction of the turbine, piping, and superheater showed that with several exceptions the alloys were in good condition. Measurements made to determine creep disclosed only small amounts.

The results of 1100-F steam-corrosion tests on 18 steels indicate that the scale formations offer material protection against subsequent steam attack and that the corrosion process is different in steam from that in air. A comparison of creep determinations made on four machined pipe sections—two in service at 380 lb per sq in. and 1100 F, and two in service at 380 lb per sq in. and 925 F—and laboratory specimens at the same temperature and stress tend to disprove the theory that total diametral elongation of a pipe subject to internal pressure is materially less than that indicated by tensile-creep tests.

IT SEEMS desirable at this time to record the final results obtained on the operation of the 10,000-kw, 1000 F turbo-generator installed in the Delray plant of The Detroit Edison Company, and to present data that have been obtained from an investigation of the materials which comprised the superheater, piping, and turbine. Results of steam-corrosion tests of various materials subjected to 1100 F steam and a field check of laboratory creep data at 925 and 1100 F which have been made in connection with the 1100 F experimental installation at the Trenton Channel plant also are presented.

Early in 1937, operation of the 1000-F installation was discontinued, as it was felt that sufficient experience had been obtained with the turbine definitely to prove the practicability of using 1000-F steam. The addition of 815-lb, 900-F capacity to the Delray Plant made it possible to have the 1000-F turbine rebuilt into a superposed unit which will use steam at the new conditions and exhaust into the existing 400-lb, 700-F system.

Since the last report of this installation in December, 1933,[3] the unit had operated satisfactorily until shut down in February, 1937. The installation had been in service a total of 26,453 hr of which 22,896 hr were with steam at 1000 F. The turbine has been dismantled and those parts of the high-pressure cylinder not reused in the rebuilt unit were cut up and examined. Samples were taken also from the piping system and different parts of the superheater.

In general, all materials examined were in good condition with the possible exception of the 18 per cent Cr, 8 per cent Ni, 2 per cent Si alloy tubing used in the superheater. This tubing, which operated with metal temperatures from 950 to 1150 F, still possessed good tensile properties. In nearly all tube samples tested, however, the impact values were extremely low and the steel was susceptible to intergranular attack, the result of chromium-carbide formation. There is no reason, however, to believe that the brittle superheater tubes would not have continued to serve for a considerable length of time. The 18 per cent Cr, 8 per cent Ni alloy pipe castings, without the high silicon addition, were in excellent condition.

The experimental 1100 F superheater and piping located in the Trenton Channel plant have been continued in operation for the testing of original materials and others which have been added from time to time. This equipment, up to Oct. 1, 1938, had been in service a total of 48,361 hr, of which 38,921 had been at 1100 F. It will be recalled that this apparatus was placed in service during 1929 to try out materials and methods of construction for later use in the design of the 1000-F turbine and superheater at Delray. Present efforts in connection with this equipment are being devoted to determining the steam-corrosion resistance of a group of steels and the creep properties of several accurately machined pipe sections. The scope of investigation was recently enlarged by lowering the steam temperature in a section of the line to 925 F.

The corrosion resistance of 18 different steels has been determined after subjection to 1100-F steam. Nine of the materials have been examined after 7500 hr of service, while the remaining number have been inspected after 3800 hr. The results so far obtained indicate that the initial scale formation offers material protection against subsequent steam attack except in the case of straight carbon steel. These data also indicate that the process of air and steam corrosion are entirely different.

The inability to secure satisfactory measurements of creep on the equipment at the Delray and Trenton Channel plants,

[1] Engineer, production department, The Detroit Edison Company. Mem. A.S.M.E. Mr. Van Duzer received the degree of B.S. in mechanical engineering from the University of Michigan in 1927. Following graduation he spent two years at the Marysville power house of The Detroit Edison Company as testing engineer and operator and was then assigned to the staff of the chief engineer of power plants. One of his assignments has been the supervision of the experimental work involved in the two high-temperature installations of the Company using steam at from 1000 to 1100 F. Other assignments have been supervision of power-plant-piping design and the operation of three small steam plants.

[2] Engineer, engineering division of The Detroit Edison Company. Junior A.S.M.E. Mr. McCutchan was educated at Monmouth College, Illinois, and the University of Michigan from which institution he received the degree of B.S. in mechanical engineering in 1926. Since graduation he has been engaged in mechanical-engineering studies with The Detroit Edison Company.

Contributed by the Power Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

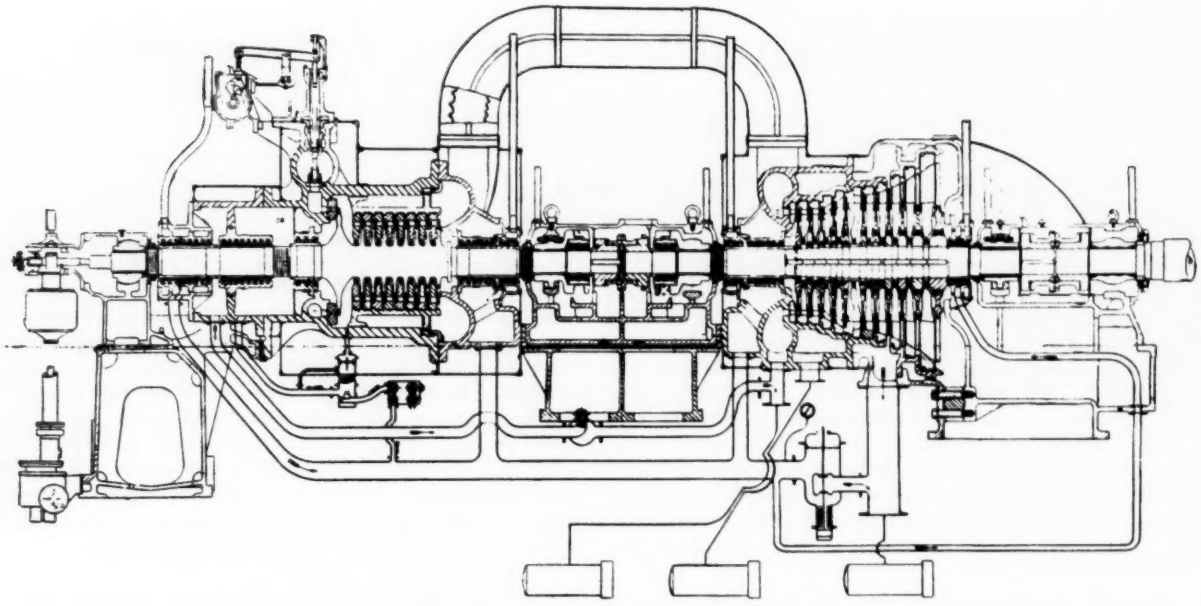

FIG. 1 CROSS SECTION OF DELRAY TURBINE

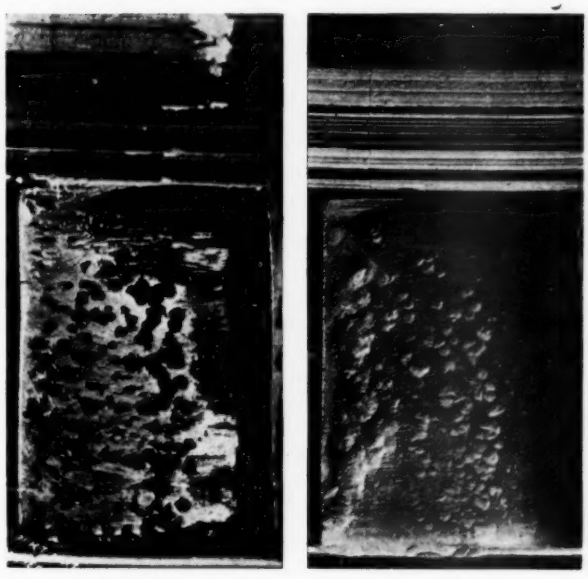
because of the low design stresses, led to the installation of four machined tube sections in which the stresses were sufficient to produce measurable creep in a fairly short period. Two of these tubes, made from Cr-Mo-Si alloy, were subjected to 380-lb, 1100-F steam, while the others of C-Mo tubing were placed in service at 925 F with the same pressure. The creep rates obtained on the first two sections have agreed fairly well with laboratory values, while those obtained on the latter sections at the lower temperature have not given such a good correlation; the diametral elongations are much greater than would be expected from laboratory results.

The subject matter of this paper has been divided into two parts; that describing the turbine installation, and that dealing with data obtained from the Trenton Channel 1100-F superheater and piping system. In the first part, the operating experiences not previously recounted[3] are detailed, as well as an account of the physical changes measured and observed. The metallurgical results obtained on twelve specimens are discussed in some detail. The Trenton Channel portion of the paper describes the steam-corrosion results obtained on a group of 18 steels, the correlation between laboratory and field creep measurements made on two low-alloy steels, and physical properties of several materials removed from service.

THE DELRAY INSTALLATION

It will be recalled that the Delray installation consisted of a two-cylinder, 10,000-kw turbogenerator, auxiliaries, connecting piping, and an oil-fired superheater utilizing 400-lb, 700-F steam which was superheated to 1000 F. The purpose of the installation was to obtain operating experience with high-temperature equipment and to determine the effect of this steam on the materials then available. A cross section of the turbine is shown in Fig. 1 in which the principal parts may be distinguished.



Operating Experience. The turbine was placed in service in October, 1930, with 700-F steam, pending erection of the superheater, and was first operated at 1000 F in November, 1931. From that time until the machine was dismantled in February, 1937, the unit had been under load for 26,453 hr, of which 22,896 were with steam at 1000 F.

The operation of the equipment, and particularly that of the turbine, was most satisfactory. Few of the troubles encountered with the turbine were directly traceable to high-temperature operation except in the case of the turbine stop valve. The principal repair encountered was the replacement of this valve. The bonnet flange which, because of the valve design, functioned as a line flange, was entirely too light for the steam conditions involved. The replacement valve was designed to approximate the 900-lb American Steel Flange and Fitting Standard, and used an oval ring-type gasket for the bonnet joint. This valve gave reasonably good service, although it was necessary to remake the joint twice, at about 6000-hr intervals. The nitralloy bushings of the five control valves and the throttle valve, installed in place of the original special cast-iron parts, gave no trouble and, except for a few spots where a scale 3 to 5 mils thick had formed and flaked off, the inner surfaces were in excellent condition.

Considerable trouble developed during the first two years of operation, when placing the turbine on the line, because of vibration caused by shaft deflection. This condition, worse when the machine was still warm after a short shutdown, was partly corrected by more rapidly increasing the vacuum. On several occasions vibration was so severe that it was necessary to stop the unit and allow it to cool thoroughly before restarting. Had the turbine been equipped with a turning device for maintaining a straight shaft, these starting troubles would not have been encountered.

During the latter part of 1933 the high-pressure shaft packing was examined and found severely rubbed. The packing, a high- and low-tooth segmental design, was refitted with a total diametral clearance of 18 mils. The turbine from then on ceased to be temperamental and gave no further trouble from vibration during the starting cycle. The previous method of adjusting the packing had been to allow it merely to touch the shaft and then run the turbine for a day at 200 rpm to wear a clearance.

A check of the shaft alignment during the packing refit showed the front of the cylinder to have moved 0.024 in. toward the left and 0.020 in. upward in relation to the shaft. This accounted for the severe rubbing and the excessive shaft deflection during starting, the result of localized heating. A subsequent check in 1937 showed the cylinder 0.032 in. toward the left and 0.015 in.

(a) After 1450 hr service (b) After 23,896 hr service (View with illumination from left.)

FIG. 2 FIRST-STAGE BUCKETS SHOWING INDENTATIONS, ×1.9

upward in relation to the shaft. This change in alignment leftward of 0.012 in. plus the 0.009-in. original radial clearance corresponded closely to the radial packing clearance of 0.023 in. as measured in 1937.

The condition was caused undoubtedly by warping of the front of the high-pressure cylinder, the result of uneven heating, a supposition further substantiated by measurements made on the top of the steam chest. This surface, approximately 6 ft long, was found to have bowed down from 0.012 to 0.015 in. at the center. The partial-admission governing system with which the turbine was provided allowed steam to be admitted through each of five individual nozzle groups around the periphery of the first-stage nozzle ring. Steam to each of these sectors passed from the steam chest through cored passages in the cylinder. Seventy-five per cent of the running time at 1000 F was at a load requiring steam to one nozzle section only, which probably caused sufficient thermal stress to be set up to account for the distortion observed.

No damage to the bucket and shrouding assembly was noted as the result of impact imposed on the first-stage wheel by the partial admission of steam. This is in contrast to reported experience with some of the recent higher-capacity 3600-rpm units using steam approximately three times as dense. There was evidence of slight rubbing on the inlet edge of the bucket shrouding on the second, sixth, and eighth wheels. This occurred only in spots and probably was the result of shaft deflection during starting periods.

No effort was made to keep a record of the availability of the turbine because of the experimental nature of the equipment. Regular and emergency maintenance of the other plant apparatus had precedence, and as a result, the installation on numerous occasions was out of service for periods much longer than otherwise would have been necessary. The longest intervals of continuous operation were four of 3 months each. The machine was started 50 times from November, 1931, to February, 1937; over half the starts were made during the first two years of this period.

Maintenance in the superheater was not considered excessive after insulation at the back of tubes in the bottom section was rearranged to provide more clearance for thermal expansion. The protecting tile on the fire side of the tubes did not fall off in quantities as was the case before this change was made. The superheater was not removed from service when the tiles dropped from the tubes as had been the practice before the lower part of the setting was rebuilt. There was no apparent damage to the exposed radiant tubes from this method of operation.

The joints in the piping system, not welded or provided with a welded seal, all gave some trouble, except one joint between the turbine stop valve and steam chest. There the bolts and flanges were left exposed to provide sufficient strength in the assembly at their lower temperature to maintain the joint. The joints at the center-pressure globe valve at the superheater outlet which was built to the 600-lb A.S.A. standard gave the most trouble, as was to be expected. The period between repairs of from 4000 to 6000 hr was lengthened by the use of compensating springs of a hairpin shape on each bolt. All the experience with the line indicated the desirability of welded construction to insure freedom from periodic maintenance.

A group of pictures is included here to show the condition of parts after prolonged exposure to the high temperature.

The condition of the inlet edge of the first-stage buckets is shown in Fig. 2. At (a) is a photograph showing a bucket as

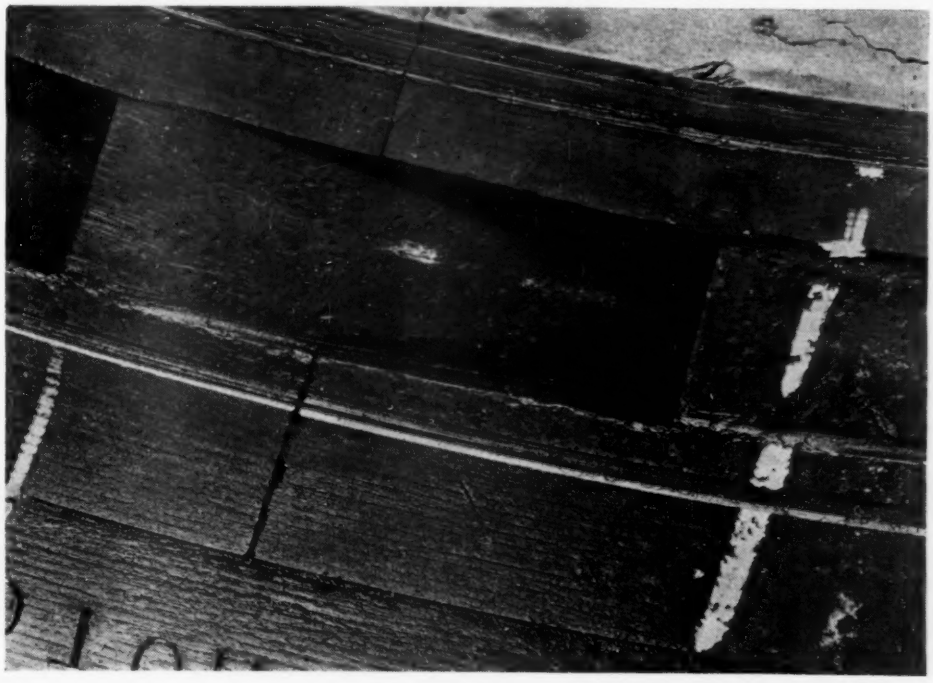


FIG. 3 SECTION OF FIRST-STAGE NOZZLE RING AFTER SERVICE, ×2.2

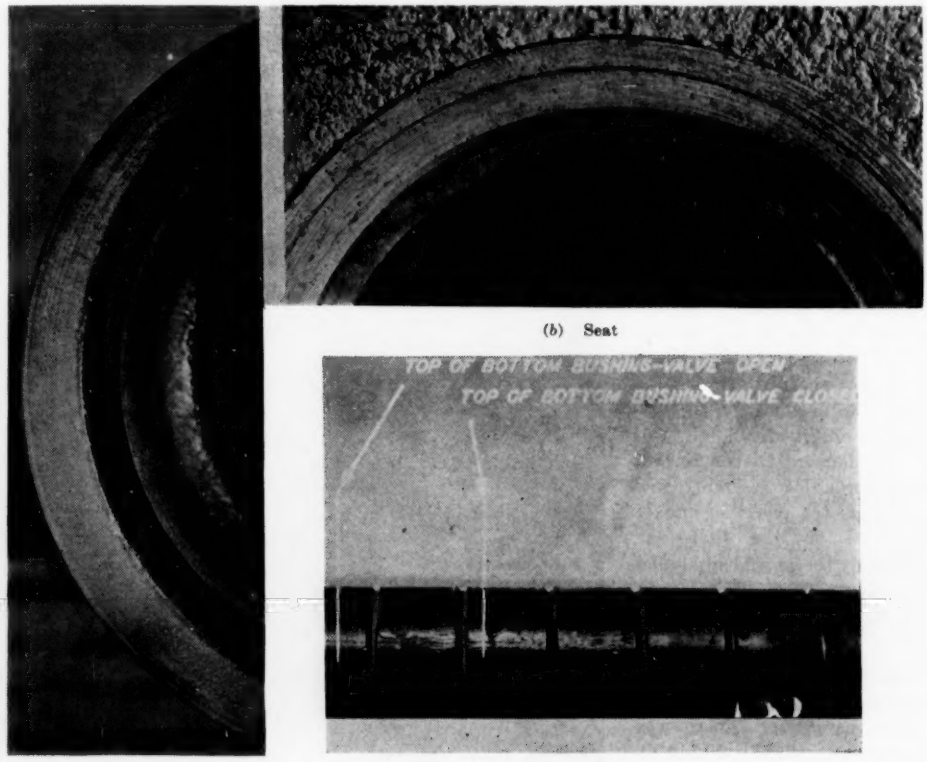
FIG. 4 SECTION OF SECOND-STAGE DIAPHRAGM AFTER SERVICE

cleaned in 1932 after service for 1450 hr at 1000 F. The dark areas are indentations caused by welding beads which were small enough to pass through the steam strainer. The picture at (*b*) is of the same bucket taken in 1937 after 22,446 additional hours with 1000-F steam. Here the light areas show the same indentations. The photograph shown in Fig. 3 was taken at the same time as that in Fig. 2(*b*) and shows the condition of the one partition in the first-stage nozzle ring. It will be observed in both views in Fig. 2 that the buckets are tight whereas the illustration of the nozzle, in Fig. 3, shows that the sections have tended to separate and in the upper-right corner, the seal weld has cracked. The only changes noted in the second-stage diaphragm, shown in Fig. 4, were slight indentations caused by the passage of welding beads. The composite construction used withstood service much better than the nozzle ring.

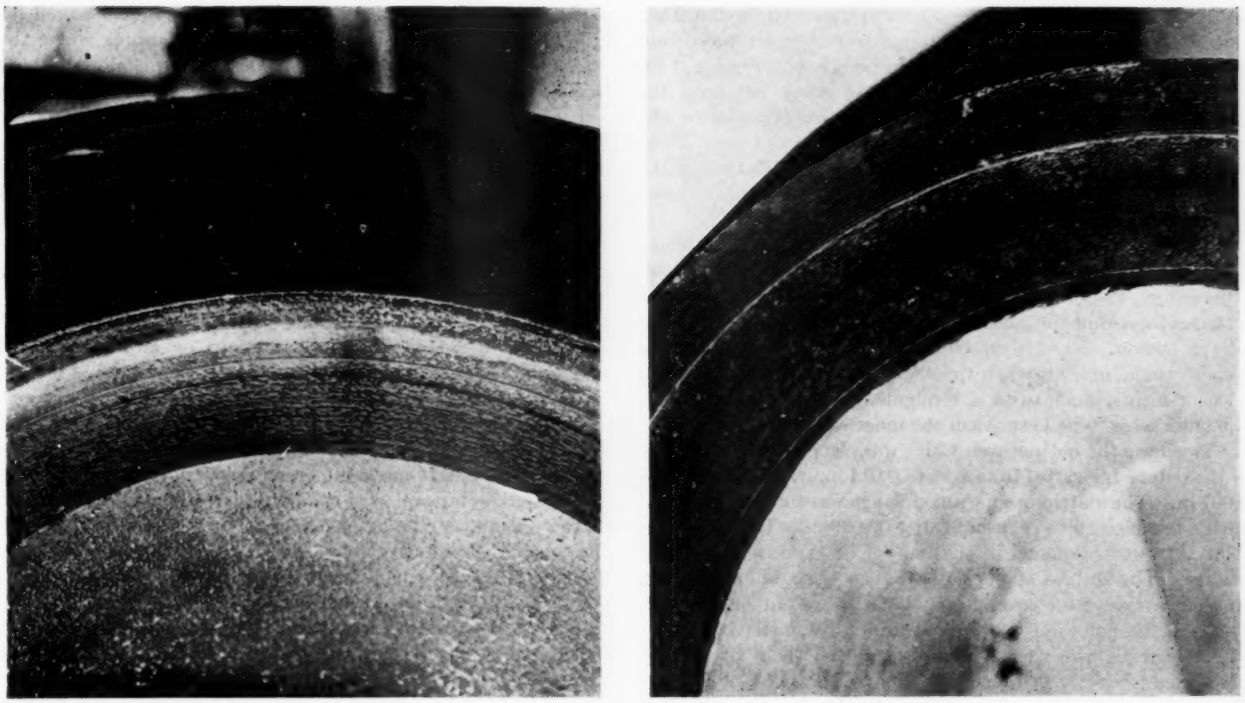
Fig. 5(*a*) shows the condition of one of the control-valve disks. The condition of this valve is representative of that of the other valve disks and seats. This material was a low alloy of the following percentage composition: 0.5 C, 1.3 Cr, 2.6 Ni, and 0.6 Mo. Typical conditions of the control-valve seats and stems are shown in Fig. 5(*b*) and (*c*). The seat material was the same as that used in the disk. The stem material was stainless steel, 18 per cent Cr and 2.5 per cent Si. The scoring shown was caused by the kinks which developed in all the stems. The scoring was not serious, however, as it did not progress to the galling stage.



One of the causes of leakage of bolted joints using metal gaskets is plastic flow of the joint faces resulting from the high compressive stresses. Two examples of this condition are shown in Fig. 6. At (*a*) can be seen the indentation, 0.009 in. deep, in a casting joint face caused by the narrow monel gasket, 0.39 in. wide. At (*b*) is shown the groove in the vanstone lap of the adjoining 8-in. low-carbon, 18 per cent Cr, 8 per cent Ni tubing. It was necessary on several occasions to regrind the joint faces after leakage occurred because of this type of creep. No evidence was ever found in any of the leaking joints of steam cutting, in contrast to experience with lower temperatures and pressures.

A more detailed description follows of the various changes which were noted, the result of creep.

Creep Determinations. Measurements made on various parts of the equipment have shown that in all except a few cases change of shape caused by plastic flow or creep has been negligible. Deformations were so slight that differences in measurements before and after service in nearly all cases could have resulted from measuring errors.



The one case in which plastic flow necessitated a replacement was in connection with the turbine stop valve, mentioned previously. Measurement extending over a period of nearly 8000 hr showed parts of the valve body to be increasing at a rate of over 6 per cent per 100,000 hr. On one occasion distortion caused binding of the valve disk and it was possible to keep the bolted bonnet joint tight only for short intervals. The replacement valve, in service for 15,000 hr and designed approximately to the standard dimensions of the 900-lb A.S.A. flange, showed a rate of increase less than 0.5 per cent per 100,000 hr.

The other cases of trouble from creep were leakage of bolted pipe joints. Leakage resulted, not only from extension of the bolts and flange dishing, but also from deformation of the flange

(*a*) Disk (*b*) Seat (*c*) Stem

FIG. 5 SECTION OF CONTROL-VALVE PARTS

(a) (b)

FIG. 6 INDENTED FLANGE FACES
(Average depth of indentations, 0.009 in.)

faces caused by compressive creep, a result of the large compression stresses imposed by the metal gaskets. The only remedy for this situation was periodic maintenance.

Numerous measurements were made in the superheater. The average rate of change in diameters of tubes in the top portion of the middle tube bank in the superheater for the total operating period of 22,896 hr at 1000 F showed the following:

Tube material, per cent	Steam temperature	Design stress, lb per sq in.	Creep rate, per cent per 100,000 hr
2½ in. 0.30 to 0.40 C, 7/16-in. wall	925 F	2000	4.0
2 in., 18 Cr, 8 Ni, 2 Si, No. 6 gage	925 F	4300	0.4

Measurements made on 1-in. steel and alloy tubes in the lower portion of this bank to determine axial change were not reliable. The alloy tubes exhibited either negative or no change while the 0.3 to 0.4 per cent C steel tubes showed positive creep rates of from 0 to 1.5 per cent per 100,000 hr. These tubes were exposed to the combustion chamber and operated with metal temperatures of about 925 F while carrying steam at from 800 to 850 F. The alloy tubes, 2 in. OD × 1/4-in. wall, in the lower section showed little change in length, roughly at a rate not over 0.25 per cent per 100,000 hr. No changes in diameter were noted in an intermediate header, 18 per cent Cr and 8 per cent Ni, at 925 F and stressed at 7400 lb per sq in. In all cases where length measurements were made, the accumulation of dirt in the measuring holes interfered with accuracy. Where diameters were obtained results were more satisfactory.

Few changes of magnitude were noted in the piping system other than at the bolted pipe joints. Changes in the 8½-in. OD, 5/8-in. wall, low-carbon, 18 per cent Cr, 8 per cent Ni tubing at the point of maximum bending stress were small. One length measurement in the horizontal plane decreased 2 mils in 20 in. and the diameter in the vertical plane increased 2 mils, indicating that a bending moment caused flattening.

The behavior of the pipe line from the superheater outlet to the turbine inlet was investigated to determine the amount of expansion and to determine any permanent change in position. The difference in position from the cold to the hot checked very well with the calculated expansion used in design. No information was obtained, however, as to any permanent change in the assembly because the line and hangers were disturbed a number of times to repair joint leaks. The whole experience with this line indicated the desirability of welded construction for trouble-free operation even though joints of the 900- and 1500-lb A.S.A. series were used for the 400-lb, 1000-F steam condition.

Changes observed in the turbine were small, and at the rate of change found, there is no reason to believe that the economic life would not have been equal to that of machines designed for lower steam temperatures.

Accurate measurement of the changes in the diameters of the first- and second-stage wheels was not obtained. The measuring points provided were damaged by foreign matter passing through the unit. The bucket connections were tight and there is reason to believe that any creep was of small magnitude. Change in length of the steam chest was at a rate of less than 0.1 per cent per 100,000 hr. Ten measurements made on the high-pressure cylinder showed both positive and negative rates of change of from −0.25 to +0.35 per cent per 100,000 hr. The negative changes found indicated slight distortion of the casting, probably caused by the relief of original internal stresses. The average unit change of these measurements was 0.0004 in. per in., neglecting the direction of change. The stresses used in the design of the casing and steam chest were under 5000 lb per sq in.

A number of the machined-joint faces in the high-pressure cylinder assembly were examined to find the amount of distortion from the original plane condition. The admission-

nozzle-ring seat, 40 in. OD × 26 in. ID, located on the inner face at the front end of the high-pressure cylinder was found warped to a varying degree around the periphery. See Fig. 1 for the location of this vertical joint. At some sections, the inner edge of the joint face was 0.005 in. lower than the outer edge. At other sections, the reverse was true. These changes undoubtedly had some part in causing cracking of the seal welds and changes found in the nozzle-ring assembly shown in part in Fig. 3.

The vertical joint face on the outside of the cylinder to which the split shaft-packing casing was bolted also was found changed. This flange, 48 in. OD × 32 in. ID × 2½ in. thick, was on a 12-in. extension of the casing and reinforced by three webs, one at the bottom and two spaced at 120 deg. The readings obtained would indicate that the flange face had been scraped. Measurements, made with a straightedge and feelers, showed the outer edge to be lower than the inner except for a section of the face near the bottom web which was plane. The depression of the outer edge varied from zero to 0.014 in. with an average of 0.007 in. The matching companion flange was substantially true with a few high spots of from 0.001 to 0.003 in. The horizontal joint between the halves of the inner split cylinder showed no change. The surface of the outlet flange of the outer cylinder was plane except for several low spots, the result of scraping. Steam at this point in the cylinder was approximately 700 F.

The changes which have been observed on the high-pressure casing may have been caused in part by the relief of internal stresses set up by the rather complicated heat-treatment given this casting. The casing was annealed and then quenched in oil from 1562 F and drawn after rough machining.

The nozzle ring was found to be distorted but not to an extent that would have impaired its reuse. The ring consisted of five nozzle sections, steam to each of which was controlled by a valve. The nozzles were mortised and doweled into inner and outer forged rings and then seal-welded. Cap screws holding the ring in place passed through each ring. The inner ring had shifted toward the first-stage wheel from 0.014 to 0.026 in. or an average of 0.019 in. In the bottom 120 deg of the assembly, the nozzles had separated from the inner edge of the outer ring an average of 0.007 in. and a maximum of 0.016 in. Practically all the seal welding had cracked. The maximum distortions occurred in the first- and second-nozzle sections which were the ones in use during the larger part of the running time. In all probability, most of this distortion was caused by the thermal stresses set up when steam was admitted to an individual section. The nozzles themselves were straight, and apparently had not changed in shape.

Some growth and distortion were found in the bushing and stem assemblies of the control and throttle valves. The control-valve bushings, of nitralloy, were made in two parts and the stems were made from a stainless steel containing 18.7 per cent Cr and 2.5 per cent Si. The bottom end of the lower bushings decreased in diameter from 1.524 to 1.523 in., while the upper end of these bushings and the bore of the upper bushings were substantially unchanged. The stems were all bowed toward the low-pressure end in varying amounts up to 0.050 in., caused, no doubt, by the stress imposed by impact. They were scored for from 2 to 3 in. at the bottom of the upper bushing where the clearance changed from 0.025 to 0.005 in. A nitralloy bushing and a 1.5-in. 18 Cr, 8 Ni stem were used in the replacement throttle valve. The bore at the end of this bushing, subjected to 1000-F steam, had decreased in diameter between 0.002 and 0.005 in., while the cold end of the bushing remained unchanged. At the time this valve was placed in service the stem clearance of 0.006 in. had been insufficient because of a decrease of 0.003 in. in the bushing diameter which occurred after 3 days' operation. The stem was ground to provide a total of 0.015 in. clearance and gave no further trouble.

The measurements made to show the changes due to creep were augmented by metallurgical examinations on all the principal materials, the results of which are given in the following section of the paper.

Metallurgical Examination. All the principal types of material were cut up and examined to determine changes in structure and physical properties. In most instances the results obtained were compared with properties of samples of the alloy in the as-received condition. Samples of materials as used in the completed parts of the installation were secured at the time of purchase, in nearly all cases, for later comparison to determine changes that occurred during service. These samples included tube ends, cast test bars heat-treated as the original part, and so on. In the case of the turbine parts reused in rebuilding the unit for higher-pressure operation, it was possible to secure samples for examination from all high-temperature materials except that of the forged Ni-Cr-Mo rotor.

Several of the samples taken from the superheater and piping system and examined are listed in Table 1. The physical properties obtained from the materials in this table are given in the tabulation of results in Table 2, except in the case of sample No. 4 from which it was impossible to cut sound specimens. Only the results of examination of one typical superheater tube are included, although several were thoroughly examined. The specimens removed from sample No. 2 were considered representative of the group of castings, 18 per cent Cr and 8 per cent Ni, at the outlet of the superheater.

The values obtained on the superheater-tube samples, 18 per cent Cr, 8 per cent Ni, and 2 per cent Si, showed that this material deteriorated in service. Examination of tubes from cooler parts indicated that the embrittlement progressed as the temperature increased, being more severe in the furnace tubes.

Samples of used and unused tubes were boiled in acidified

copper sulphate (Strauss solution) for 72 hr to determine the susceptibility to intercrystalline corrosion. All unused material showed no change in electrical resistivity whereas all the used samples disintegrated in the solution. Specimens from the casting, sample No. 2, showed no change in this test, whereas the $8^1/_2$-in. tubing showed a 58 per cent increase after the test. Previous work has shown that the low-carbon variety of 18 per cent Cr, 8 per cent Ni steel will become restabilized after prolonged exposure and entirely resist the attack of this solution. Another fairly definite proof of the embrittlement of material No. 1 was the fact that the impact fractures were intercrystalline rather than transcrystalline, as was the case in the unused material examined.

The typical structure of the tube before and after service is shown in Fig. 7, which represents the greatest change that took place during service. In connection with the tube examination, the structure of a tube flash weld was examined. Fig. 8(*a*) shows the typical structure of a weld before service, while at (*b*) is shown the condition of a similar weld after service. A definite grain structure has been formed by recrystallization. An examination of the structure of the 4-in. casting showed that the dendritic pattern present in the unused sample was changed to a distinct hexagonal-crystal structure.

Tubes of 0.35 per cent C steel surface-protected by calorizing and metal spraying had been installed in the middle section of the superheater to observe the surface protection afforded by the two coatings. The aluminum coating of the calorized tubes was still partly intact, while the sprayed 18 per cent Cr, 8 per cent Ni coating had nearly all disappeared allowing considerable scale formation and decarburization of the tube wall.

The structure of the 8 × 10-in. reducer, sample No. 3 shown in Fig. 9, is typical of that for a casting. After service, the grain had become more equiaxed and some grain growth had occurred. Likewise, considerable carbide migration had taken place. The condition of the 8 × 10-in. reducing ell is shown in Fig. 10. A number of inclusions are evident and the partial formation of pearlite can be observed in the after-service section. The microstructure of the $8^1/_2$-in. tubing underwent some change as evidenced by some grain growth and migration of chromium carbide to the grain boundaries. A summary of investigations on similar material from the Trenton Channel 1100-F installation is contained in a following section of the paper.

One of the field position welds in the 8-in. line was cut up and examined and the tensile strength of standard pipe-wall coupons taken across the weld was found to vary from 38,000 lb per sq in. at the bottom to 62,000 lb per sq in. at the top of the joint. The corresponding variation in elongation was from 2 to 6 per cent. The weld was made without a backing ring, and lack of penetration and cracks in the first bead account for the low strength. A position test weld made prior to the field weld gave corresponding tensile strengths of from 65,000 to 75,000 lb per sq in. with elongations of from 13 to 17 per cent, respectively. The Izod

impact value of the test weld was 42 ft-lb as against 22 ft-lb in the field joint. The carbon content of the weld metal in both cases was 0.07 per cent. As a safety precaution, joints of this type had been provided with bolted backing-up flanges in anticipation of weld embrittlement, which might have caused failure of the joint.

The materials listed in Table 3 are those which comprised all the high-temperature parts of the turbine with the exception of the forged rotor and bolting.

[b] Contains 1.80 per cent Al.

The physical properties of these materials are given in Table 4. In the case of sample No. 11, only photomicrographs were taken. Sufficient material for physical tests other than impact were not obtained from the used turbine buckets. It was possible in the case of the high-pressure casing to compare the effects of both 700- and 1000-F service.

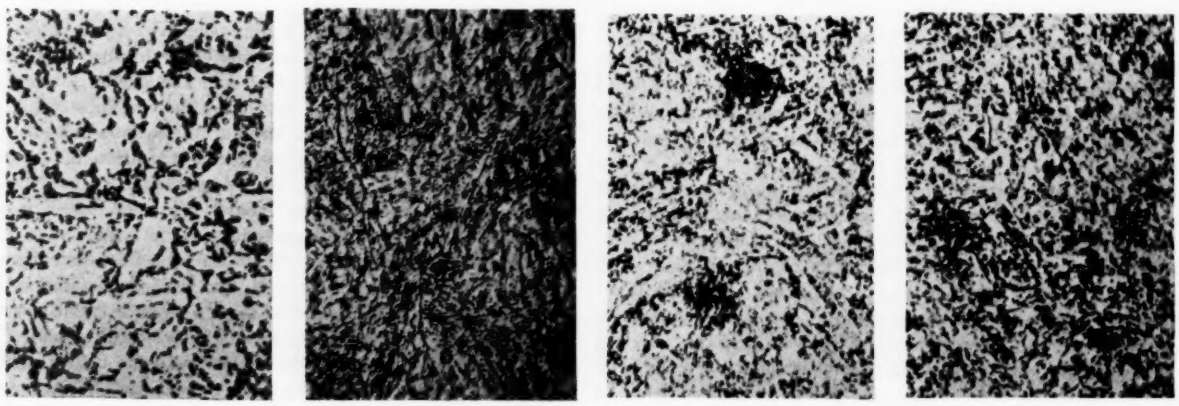
[i] Rockwell C.

The results obtained on the Ni-Cr-Mo steel used for the original throttle valve and casing, samples Nos. 6 and 7, are rather interesting in that a range of time and temperature conditions is given. The results indicate that the material underwent changes due to service, but that the change did not progress at a uniform rate. The properties of the throttle-valve material for instance, changed approximately the same in 8000 hr as the decrease exhibited by the casing material during 23,000 hr of service. The material from the exhaust end of the casing, while not having lost as much in tensile strength, showed about the same ductility with an appreciably lower impact strength. Part of the apparent discrepancy in the ductility values shown may be in part explained by inclusions always present to some degree in a cast structure.



The various conditions of the structure of these samples are shown in Fig. 11. The material is extremely fine-grained both before and after service. Other sections etched to reveal carbides showed them to be evenly distributed throughout the used specimens. Their presence probably accounted for the increase in hardness shown in Table 4.

The results obtained on the C-Mo casting, sample No. 8, are of particular interest because the chemical composition is identical with that which is being used extensively in recent high-temperature-steam equipment. The differences in physical properties found in the before- and after-service condition were

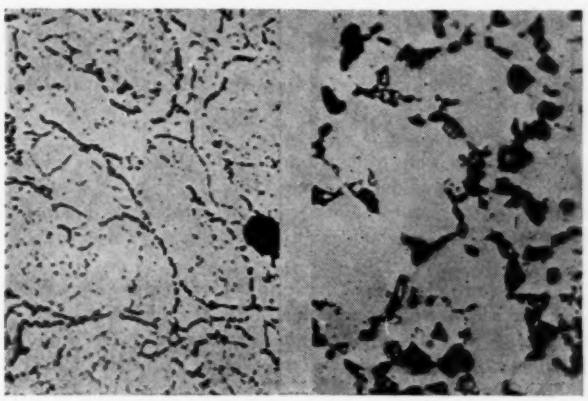
small and may be accounted for, again in part, by the number of inclusions which were present. These undoubtedly were responsible for the low impact values obtained. The structure of this alloy before and after service is shown in Fig. 12.



Although the impact values obtained on the new and used material of the first-stage bucket, sample No. 9, show no change in this property, the microstructure as shown in the set of pictures in Fig. 13 indicates that a change has taken place. The grain size has increased and the crystal structure in the used specimen is clearly outlined by the chromium-carbide migration to the grain boundaries. Samples of both the new and used material were subjected to the Strauss test to determine change in electrical resistivity with the result that they both disintegrated during the test. This is in direct contrast to the findings of French investigators who have reported on similar tests no attack by the copper-sulphate reagent.[4]

The condition of the second-stage bucket material before and after use is shown in Fig. 14. Apparently the only effect on the structure was that of aging which accounts for the darker condition of photograph (*b*). The material remained in a fine-grained condition and was identical with that observed in a section of a ninth-stage bucket. The impact results were somewhat erratic. Those values reported in Table 4 show a higher value for the used buckets, whereas results obtained on 0.394 × 0.228-in. notched Izod specimens gave 75 ft-lb for the new and 34 ft-lb for the used, with one of the latter specimens breaking at 13 ft-lb.

The second-stage buckets operated in a temperature range of from 790 to 900 F at from 40 per cent to full load. The corresponding range for the first stage was from 810 to 925 F. The maximum temperature at the ninth stage was 700 F.

Sections of the 18-in. nitralloy bushing removed from the original throttle valve are shown in Fig. 15. That shown at (*a*) was from the cold end exposed to atmosphere, while the section shown at (*b*) was taken from the 1000-F end. Some scale is evident on both sections and the extensive diffusion of the case, the result of long exposure to temperature, can be observed at (*b*). The hardness had dropped from a Brinell of from 690 to 730 at the cold end to approximately 560 at the hot end. This reduction had not changed the serviceability of the part.

Structural changes of the control-valve stems, sample 12, can be seen in Fig. 16. This material had deteriorated to such

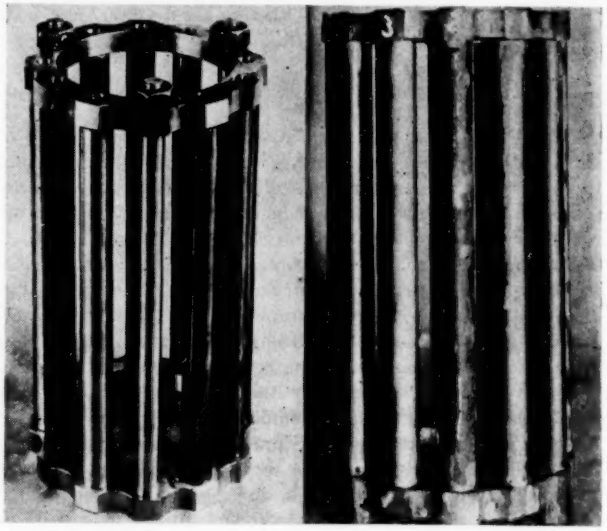
an extent that had the stems been subjected to continued stress or any shock, failure might have resulted.

The Trenton Channel Installation

The experimental work that has been undertaken at Trenton Channel during the last several years in connection with the 1100-F superheater installation, aside from the service testing of the original and replacement materials, has been that of determining the extent of steam corrosion and securing of accurate creep information on pipe. The corrosion and creep investigations were undertaken with the idea in mind that the data obtained would more nearly duplicate the results secured from actual high-temperature plant operation as contrasted with the results obtained from laboratory work. The steam conditions of 380 lb per sq in. and 1100 F or 925 F, to which the samples were subjected were not held, therefore, to the extremely narrow limits prescribed for laboratory tests. The samples also were subject to heating and cooling cycles which is not usually the case in laboratory work.



Results are included of the examination of 5 per cent Cr, Mo tubing; a 5 per cent Cr, W casting; an 18–8 superheater tube, and two grades of stellite used for valve trim.

Steam-Corrosion Experiments. Two groups of materials, designated as A and B in Table 5 and containing nine different steels each, have been subjected to the attack of 1100-F steam. Four sets of samples were made up from each group, assembled in holding cages, and the eight cages were fixed in the 1100-F steam main. The rate of steam attack will be determined as successive cages are removed at approximately six-month intervals. This has been done in the case of three cages, two from group A and one from group B.

The samples were ground bars $^1/_2$ in. OD × 6 in. and were held in the cage under no stress. Fig. 17, showing a new cage and one after service, illustrates the method of holding the samples. The steam velocity through the cages was from 1000 to 1500 fpm.

The loss in weight resulting from corrosion was determined by weighing sections of the specimens after removal of the scale and comparing with the original calculated weight. The scale from specimens in the first cage was removed in a solution of 100 parts by weight of concentrated HCl, 5 parts of stannous chloride, and 2 parts antimony oxide.[5] In the case of the stainless steel, a solution of one per cent by weight of quinoline ethiodide in concentrated HCl was used. An electrolytic stripping cell was used in removing the corrosion products from the specimens in the second and third cages. A solution of 10 per cent H_2SO_4 plus 0.1 per cent quinoline ethiodide was used in the cell with a current density of 0.5 ampere per sq in. The amount of parent material removed by both methods was too small to be weighed by an analytical balance and therefore was disregarded. The overall laboratory error involved in the weight determination was not greater than ±5 per cent. The greatest change in density of the specimens during service was 0.05 per cent.

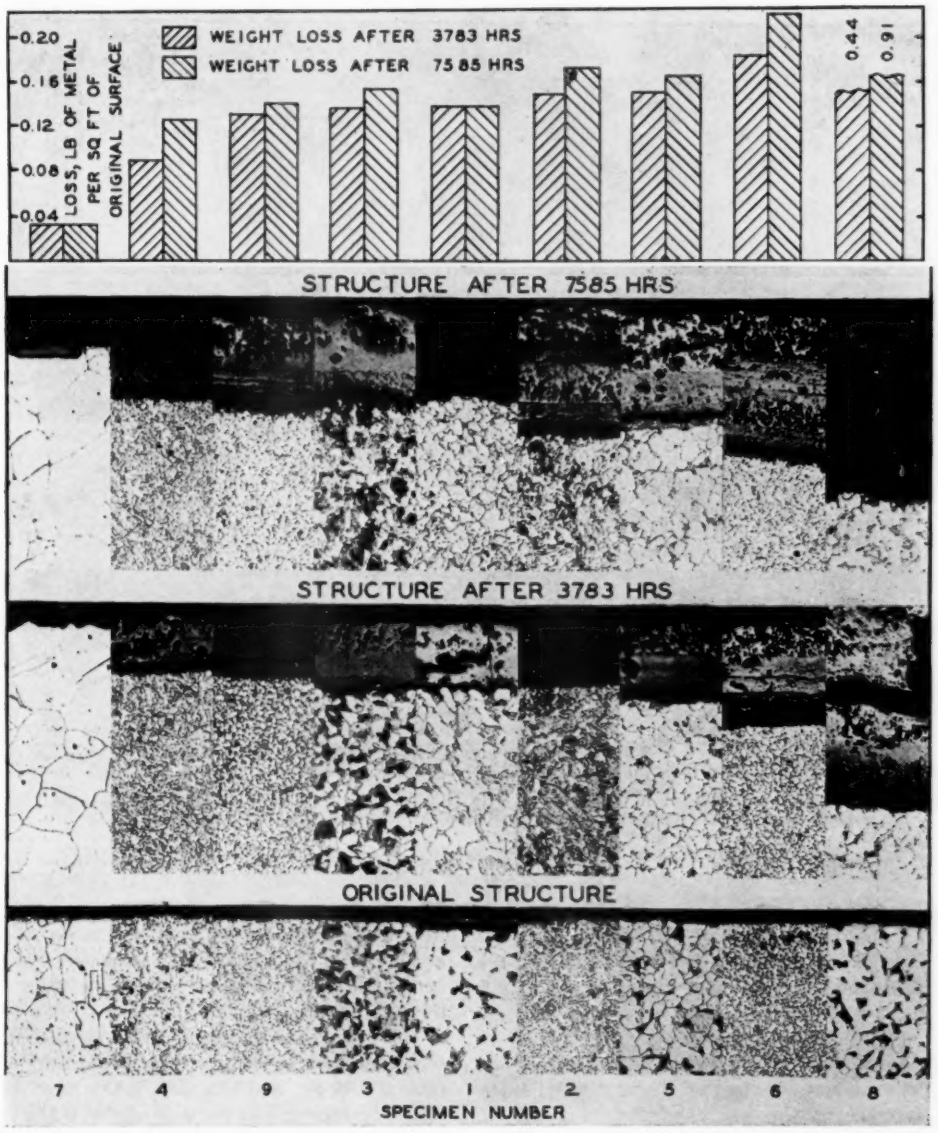

FIG. 18 MICROSTRUCTURE AND WEIGHT LOSS FOR 1100 F STEAM-CORROSION SPECIMENS IN GROUP A, ×72

The two groups of materials tested are listed as A and B in Table 5.

The number of hours at different steam temperatures to which the two groups were subjected is shown in Table 6.

The samples in cages 1 and 3 were heated and cooled six times while those in cage 2 were subjected to twelve heating-and-cooling cycles.

The results of examination of the group A materials are shown in Fig. 18. Because of space limitations, only small portions of the original photomicrographs are reproduced, but the areas shown are typical of the structures and give an idea of the scale formation except for a few specimens where the scale cracked off during the polishing operation. In the case of specimen No. 8, S.A.E. 1010, the scale layer was so thick that it could not all be included in the section shown.

Two interesting conclusions can be drawn regarding the weight-loss data shown at the top of this figure for the alloy steels; first, that the early scale layers formed, materially inhibit subsequent attack by the steam, and second, that increasing the silicon content of the Cr-Mo alloys does not increase resistance to steam corrosion, as has been expected from laboratory air-corrosion tests. In what respect the process of air and steam corrosion differ is not known, but is now being investigated. In the several cases where intercrystalline corrosion can be observed, it has not progressed deeper than one or two crystals.

The effect of even small additions of alloying elements is quite evident from an inspection of the weight-loss data. Only in the case of the low-carbon-steel sample has the corrosion progressed at a constant rate. From work at present in progress by other investigators, a boundary layer rich in the alloying elements is built up which tends to inhibit attack. It is quite probable that most of the scale formation observed on the alloy samples could have been formed in the first thousand hours or so of operation.

The effect of stress on the rate of corrosion is not known except in the case of sample No. 6, where it was possible to determine the amount of scale formed on the inner surface of a machined tube made from the same heat of steel and subjected to 7000 lb per sq in. stress during 8000 hours' service with 1100 F steam. In this case the observed amount of scaling was 16 per cent

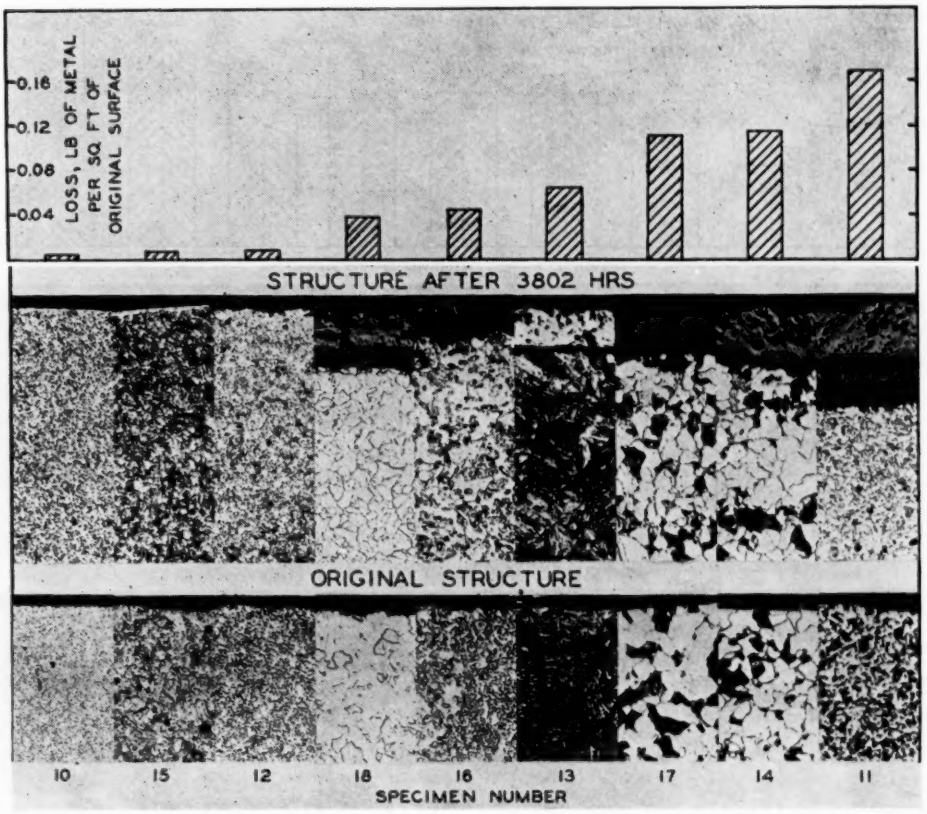

FIG. 19 MICROSTRUCTURE AND WEIGHT LOSS FOR 1100 F STEAM-CORROSION SPECIMENS IN GROUP B, ×72

greater on the tube than that obtained on the test specimen in 7600 hr when expressing the amount of corrosion in terms of pounds of Fe lost per sq ft of surface. The surface in this case is the mean of the original and the final expanded inside tube surface. It is quite possible that had a more conservative stress been used than the 7000 lb which caused creep at about the rate of one per cent per 1000 hr, the amount of corrosion would have been nearer the amount obtained on the unstressed specimen. Visual inspection of the inside surface of a 4000-lb stressed tube, still in service, shows none of the hairline scale cracks found on the inside of the 7000-lb section. See Fig. 22. The authors are led to believe that where conservative stresses are selected for steam equipment, the additional scale resulting from stress should not be a serious factor.

In the case of the stressed tube, approximately the same amount of scale was obtained on the outside surface as was obtained on the inner one. Microscopic examination showed the scale formed by steam to have a much better bond to the parent metal than the more porous scale formed on the outside of the tube, the result of air attack. Unstressed laboratory air-corrosion samples also exhibit a loose flaky scale. The microstructure of the tube and the scale formed by steam attack are shown in the after-service photomicrograph in Fig. 21. No intercrystalline cracking was evident on the inner or outer surface.

The data obtained from an examination of group B are shown in Fig. 19. Three of the four stainless steels exhibit substantially the same weight losses, while the fourth, containing 2 per cent Mo, scaled appreciably more than those containing no Mo. The results on these specimens are of interest because of the carbon range covered and the different heat-treatment. It should be observed that sample No. 10 is of the high-sulphur free-machining grade of stainless steel.

The effect of carbon in straight-carbon steel can be noted from a comparison of losses on specimens Nos. 8 and 11. The higher-carbon steel scaled only 25 per cent as much as the low-carbon sample. The reverse of this condition would be expected from air-corrosion tests.

The two groups of samples contain three alloys of the 5 per cent chromium series. Of these materials No. 18, the one containing 0.46 per cent titanium, is the most resistant to scaling. No. 9, containing 1.55 per cent silicon, is the least resistant, and No. 4, containing only the molybdenum is intermediate. Air-corrosion tests at 1250 F have shown the high-silicon composition to be much superior.

The authors would like to call attention to the fact that the corrosion results given are based on the examination of either one of two specimens of each steel and therefore they are not as conclusive as it would be desirable to have them. Then again, it is possible that by using steam with other amounts or types of impurities, somewhat different results might be obtained. These results, however, have been obtained over a long enough period to average out variations due to from 10- to 20-deg changes in temperature and relative position in the steam path and to make them indicative of the relative corrosion resistance of the various alloys tested using commercially pure and oxygen-free steam. The data already secured are of so much interest that it has seemed worth while to discuss them at some length in this paper.

Creep of Pipe Under Internal Pressure. In the hope of securing data from which some correlation might be made between actual performance of pipe and tubes in service and laboratory creep data on conventional tensile specimens, four machined tube sections were installed in the high-temperature experimental steam line at Trenton Channel. Two of these sections of Cr-Mo-Si alloy were subjected to 1100 F steam while the remaining

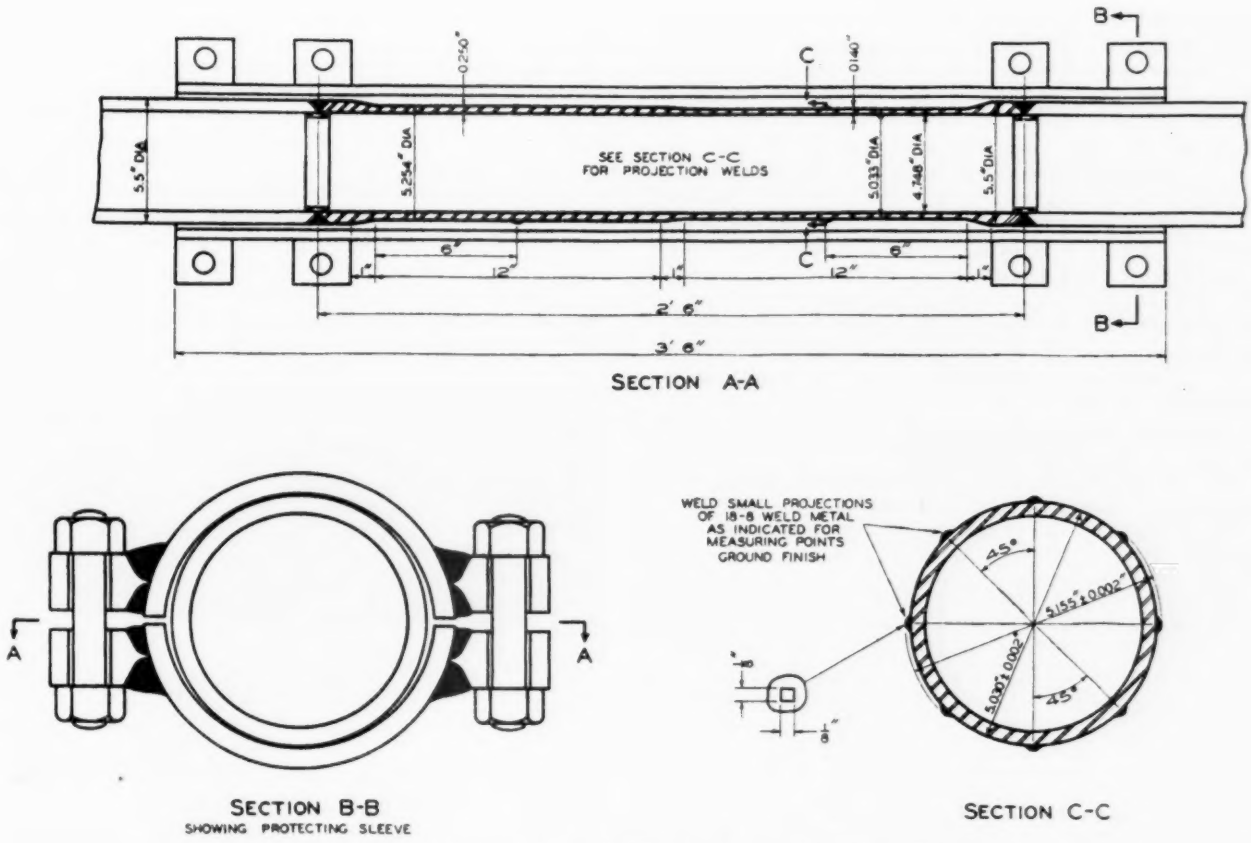

FIG. 20 DETAILS OF SECTION OF CR-MO-SI TUBING FOR CREEP DETERMINATIONS

two sections of C-Mo tubing were placed in service at 925 F. The laboratory data used for comparison have been obtained from the University of Michigan.

The tubes were machined inside and outside to give wall thicknesses such that the internal pressure of 380 lb per sq in. gage would produce easily measurable increases in diameter. Stainless-steel measuring points were welded at intervals of 45 deg around the circumference near the mid-point of each section to secure accurate measurements of diametral change and to insure freedom from effects of oxidation. The details of the Cr-Mo-Si tube sections are shown in Fig. 20.

The lengths of the test sections were only a little over two times the diameters, but it was found that the restraint offered by adjacent heavier sections did not extend more than 3 in. from each end, leaving approximately 6 in. free to expand under the internal pressure. The effect of end restraint is clearly evident in Fig. 22.

A guard sleeve shown in Fig. 20 was provided to protect the thin-walled sections from the effect of line bending moments, and in the event of failure of the thin-walled section, to restrict the steam flow and direct it in a horizontal plane. Since the use of a guard sleeve may imply that failure of the thin-walled section was anticipated, it should in fairness be stated that on the basis of information existing at the time of the installation, the working stresses were considered reasonably conservative for the Cr-Mo-Si tubing at 1100 F. The nominal stress of 4000 lb per sq in. in the section with 0.250-in. wall was thought to correspond to a creep rate of one per cent in 100,000 hr, while the 7000-lb per sq in. stress in the section with the 0.140-in. wall was considered to cause creep at the rate of one per cent in 10,000 hr. Subsequent laboratory tests showed that the material which

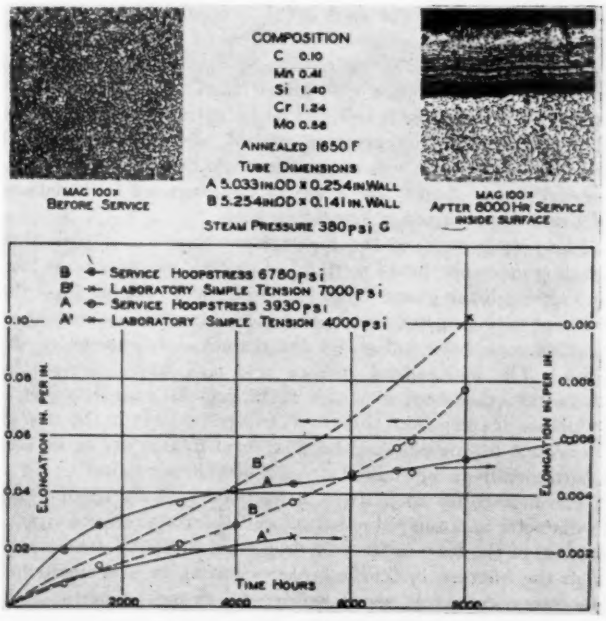

FIG. 21 COMPARISON OF LABORATORY- AND SERVICE-TIME ELONGATION CURVES CHROMIUM-MOLYBDENUM-SILICON PIPE AT 1100 F

(Magnification reduced to ×47.)

was obtained for the test sections elongated at the rate of about 4 per cent in 100,000 hr under a stress of 4000 lb per sq in. and 10

per cent in 10,000 hr under a 7000-lb per sq in. stress at 1100 F.

The diametral or circumferential elongations of the Cr-Mo-Si tubes under internal pressure are compared with results of conventional creep tests in simple tension on the same material in Fig. 21. It may be noted that the rates of creep for certain time intervals agreed quite well with tests in simple tension. The total elongations, however, were quite different. Since all measurements on the tubes were made in the cold condition with no stress acting and after creep recovery, if any, had occurred, it might be expected that the total elongation of the tube would be less than that of the tensile specimen. In the case of the tube having a hoop stress of approximately 7000 lb per sq in. this was found to be true. The lower-stressed section of Cr-Mo-Si tubing at 1100 F and the two samples of C-Mo tubing at 925 F, however, exhibited much greater elongations than the laboratory specimens.

Photomicrographs of the Cr-Mo-Si material before and after service, the heat-treatment, and chemical composition are given in Fig. 21. The time in hours at temperatures of 1000 to 1100 F was used as a basis for plotting the results.

The hours in service at the various temperatures are summarized in Table 7.

TABLE 7 HOURS IN SERVICE OF CR-MO-SI TUBES

Average wall thickness	0.141 in.	0.254 in.
Below 900 F	76	86
900 F	62	72
950	106	116
1000	870	950
1050	416	426
1100	6714	9615
Total	8244	11,265
Total, 1000–1100 F	8000	10,991

The condition of the Cr-Mo-Si tube with 0.140-in. wall after service is shown in Fig. 22. The total increase in diameter amounts to approximately $^3/_8$ in. The section with 0.250-in. wall is still in service and has been operating for the last 2900 hr without a guard sleeve. Omission of this sleeve has had no appreciable effect on the rate of diametral increase.

The method of measuring changes in diameter by means of a micrometer, while much less refined than ordinarily used for creep determinations, is believed to be entirely satisfactory for the purpose. The temperature control, allowing variations of from 10 to 20 deg F, was as good as might be expected in a commercial steam plant. These are to be compared to variations of 1 or 2 deg obtained in laboratory work.

The arrangement of the high-temperature line is such that bending moments due to restraint of thermal elongation are low, and although the guard sleeve was designed to further limit the moment acting on the thin-walled sections, a certain amount of bending may have influenced the diametral extensions of the tubes. The longitudinal stresses also may have affected the diametral extensions, although there was little evidence of a reduction in creep from this cause, except possibly in the case of the section having a normal hoop stress of 7000 lb per sq in. and a corresponding longitudinal stress of 3500 lb per sq in.

The increase in hoop stress, occasioned both by the increase in diameter and the reduction in wall thickness, caused by expansion of the tube as the test progressed, differed considerably from the increase in tensile stress occurring in a conventional laboratory creep-test specimen due to change in section. It was estimated that the original wall thickness of the tube having an original average wall thickness of 0.141 in. had been reduced 3.1 per cent by steam oxidation on the inside and 2.8 per cent by air oxidation on the outside of the tube. The increase in diameter and reduction in wall thickness caused by expansion of the tube, together with the reduction due to oxidation, resulted in an increase in the working stress in the latter stages of the test of approximately 24 per cent, or from 6780 to 8420 lb per sq in.

Two additional test sections of C-Mo tubing, similar to those shown in Fig. 20 were prepared for test at 380 lb per sq in. and 925 F, after experience with the Cr-Mo-Si tubes had demonstrated the practicability of this type of test. The wall thickness of the 4.95-in. OD tubes was 0.102 in., giving a hoop stress of 9220 lb per sq in. A comparison of the service results obtained in some 4200 hr at 925 F for the two heats of steel and the laboratory results for the same materials is given in Fig. 23. Photomicrographs of the two heats of C-Mo steel, the heat-treatment, and chemical analyses also are included in that figure.

The working stress used in these tests was only a few per cent higher than the allowable stress proposed for C-Mo pipe at

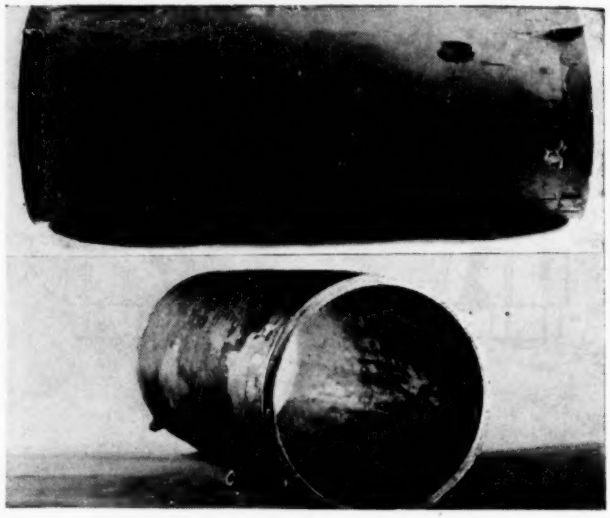

FIG. 22 INTERNAL AND EXTERNAL VIEWS OF SECTION OF 0.140-IN. CR-MO-SI TUBING AFTER 8244-HR SERVICE

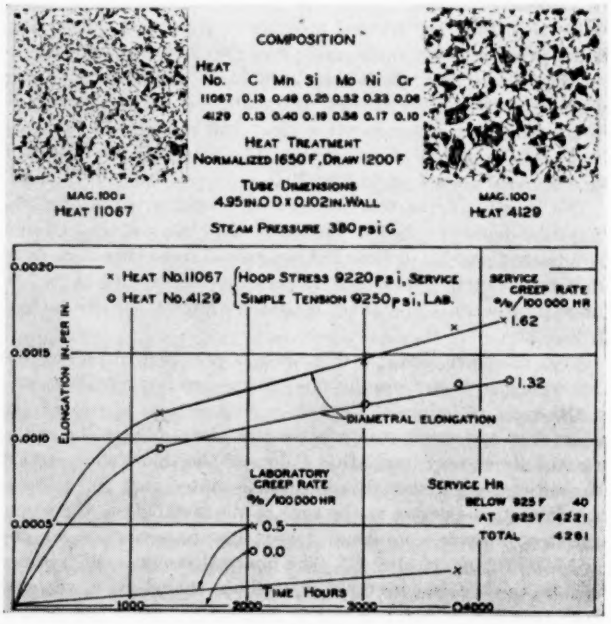

FIG. 23 COMPARISON OF LABORATORY- AND SERVICE-TIME ELONGATION CURVES CARBON-MOLYBDENUM PIPE AT 925 F
(Magnification reduced to ×47.)

925 F.[6] These data show considerably greater elongations than the results of laboratory tests in simple tension and much higher rates of creep, although the creep resistances of the two heats of C-Mo bear somewhat the same relationship to one another as in the laboratory tests. Present indications are that oxidation of the C-Mo test sections will not affect the expansion of the tubes to an appreciable extent at 925 F. The inside and outside surfaces are covered with a fine reddish-brown oxide with no evidence of scaling.

In drawing the curves of Fig. 23, the 3800-hr test points which were measured with the pipe at 138 F were disregarded. It was felt that the correction for temperature of measurement made for this point may have been in error. All measurements were corrected to 80 F, but in most cases the corrections involved less than 10-deg temperature differences.

Efforts have been made to check the effect of axial creep resulting from longitudinal pressure and bending stress in these tests. Since the means provided for measuring changes in length of the Cr-Mo-Si tubes at 1100 F had proved unsatisfactory, special precautions were taken in establishing longitudinal measuring stations on the C-Mo sections. The experimental high-temperature line in which these thin-walled sections were installed is disposed in a horizontal plane, and bending moments existing in the unusually flexible line act principally in this plane. The measuring points were located on the thin-walled sections on the inside and outside of the loop which comprised the high-temperature line.

Measurements between points on the outside of the loop showed increases in length of 0.003 in. per in. and 0.0015 in. per in., respectively, for the tubes from heat No. 11067 and heat No. 4129 after 4201 hr at 925 F. Measurements on the inside of the loop showed a decrease of 0.001 in. per in. for heat No. 11067 and an increase of 0.0005 in. per in. for heat No. 4129. Since these elongations are of the same magnitude as the diametral increases given in Fig. 23, it is apparent that despite the guard sleeve and unusual flexibility of the line, bending moments affected the longitudinal creep of the tubes. Removal of the guard sleeve from the section of Cr-Mo-Si tube with 0.250-in. wall at the end of the 8000-hr period, however, caused only a negligible change in the rate of diametral increase. The increase during the last 3000 hr was at the rate of 3.26 per cent in 100,000 hr as compared with 3.15 per cent for the 2000-hr period between 5000 and 7000 hr. This would seem to indicate that the guard sleeve had little effect on the bending moments acting on the thin-walled section, or that the bending moments had little effect on the diametral changes.

The authors wish to emphasize that the creep measurements made on thin-walled sections of pipe under service conditions cannot be considered in the same manner as refined laboratory determinations. Fluctuations in temperature, change in stress, corrosion of surfaces, and intermittent operation are factors which affect the total elongations obtained with operating equipment. The measurements under service conditions, however, do have a certain finality, and serve to bridge the gap between laboratory findings and actual plant use.

Trenton Channel Metallurgical Examination. The collection of further service data on materials at 1100 F has been confined to three materials. A section of $5^1/_2$-in. 5 per cent Cr-W tubing was removed after 18,150 hours' service, an integral test bar was removed from a 5 per cent Cr-Mo valve after 15,010 hr, and a low-carbon, 18 per cent Cr, 8 per cent Ni superheater tube was examined after 28,162 hr of service. Hardness values on stellite valve trim for different periods of service also are included.

The results obtained on the 5 per cent Cr-W tubing are summarized in Table 8.

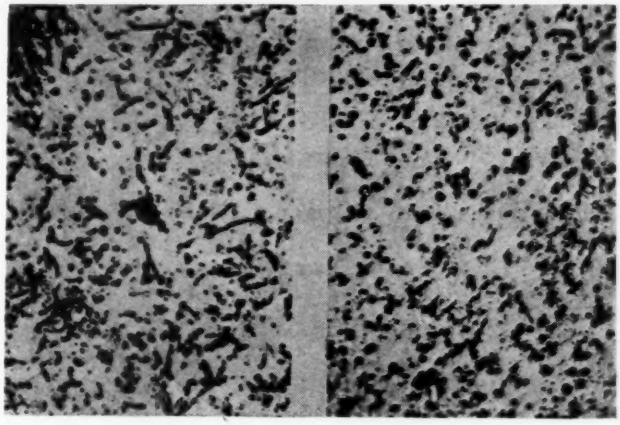

TABLE 8 FIVE PER CENT CR-W TUBING IN SERVICE FOR 18,150 HR AT 1100 F

(Composition, per cent: C, 0.11; Cr, 5.6; W, 0.94; Mn, 0.25; Si, 0.30)

Condition	Yield point, lb per sq in.	Ultimate strength, lb per sq in.	Elongation in 2 in., per cent	Reduction of area, per cent	Izod impact, ft-lb	Hardness Rockwell B
Unused...	42,800	77,800	34	71	39	80
Used.....	41,000	74,900	33	71	30	77

The structure of the material before and after service exhibited practically no change as shown in Fig. 24. The number of precipitated carbides was nearly the same, and the grain size remained the same. Apart from some softening of the material, the only noticeable change was a decrease in the impact strength.

Measurements made on welded stainless-steel points showed creep rates of 1.2 and 2.8 per cent per 100,000 hr for the horizontal and vertical diameters, respectively, during the last 9500 hours' operation of the pipe. The working stress was approximately 2500 lb per sq in.

underwent a slight annealing and grain refinement. The impact-test results, however, show a pronounced reduction in resistance of a notched section to shock. The numbers of specimens available for each test were one tensile bar and six impact specimens.

The results of tests on the 18 per cent Cr, 8 per cent Ni superheater tube are given in Table 10 together with information on an adjacent tube which was removed and examined in 1933 after 15,159 hours' service at 1100 F. The latter tube is designated as specimen No. 1.

The crystal structure shown in Fig. 26 is of specimen No. 2 and is practically identical with No. 1, not shown. These results point to the interesting conclusion that the material has stopped deteriorating and that further service may even result in a continued improvement in the physical properties and, in particular, the impact value. A change in electrical resistivity of the samples after boiling in Strauss solution showed an increase of 0.9 per cent for No. 1, while the increase was only 0.6 per cent for specimen No. 2. This was a further proof of a more stable condition.

The 5 per cent Cr-Mo valve of which results were given in Table 9 was equipped with two different grades of stellite for seat and disk trim. One side of the gate and the corresponding seat ring were finished with stellite No. 1, while the other half of the valve was trimmed with the No. 6 grade. The hardness of the plug faces has been secured at different time intervals and is given in the following tabulation together with those obtained before the valve was placed in service:

	Brinell hardness	
	No. 1 stellite	No. 6 stellite
Specified by manufacturer	512	402
Before service	387–421	373–398
After 7145 hr of service	473–510	466–478
After 15,033 hr of service	472–509	427–460

Long exposure at 1100 F has had the effect of a hardening heat-treatment. The variation in hardness was probably caused by dilution of the stellite with the base metal when it was applied. The No. 6 side was in excellent shape and drop tight when the valve was subjected to a 600-lb hydrostatic test, whereas the No. 1 facing on the plug had several large cracks and a number of hairline cracks, and at one of the larger cracks, the stellite had erupted enough to prevent that side of the valve from seating. Neither of the body rings was cracked, and no corrosion had occurred on either grade of stellite.

CONCLUDING COMMENT

With the use of high-temperature steam approaching nearer to the 1000-F limit used in the Delray turbine, it is reassuring to realize that in over 4 years of actual operation, this unit and the materials of construction withstood the service conditions rather well. With the recent advances in knowledge of the high-temperature characteristics of alloys now available, and the advances made in the construction of power-plant equipment, the design and operation of a 1000-F plant is a practical thing if the savings to be gained are justified economically.

While considerable information on steam corrosion has been presented in this paper, much more is necessary before the effects of corrosion on the life of high-temperature apparatus can be evaluated. The service-creep-test data presented indicate that a better correlation between laboratory and field conditions also is necessary.

The authors wish to acknowledge the cooperation of The Timken Steel & Tube Company in the conduct of the steam-corrosion work and the creep testing of the Cr-Mo-Si tubing. Acknowledgment also is made of steam-corrosion samples supplied by the General Electric Company, The Lunkenheimer Company, and The National Tube Company.

Discussion

HANS DAHLSTRAND.[7] It is interesting to note that there was practically no difficulty in the steam turbine, which is the subject of this paper, that could be attributed to high temperature. The bucket and shrouding assembly has been trouble-free, indicating that the mechanical stresses from vibration, impact, and other forces were kept within safe limits for the materials used in their construction. The indentations shown on nozzle walls and blading indicate the importance of having the whole system, including boiler and piping, thoroughly cleaned before the plant is put into operation. While this experiment conclusively indicates that temperatures up to 1000 F are practical and may, with proper design and the correct choice of materials, be adopted for steam turbines of large capacities, nevertheless, the fact should be kept in mind that the experiment was conducted under constant conditions without any appreciable changes in temperature during

[7] Engineer in Charge, Steam Turbine Department, Allis-Chalmers Manufacturing Co., Inc., Milwaukee, Wis. Mem. A.S.M.E.

operation. It is known that the coefficient of expansion in steels is greatly increased with higher temperatures and at the same time the ductility of many of these steels is greatly decreased. Consequently the same sudden changes in temperature, when operating at high temperature, will undoubtedly be more destructive than when these same changes take place during the operation at lower temperature. It is important to realize this condition when designing power plants for high temperatures. Constant loads on the steam-turbine units cannot in all cases be maintained, therefore, the main problem will be a boiler and superheater design which will maintain constant temperature over the entire range of operating loads. Practical experience indicates the importance of maintaining constant temperature in order to realize maximum efficiency.

The experience with steam pipes in this experiment, as well as in power-plant installations, has indicated the necessity of eliminating all bolted flanges whenever possible, not only in pipes but also in all parts exposed to high temperatures.

The structural changes in many of the materials indicate that it must be known beforehand whether they are suitable for high-temperature service covering the normal life of operation of the equipment. The information given will in this respect prove valuable. It is undoubtedly true that many of these materials have been improved in later years making them more suitable for high-temperature service. This is particularly true in the case of some of the austenitic steels where stabilizing elements are used to eliminate carbide precipitations.

The steam-corrosion experiments are of special interest. Up to this time very little information has been available covering the corrosion effect of high-temperature steam on various types of steel. Some difficulties have been experienced even at lower temperatures that have been attributed to corrosion. It is realized that the effect from corrosion is influenced by several factors and therefore difficult to analyze without extensive and laborious experiments. These factors are the surrounding atmosphere, temperature, and stress conditions, each of which will have a different effect on the various types of steels. In modern power plants, the condition of the steam due to the variety of feedwater treatments and the state of the make-up water may have a different effect on different materials. This effect may be different through the expansion range caused by chemical changes in feedwater treatment compounds. It is therefore of some importance to know what this effect will be with different conditions of the steam. Differences in temperatures will naturally produce varying effects. The effect of stresses must be known, as the corrosion is likely to be more serious at higher stresses, particularly if the stresses are of such magnitude as to cause corrosion through the grain boundaries of the material.

The first corrosive covering as mentioned appears to form a protective coating which apparently prevents further corrosion quite effectively. This effect has been noted and in some cases has been utilized by giving the material a corroded surface deliberately. There is a possibility that this method of protection may be used in making materials more resistant to corrosion in the operating atmosphere by producing the protective coating in a different atmosphere.

F. O. ELLENWOOD.[8] It is gratifying to note that for all of the steels, except the straight-carbon one, the initial scale formation affords considerable protection against further steam attack. This fact, coupled with the success obtained by welding the pipe joints, should give considerable encouragement to those engineers who are now planning to use steam of a much higher temperature than they have heretofore considered feasible. The authors point out that the high compressive stresses in the bolted joints with metal gaskets cause leakage by plastic flow and that the only remedy is periodic maintenance if such joints are used. They have left to the imagination of the reader what that means in a large plant in which all of the steam mains are to be kept tight when at a temperature sufficiently high to cause the pipes to be a dull red. This still further emphasizes the importance of the welded pipe line for high temperatures.

The concluding comment states, ". . . the design and operation of a 1000-F plant is a practical thing if the savings to be gained are justified economically." This sums up the situation concisely for the use of the designing engineer, because he can usually estimate fairly well his annual capacity factor, fuel cost of energy, and the first cost of the equipment; hence, he can now design with confidence, based on the Detroit experiments, his high-temperature plant wherever he finds that his annual use factor will justify the additional cost due to the high temperature of the steam.

H. J. KERR.[9] The two high-temperature steam installations in Detroit may well in the future be regarded as the milestone in history when steam at a temperature of 1000 to 1100 F was first utilized in this country for power generation. The data in the paper give further evidence of the advancement in the manufacture of steam-generating and steam-utilizing equipment. The paper also shows clearly the progress which has been made in alloy steels.

The large steam-generating installations of the last few years show that advantage has already been taken of the experience gained from these Detroit units, as practically all of the high-pressure installations have been for steam temperatures from 900 to 950 F. None of the materials used in building these installations has actually failed and a great majority of the materials used have been found quite satisfactory for the purpose. Undoubtedly, this result would not have been obtained had it not been for the experience in the oil refineries at high temperature with alloy steels.

With high-temperature steam the oxidation problem is quite different from that encountered in the oil industry and the data on this phase of the problem in the paper will need careful study. Some of the points brought out which might be emphasized for careful consideration are:

1 The comparison of steam and air oxidation.

2 The type of oxide scale found in the case of steam oxidation and the effect of variation of temperature and stress.

3 The fact that intercrystalline oxidation effects, in the presence of steam, are materially less than in the case of air oxidation.

4 Oxidation of 0.3 carbon steel less than low-carbon steel.

5 The relatively greater resistance to oxidation (obtained by small percentages of alloys) in steam than in the case of air oxidation.

The paper gives certain data on the creep of tubular specimens in comparison with tension-creep specimens. Much of these data are at variance with those of other investigators. In other words, it is generally believed that the diametrical creep of a normally stressed cylinder will be less than that obtained with a normal tension-creep test, at least above the equicohesive temperature.

The 1100-F superheater at Trenton Channel is still in operation. In many ways it is an ideal apparatus for high-temperature testing. It is hoped the authors may continue to add to the fund of knowledge from its further use.

[8] Professor of Heat-Power Engineering, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

[9] Executive Assistant, The Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

Further data are required on three phases of the problem: (*a*) Oxidation effects, (*b*) creep of a cylinder under simple pressure and in the case of bending stresses, and (*c*) the total creep permissible on tubular members with a variation in time.

C. H. McCollam[10] and C. L. Clark.[11] The authors have added further evidence of the apparent difference in the mechanism of oxidation of ferrous materials at elevated temperatures when exposed to air and to steam. Both the type of oxidation products formed and the relative merits of the several materials tested are different in the two media. In other words, alloy additions which impart high resistance in one medium may not have the same relative merit in another atmosphere.

In order to eliminate any misunderstanding in regard to the apparent discrepancy in the originally assumed creep characteristics of the Cr-Mo-Si tubing at 1100 F and those actually obtained from both service and laboratory tests, it should be further emphasized that the composition of the steel used in the service tests differed from the steel on which the original creep characteristics, used for the basis of the authors' design stress, were obtained.

The comparison of the service and laboratory creep tests is of considerable interest. The two types of tests at 1100 F are in good agreement, while at 925 F the service tests revealed a considerably greater rate of creep than did the laboratory tests. From this it might follow that the relationship between creep in tubular sections and that in straight tension varies, depending on the relative degree of plasticity and strain hardening. For example, the Cr-Mo-Si steel at 1100 F is distinctly plastic in its behavior and the two types of test are in good agreement. On the other hand, the 0.50-Mo steel at 925 F is capable of pronounced strain hardening and, under this condition, the two types of test are not in agreement. The difference in the results at 925 F may indicate that strain hardening can occur more rapidly and to a greater extent under simple tension than under the combined stresses present in a tube under internal pressure.

E. L. Robinson.[12] Actually, this paper constitutes two separate reports; one covering the performance of the Delray turbine; and the other, the Trenton-Channel piping. Both reports contain a great many briefly stated facts of experience and there are no better precepts for guidance than such facts.

There are many hopeful conclusions: Creep distortions in the turbine were negligible. The satisfactory performance of the welded joints in the piping lead the authors to recommend this type of construction. Such scale as was formed by the steam proved to be protective in nature and more tenacious than oxides formed in the air. Scaling did not appear to be increased by the presence of such stresses as are considered allowable in good design. All in all, the authors conclude that it is quite feasible from the point of view of strength to operate at 1000 F.

It is important to note that the materials used in the Delray turbine were not the same as the materials most generally used in the United States. The turbine was built in England and except for the replacement throttle valve which was a carbon-molybdenum casting, all the materials differed in some significant respect. While the replacement throttle was made in England, it was made to the purchaser's specification and is probably reasonably representative of an American material. While, in general, the turbine materials gave a good account of themselves, American materials now available are believed to be even better.

The authors note that the enlargement of diameter in the piping, instead of being less than occurred in the tensile specimens, was fully as great or even greater. The writer would like to point out that this extra creep was not more than might occur between different tensile specimens in a laboratory. The authors express too much respect for the precision of laboratory creep tests. In order to be sure that laboratory creep tests will yield comparative results, it is necessary to cut the various samples from the same bar of material and also to examine the various samples with the microscope to see that they do not vary from place to place in the bar.

The authors have clearly pointed out that it is too much to expect that piping will enlarge on the diameter less than an ordinary tensile specimen. However, if designers have already made suitable allowance for the possible variation in creep strength of materials as ordinarily used, it does not seem necessary to discount these results any further, although it may be wise not to take credit for the theoretical 15 per cent advantage in strength which is supposed to go with the biaxial loading. These results are worthy of study in comparison with the creep tests on tubular members recently completed under the sponsorship of the A.S.M.E.–A.S.T.M. Joint Research Committee on the Effect of Temperature on the Properties of Metals.

G. B. Warren.[13] There is a question as to how generally the public appreciates its indebtedness to the utility companies and to the power-using industries for the remarkable progress which has been made over the last forty years in reducing the fuel cost of power. It is the writer's opinion that this remarkable reduction has only been accomplished by the willingness of first one and then another public-utility organization or industry to advance into regions in which, at the time, there are inadequate engineering data upon which to base such a step with perfect assurance and without risk. Progress has been made as a result of the sum of all of these individual steps.

The point which most forcibly impresses the writer, as a designer of equipment, much of which is now in service at high temperature, is that on the whole the results cited bear out the practice which has crystallized during the last few years as proper for high-temperature power plants. In other words, no failures as such have occurred even at temperatures well above those now being used in commercial practice. Particularly in the Trenton-Channel tests, the materials which are giving satisfactory and in some cases superior service are in general basically the materials which are accepted as standard practice today. For example, the use of nitralloy bushings for valves apparently has been satisfactory to an outstanding degree. The stellite-faced valves have given promise of satisfactory service. The 12 per cent chrome bucket material, now more or less standard for turbine buckets has almost the lowest rate of corrosion.

The experience with chrome-molybdenum-silicon piping has also been reassuring. It is believed the results can be interpreted as confirming other indications that the stresses, temperatures, and even improved materials, which are now being installed and used on recent high-temperature installations, are well on the side of safety.

A. E. White.[14] The corrosion resistance of most metals when at high temperatures is usually determined in air. The results of the corrosion findings reported in this paper are in an

atmosphere of steam. The results are most interesting and valuable.

When high-temperature corrosion or oxidation tests have been made in air, intercrystalline cracks have been found in some steels, if the tests were carried out for a sufficient period of time. These cracks, however, have been found only when the sample was in a state of stress.

The work on the samples reported in the paper was done on specimens in an unstressed condition. What would have happened had they been in a highly stressed state? Would intercrystalline cracks have been found, especially if the time periods were of the order of 20,000 hr or more?

These are vital questions for power-plant operation, as most, if not all, of the units in a power plant should have a life of at least 100,000 hr for successful performance. It is understood that tests are contemplated or are under way which will throw light on the stress factor.

Authors' Closure

Mr. Dahlstrand has summarized very well in his discussion the various factors that enter into the question of resistance to steam corrosion. It is only when considerably more data are available that engineers will be able intelligently to design for the high temperatures that are now being encountered in portions of recent superheaters.

An example would serve best to illustrate this point. Assume that a 5 Cr-0.5 Mo tube, 1.75 in. outside diameter and 0.160 in. wall thickness, is considered for use in a superheater at 850 lb per sq in. and that the operating temperature is near 1100 F. The nominal bursting stress using Barlow's formula is 4650 lb per sq in. If a proper allowance for steam corrosion is made, so that the stress is not appreciably greater at the end of 10 years than that originally selected, an average corrosion factor is necessary. An allowance, based on the weight loss[15] observed after 1000 hr, would require 0.089 in. added to the original wall thickness, whereas the rate of metal loss observed on a sample removed from the Trenton-Channel line after 11,400 hr would indicate that 0.030 in. would be sufficient to allow for corrosion. Air-corrosion loss and the effect of stress on corrosion have been neglected in the foregoing discussion.

At the present time, tests have been started in the 1100-F line to determine the effect of stress on the scale formation.

The authors are not certain that a general statement can be made to the effect that the low alloys exhibit a greater relative resistance to oxidation and corrosion in steam than they do in air, as mentioned by Mr. Kerr. To their knowledge no air-corrosion data are available from long-time tests to compare with results given in the paper. Where additions of silicon over 1 per cent have been used in some of the low alloys, a comparison of extrapolated values of weight loss for 1000 hr exposure to steam shows a greater loss than corresponding values reported from air tests.

Mention was made in the paper of nominal variations in steam temperature at Trenton Channel of plus or minus 20 F from 1100 F. These limits have been exceeded since oil was replaced with refinery gas as a fuel for the superheater. An examination of recorded temperature for the past 3 years showed a weighed-average steam temperature of 1094 F with a variation as follows:

Temperature variation, F	Per cent of service, hr
1080–1120	64.5
1060–1140	81.3
1000–1140	96.5

The installation of a temperature controller to compensate for the sudden wide variation in heating value of the gas has been considered. One has not been installed, however, as the present method of operation more nearly duplicates plant conditions, although such wide fluctuations perhaps would not be tolerated in a regular plant installation.

The Vectorscope

By GEORGE J. DASHEFSKY,[1] NEW YORK, N. Y.

This paper describes a new instrument capable of rapidly summing up a number of vectors. The machine consists of a disk, mounted in gimbals in the manner of a nautical compass, on which are placed weights representing the vectors to be added. A spot of light on the screen indicates directly the resultant vector and its direction, as well as its horizontal and vertical components.

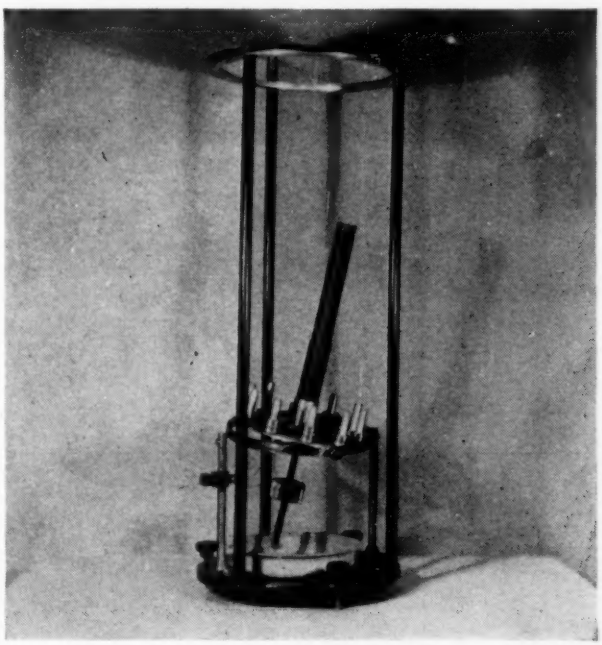
The mathematical principle is developed and the instrument is shown to be suitable for studying crankshaft arrangements with respect to unbalanced moments and torsional vibration. The suitability of any firing order for any crankshaft configuration may be ascertained simply and quickly.

It is shown that the instrument is inherently adapted to making harmonic analyses of periodic functions and the theory of this application is discussed. Results by this method of analysis compare favorably with other methods.

THE INSTRUMENT described in this paper was devised and built by the author early in 1936 while engaged on an engine problem which required the study of a considerable number of firing orders, particularly as they affected the characteristics of engine balance and torsional vibration. Shortly afterward in the same year, the instrument was rebuilt at the New York Navy Yard into the form shown in Fig. 1. In 1937, Prof. K. J. DeJuhasz kindly called the author's attention to a contemporary instrument[2] somewhat similar in function and used in studies of color.

Our instrument was dubbed "Vectorscope" because of its designed function of effecting rapid addition of a number of vectors. Analyses of both engine balance and torsional vibration involve vector addition and the instrument is therefore well adapted to the solution of these problems. The harmonic analysis of periodic functions may also be reduced to a process of vector addition, and the Vectorscope therefore lends itself nicely to solution of this problem. Such uses of the instrument appear to be of greatest interest to the fraternity of engine designers and the present paper is therefore limited to a discussion of these problems and the manner of effecting their solution with the Vectorscope.

Description of Instrument



The mechanical arrangement of the instrument as now constructed is shown in Fig. 1. One of the several interchangeable disks (1) is carried by member (2), which is mounted in gimbals in the manner of a nautical compass. Member (2) is free to rotate in a pair of pivot bearings (3) carried on the ring (4). The ring (4) in turn is also mounted in pivot bearings (5) permitting rotation about an axis at right angles to the axis of rotation of the disk. The pivots are arranged so that the mutually perpendicular axes of rotation pass through the center of the disk. The ring (4) is supported on a base which may be leveled off by means of screws (6). Member (2) carries a light-projection system (7) comprising a flashlight lamp with a filament of the concentrated type. Current is fed to the lamp by very flexible leads passing through holes in (2). An image of the lamp filament is focused on a translucent screen (8), graduated in polar coordinates. The graduated screen, sandwiched between two plates of glass may readily be replaced with other screens graduated in any required manner to permit direct readings in units pertinent to the problem in hand. Deflections of the disk (1) are measured by the displacement of the light spot from the center of the screen, indicating both magnitude and direction.

A threaded rod (9), forming the lower part of (2) carries a movable weight (10), by means of which the instrument sensitivity and scale reading are controlled.

The disks (1) are provided with pegs (11) with appropriate angular spacing. Weight holders (12) carrying preweighed groups of washers (13) of 1 unit, 0.1 unit, and 0.01 unit may be shifted from peg to peg as requisite. The weights (13) representing the vector magnitudes are thus adjustable by a simple counting process rather than by weighing.

The oscillations of the disk in its gimbals are damped out by vanes (14) carried at the extremity of rod (9) and moving in a dish of mercury. The time required for the disk to come to rest is thus greatly reduced, and the instrument is rendered deadbeat.

It will be noted in Fig. 1 that the disk (1) is free to rotate about each of the mutually perpendicular axes. It may of course

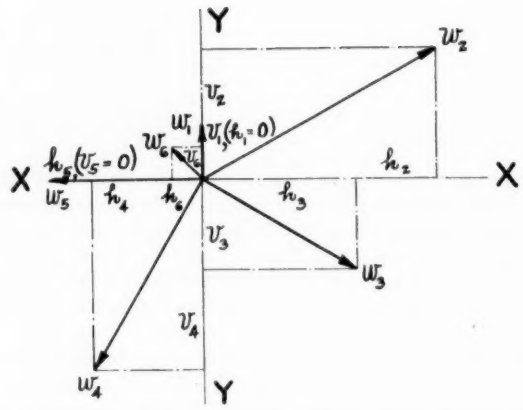

FIG. 3 VECTORS RESOLVED INTO COORDINATE COMPONENTS

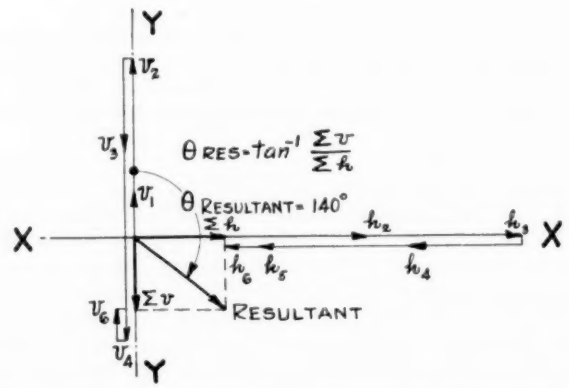

FIG. 4 RESULTANT VECTOR FROM COORDINATE COMPONENTS OF FIG. 3

rotate simultaneously about both axes. Any tilting action of the disk due to weights (13) is balanced by the weight (10), which assumes a deflected position about the two axes of rotation, in accordance with the magnitudes of weights and their disposition on the disk. Actually the weight of the light-projection system, member (2), and threaded rod must also be considered. However, there is a net weight W which represents the combined effect of all of these.

ADDITION OF VECTORS

Fig. 2 represents six vectors w_1 to w_6, inclusive, having directions as indicated. Two familiar methods for finding the sum or resultant of these vectors are shown. In Fig. 2, the resultant is obtained by closing the vector polygon in the usual manner.

A second method is shown in Figs. 3 and 4. Each vector is resolved into vertical and horizontal components, which are then added separately as shown in Fig. 4, giving the net components, Σh and Σv. The magnitude of the resultant is readily obtained by a composition of Σh and Σv.

The following example involving the addition of the vectors shown in Figs. 2, 3, and 4 will demonstrate the mathematical principle of the Vectorscope. Refer to Fig. 5 showing the Vectorscope in elemental form. Each vector is represented by a weight placed on the disk at a common radius r. These weights have the same relative values as the original vector magnitudes, while the direction of the vectors is cared for by disposing the weights on the disk in the same angular relationship as the original vectors. The weights so disposed result in a net moment about axes X-X and Y-Y, producing rotation about these mu-

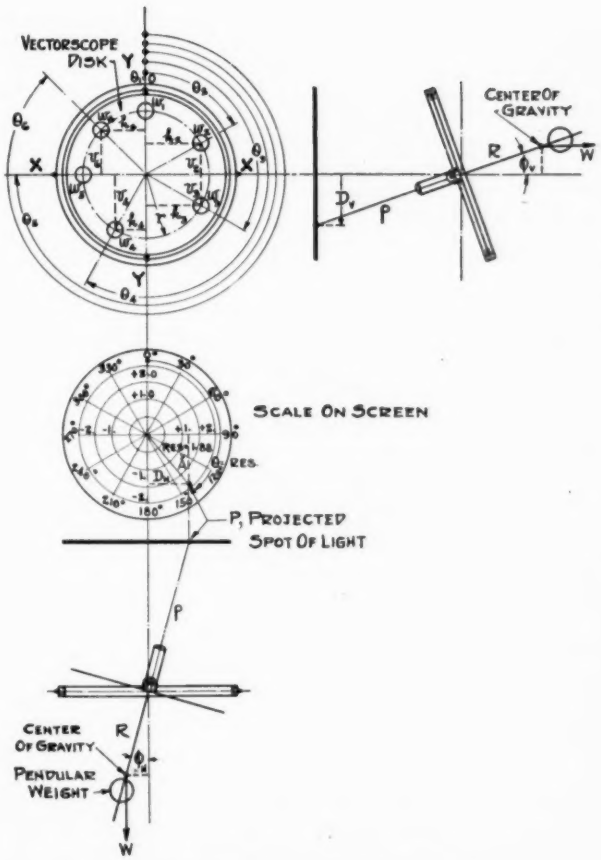

FIG. 5 ELEMENTAL FORM OF VECTORSCOPE

tually perpendicular axes, displacing the net pendular weight W from its previously plumb position. The net moments of weights w_1 to w_6 about the two axes are balanced by the moment of the displaced weight W. For this condition of equilibrium, about Y-Y

$$WR \sin \phi_H = w_1 r \sin \theta_1 + w_2 r \sin \theta_2 + w_3 r \sin \theta_3 + w_4 r \sin \theta_4 + w_5 r \sin \theta_5 + w_6 r \sin \theta_6$$

or, in general

$$WR \sin \phi_H = r\Sigma(w \sin \theta) \quad [1]$$

About X-X

$$WR \sin \phi_V = w_1 r \cos \theta_1 + w_2 r \cos \theta_2 + w_3 r \cos \theta_3 + w_4 r \cos \theta_4 + w_5 r \cos \theta_5 + w_6 r \cos \theta_6$$

or, in general

$$WR \sin \phi_V = r\Sigma(w \cos \theta) \quad [2]$$

The optical system attached to the Vectorscope disk projects a spot of light on the graduated screen. The displacements of this point of light from the zero position are

$$D_H = \rho \sin \phi_H \quad [3]$$

$$D_V = \rho \sin \phi_V \quad [4]$$

Combining Equations [1] and [2] with [3] and [4]

$$D_H = \frac{\rho r}{WR} \Sigma(w \sin \theta) \quad [5]$$

$$D_V = \frac{\rho r}{WR} \Sigma(w \cos \theta) \quad [6]$$

For small values of ϕ_H and ϕ_V, ρ may be considered constant. For deflections of 5 deg the error introduced is 1 — (1/cos 5 deg) or about 0.38 per cent. D_V and D_H are therefore measures of the net vertical and horizontal components of the original vectors.

Corresponding to displacements D_V and D_H the point of light on the screen assumes the position shown in Fig. 5. The radius to point P, therefore, represents the resultant vector, while D_V and D_H are the respective vertical and horizontal components. The direction of the resultant is also indicated directly on the calibrated screen.

Examination of Equations [5] and [6] shows that the scale or sensitivity of the instrument may be controlled by varying WR. Moving the pendular weight toward the disk, decreases R and magnifies the readings. This offers a convenient means for calibrating the scale in terms of any one of the vectors. One of the weights, say w_1, is placed on the disk. See Fig. 5. This weight has a moment about X-X, but not about Y-Y. The vertical position of the pendular weight is now adjusted until the spot of light reaches a point on the screen, which yields convenient readings in terms of the vector represented by w_1. As an example, if w_1 represents a vector of 105 units, the vertical position of the pendular weight is adjusted until a scale reading of 1.05 obtains. Subsequent readings of vector sums are therefore readily obtained by multiplying scale readings by 100.

USE OF VECTORSCOPE IN STUDY OF ENGINE BALANCE AND FIRING ORDER

The condition of engine balance is intimately associated with the choice of firing order. It is beyond the scope of this paper to discuss this problem except as it is necessary to demonstrate application of the Vectorscope to such problems.

Fig. 6 shows the crankshaft of a five-cylinder two-cycle engine. Due to the reciprocating weight and crankshaft angularity there exists at each crank an inertia force acting in the line of the piston stroke. There is no horizontal component.

The inertia force at each crank is expressed by

$$F = \frac{4\pi^2 N^2 r_c}{3600g}\left[\cos \theta + \frac{r_c}{l} \cos (2\theta) + \ldots\right] \quad [7]$$

This indicates that the inertia force is equivalent in effect to a series of harmonic forces recurring once per revolution, twice

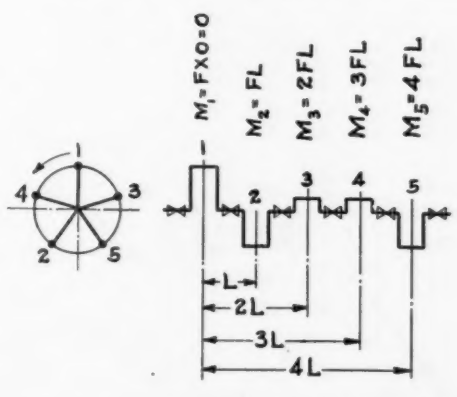

FIG. 6 CRANKSHAFT OF FIVE-CYLINDER TWO-CYCLE ENGINE (Indicating moments about cylinder No. 1 of inertia forces of reciprocating parts.)

per revolution, and so on. The first two harmonics are the most important, but the 4th, 6th, ... harmonics though progressively smaller also exist. In high-speed engines the 4th harmonic may be of importance. If the discussion is limited to the first two harmonics, only two separate forces need be considered.

$$F_{\mathrm{I}} = \left(\frac{4\pi^2 N^2 r_c}{3600g}\right)\cos\theta \quad \ldots\ldots\ldots\ldots\ldots [8]$$

$$F_{\mathrm{II}} = \left(\frac{4\pi^2 N^2 r_c}{3600g}\,\frac{r_c}{l}\right) \times \cos(2\theta) \quad \ldots\ldots\ldots\ldots [9]$$

Where

F_{I} = primary force, lb
F_{II} = secondary force, lb
N = engine speed, rpm
l = length connecting rod, inches
r_c = crank radius, inches
g = gravitational constant, inches per sec per sec
θ = angular displacement of crank from top dead center of cylinder No. 1 taken as reference position.

Take crank No. 1 as a reference point for expressing moments. Since the same force exists at each cylinder, the moment of any cylinder is proportional to its distance from the reference point. The phase relation for successively firing cylinders is 72 deg for the primary forces and moments, and 2 × 72 = 144 deg for secondary forces and moments. Assuming equal cylinder spacing the moments of cranks 2, 3, 4, and 5 are in the proportion of 1:2:3:4. The moment of crank No. 1 is zero. Vector diagrams for primary and secondary moments are shown in Figs. 7 and 8.

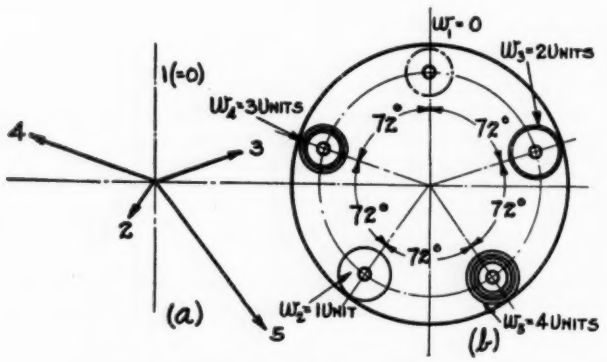

FIG. 7 PRIMARY MOMENTS OF FIG. 6
[(b) Disposition of weights on Vectorscope for evaluating the vector diagram (a).]

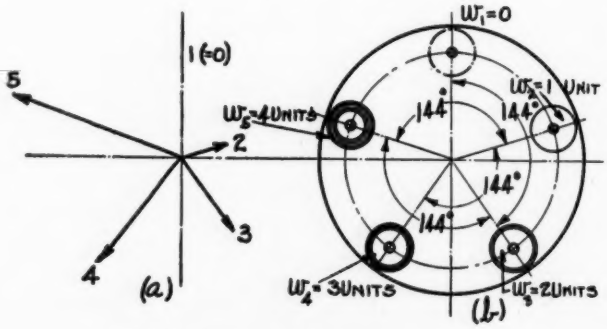

FIG. 8 SECONDARY MOMENTS OF FIG. 6
[(b) Disposition of weights on Vectorscope for evaluating the vector diagram (a).]

Consider a Vectorscope disk having 5 pegs disposed 72 deg apart, and weights in the proportion of 0:1:2:3:4 selected to represent, respectively, the moments of the cranks 1, 2, 3, 4, and 5. Each of these weight groups is marked with the cylinder number. To evaluate the vector diagrams the following procedure is followed: Temporarily place one of the weights, preferably w_2 which represents one weight unit, on the peg at $\theta = 0$, that is, the top peg shown in Fig. 7(*b*). Adjust the pendular weight (10), Fig. 1, until a convenient scale reading is obtained in terms of the primary moment

$$\left(\frac{4\pi^2 N^2 r_c}{3600g}\right) \times L$$

After the instrument is thus calibrated, place the weights on the pegs in proper phase relation with respect to firing order. There is no weight for w_1 since crank No. 1 has zero moment. For the primary moment the vectors are 72 deg (one interval on the disk) apart and the weights are disposed as shown in Fig. 7(*b*). The vector sum and the direction of the resultant are indicated directly on the screen.

To obtain the resultant secondary moment, that is, to evaluate the vector diagram of Fig. 8(*a*), readjust the scale as described for primary moments. Since the phase relation is 2 × 72 deg for secondary moments, dispose the weights, in firing sequence, on every second peg as shown in Fig. 8(*b*).

In similar manner, the 4th harmonic may be obtained by putting these same weights on every fourth peg. Higher harmonics are similarly summed up by distributing the weights by counting off each time a number of peg spaces equal to the harmonic under consideration.

Study of Firing Orders by Vectorscope. The moment of any crank is determined only by its distance from crank No. 1, and is independent of firing order. The resultant however *is* influenced by firing order. After once calibrating the Vectorscope and fixing the weights representing cylinder moments, the resultant unbalanced moments for a large number of firing orders may be quickly investigated.

For the five-cylinder two-cycle engine the number of firing orders possible is $(n - 1)!/2 = (4 \times 3 \times 2 \times 1)/2 = 12$. By systematic shifting of the weights a reading for each of the possible firing orders is quickly obtained. A similar procedure is now carried out for the secondary moments but, in reading off the firing order, successively firing cylinders are displaced by two peg spaces or 144 deg. If required, similar procedures may be carried out for the higher harmonics.

Thus far, moments due only to the inertia of reciprocating weights have been considered. These inertia forces act vertically only, having no horizontal component. Centrifugal forces due to unbalanced weights also produce moments of importance, having components in both vertical and horizontal planes of the engine. They are of primary frequency only. Higher harmonics do not exist. The response of the engine and structure in the two planes is usually different, and it is desirable and customary to determine the horizontal and vertical components, rather than the resultant unbalance. The vector diagram of moments and the procedure in the use of the Vectorscope to evaluate these moments are the same as previously described. The horizontal and vertical components may be read off directly from the screen.

A listing of Vectorscope readings permits choice of a suitable firing order. In interpreting these results, it must be borne in mind that other factors such as manifolding, bearing pressures, and torsional vibration, are also influenced by the choice of firing order.

For an engine with a large number of cylinders, the number of

TABLE 1

No. of cylinders	3	4	5	6	7	8	9	10	11	12
No. of firing orders	1	3	12	60	360	2520	20,160	181,440	1,814,400	20,958,840

possible firing orders rises rapidly, as is shown in Table 1.

From this it would appear quite feasible to completely explore the whole range of firing orders for engines up to eight and possibly even nine cylinders.

The present arrangement of the Vectorscope includes a set of disks with holes spaced as shown in Fig. 9. These disks would care for all in-line engines having from 3 to 12 cylinders. Paper masks are slipped over the disks to clearly indicate the holes to be used for a particular engine. The instrument is arranged to permit simple interchange of disks.

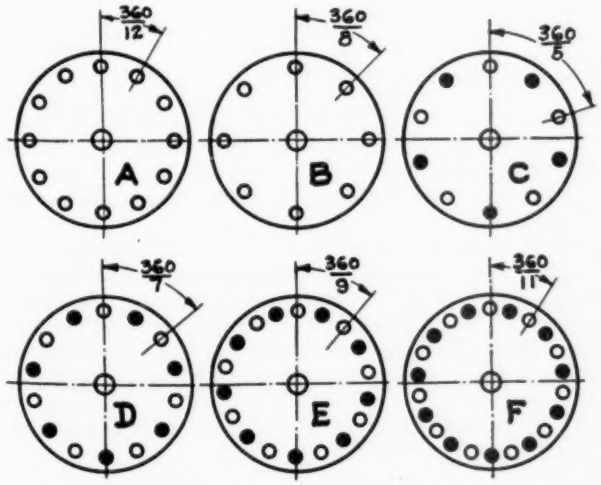
Disks may be arranged to suit any particular configuration of cranks. In studying the balance of the Vee engine, special disks may be made up to suit the particular configuration of cylinders. Fig. 10 represents a 12-cylinder 2-cycle Vee engine comprising two 6-cylinder banks in 90-deg Vee. Disks permitting the study of primary and secondary unbalance are shown in Fig. 11.

The Torsional-Vibration Problem

The Vectorscope is useful in solving a certain phase of the torsional-vibration problem. The input of vibration energy (inch-pounds) in a multicylinder engine is

$$K_I = (\pi^2/180) M_v \alpha (\Sigma\beta) \quad [10]$$

where α = amplitude of vibration at the free end of the crankshaft, degrees



M_v = harmonic torque of cylinder for particular order of vibration under consideration, pound-inches

$\Sigma\beta$ = vector sum of the amplitudes of vibration at the respective cylinders, their relative phase being that of the successively firing cylinders.

The phase relation for a given order of vibration is

$$\phi = m\theta \quad [11]$$

where ϕ = phase angle, degrees

No Of Cylinders	3	4	5	6	7	8	9	10	11	12

Fig. 9 Set of Vectorscope Disks

(For in-line engines of from 3 to 12 cylinders. Disks *C*, *D*, *E*, and *F* have additional holes, shown solid, diametrically opposite the basic ones. These are for negative vectors which require a shift of 180 deg.)

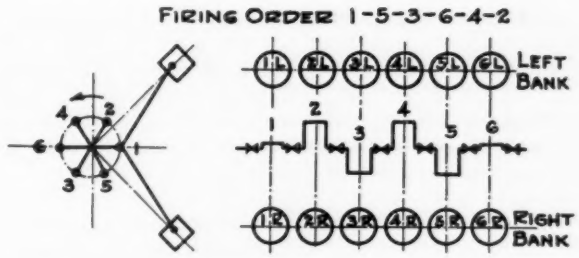

Fig. 10 A 12-Cylinder 2-Cycle 90-Deg Vee Engine

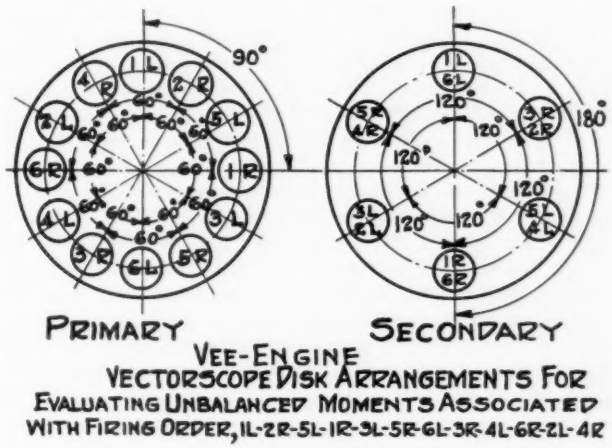

Fig. 11 Vectorscope Disks for Engine of Fig. 10

m = order of vibration (number of vibrations per revolution of engine)

θ = crank displacement between successively firing cylinders.

When in a critical speed of amplitude α, the absorption of damping energy K_D is equivalent to the energy input K_I, coming from the harmonic torques. Assume a law for damping,

$$K_D = K_d \alpha^\lambda \quad [12]$$

$$K_I = K_D$$

$$(\pi^2/180) M_v \alpha (\Sigma\beta) = K_d \alpha^\lambda$$

$$\alpha = \sqrt[\lambda-1]{\left(\frac{\pi^2 M_v (\Sigma\beta)}{180\ K_d}\right)} \quad [13]$$

It is apparent that the amplitude of vibration depends on $\Sigma\beta$. From Equation [11], as applied to the seven-cylinder engine of Fig. 12, $\theta = 720/7$ deg. When $m = 3.5$, 7, or 10.5, $\phi = 360$, 720, and 1080 deg. For these orders of vibration, known as majors, the β's add up arithmetically, since their phase relation is 360 deg or a multiple thereof. All other orders, known as minors, have a phase relation ϕ, as listed in Table 2. Groups marked with the same letter are equivalent as regards the magnitude of the resultant vector, but of different resultant phase. The $\Sigma\beta$ for major orders is independent of firing order, whereas $\Sigma\beta$ for minor orders is very much affected.

In Fig. 13 is shown a typical vector diagram for the third-

TABLE 2

	$\phi = m\theta$

[a] In terms of number of peg intervals. Each interval = 720 deg × m.

order vibration associated with the relative-amplitude curve of Fig. 12, and the firing order 1-7-2-6-3-4-5. To evaluate this vector diagram with the Vectorscope, in the now familiar manner, weights in proportion to the β values are placed on the seven-peg disk, in proper phase relation. The screen is calibrated by placing the weight representing β on the disk and adjusting the pendular weight to a position giving a suitable scale.

For each firing order, the whole range of orders may be investigated by simply shifting the weights to their appropriate angular positions. Starting with the one order, each weight, in sequence of firing, is placed on the pegs in succession, progressing in a clockwise direction. For the second order, the weights are placed on every second peg; for the third order, every third peg, and so on. Usual interest would center about the magnitude of the resultant, since the phase is unimportant, so that in the seven-cylinder engine there are only three groups of minor orders to be evaluated. The number of groups corresponding to engines with other numbers of cylinders may be found elsewhere.[3,4]

In any particular problem, the β values are fixed, and a change in firing order does not call for readjustment of the weights representing them. Thus to investigate the whole range of possible firing orders calls merely for a proper shifting of these weights. The values of $\Sigma\beta$ for a whole set of firing orders may thus be quickly and accurately determined. In the seven-cylinder engine there are 360 possible firing orders. Since there are 3 groups of minors, the complete investigation involves 1080 shifts of weights. With the aid of the Vectorscope this appears to be an entirely feasible task requiring a minimum of skill and care.

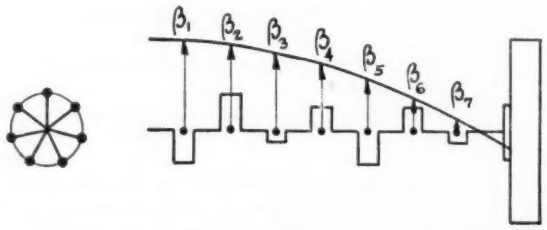

FIG. 12 TORSIONAL VIBRATION, RELATIVE-AMPLITUDE CURVE

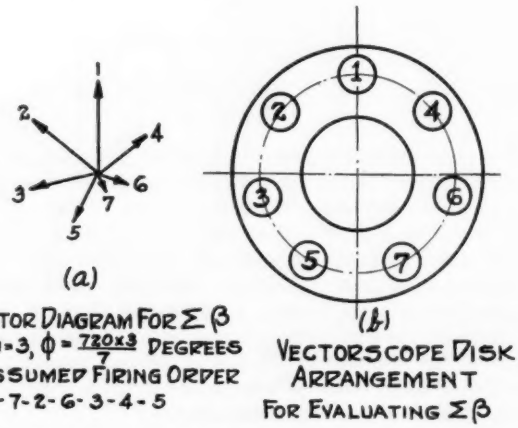

FIG. 13 DIAGRAM AND DISK FOR THIRD-ORDER TORSIONAL VIBRATION FOR FIG. 12

[3] "Torsional Vibration in the Diesel Engine," by F. M. Lewis, Trans. Society of Naval Architects and Marine Engineers, vol. 33, 1925, pp. 109–140.

[4] "The Elimination of Torsional Vibration," by G. J. Dashefsky, Pennsylvania State College Bulletin, vol. 24, no. 44, November, 1930, pp. 193–265.

RELATION OF ENGINE BALANCE AND TORSIONAL VIBRATION AS AFFECTED BY FIRING ORDER

In the usual problem met in the study of engine dynamics, it is necessary to compromise the characteristics of torsional vibration and engine balance. This means a search for a firing order which will yield small unbalanced moments primary and secondary, without aggravating the minor-order torsional vibrations, that is, $\Sigma\beta$ must also be small.

Fig. 14, indicates a more or less typical relative-amplitude curve, and shows that cylinders having large β values also have large moments about cylinder No. 1. Thus the same harmonics or orders of vibration will give similar vector diagrams. As regards unbalanced moments, only the first, second, and fourth

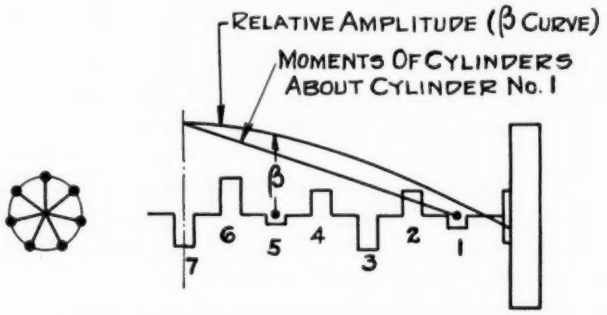

FIG. 14 RELATIVE-AMPLITUDE AND MOMENTS CURVES

harmonics are important. It is apparent that these harmonics correspond to the first, second, and fourth orders of torsional vibration. A firing order which yields a small or large value of unbalanced moment, also yields a small or large value of $\Sigma\beta$ for the corresponding order of torsional vibration. This link between unbalanced moment and torsional vibration makes it necessary to consider both of these problems as of mutual importance.

THE VECTORSCOPE AS A HARMONIC ANALYZER

Any periodic function such as the torque curve illustrated in Fig. 15 may be represented by Fourier's trigonometric series, so that

$$T = f(\theta) = A_0 + A_1 \sin\theta + A_2 \sin 2\theta + A_3 \sin 3\theta + \ldots A_n \sin n\theta + B_1 \cos\theta + B_2 \cos 2\theta + B_3 \cos 3\theta + \ldots B_n \cos n\theta \ldots [14]$$

The coefficient, A_0, represents the mean torque of the engine, while the coefficients $A_1, A_2, \ldots A_n$ and $B_1, B_2, \ldots B_n$ represent the sine and cosine harmonic components of the turning-effort curve.

These are important coefficients in many engine problems and it is frequently necessary to evaluate them. Schematic tabulations and mechanical devices are available for performing harmonic analyses. The Vectorscope seems to be well adapted to speedy determination of one or many of these coefficients by simple mechanical procedure requiring a minimum of care and concentration.

If the periodic function is considered as occurring over 2π radians it can be shown that

$$A_0 = \frac{1}{2\pi}\int_0^{2\pi} T d\theta \ldots [15]$$

$$A_m = \frac{1}{\pi}\int_0^{2\pi} T \sin m\theta \, d\theta \ldots [16]$$

$$B_m = \frac{1}{\pi}\int_0^{2\pi} T \cos m\theta \, d\theta \ldots [17]$$

A_m and B_m represent the harmonic coefficients for the mth harmonic of the Fourier series of Equation [14].

The coefficient A_0 is obtained from evaluation of Equation [15], where the integral represents the net area under the original curve. The integral involved in the expression for A_m is the area under the curve, $t = f(T \sin m\theta)$. See Fig. 15. This latter function is determined by multiplying each ordinate of the original function by the appropriate sin $(m\theta)$. The area under this curve multiplied by $1/\pi$ is the value of A_m. The values of B_m may be obtained in a similar manner, excepting, of course, that the auxiliary curve $t = f(T \cos m\theta)$ is obtained by multiplying ordinates of the original curve by the appropriate cosines of $m\theta$.

As a general matter, the process for determining the areas representing the integrals of Equations [15], [16], and [17] is

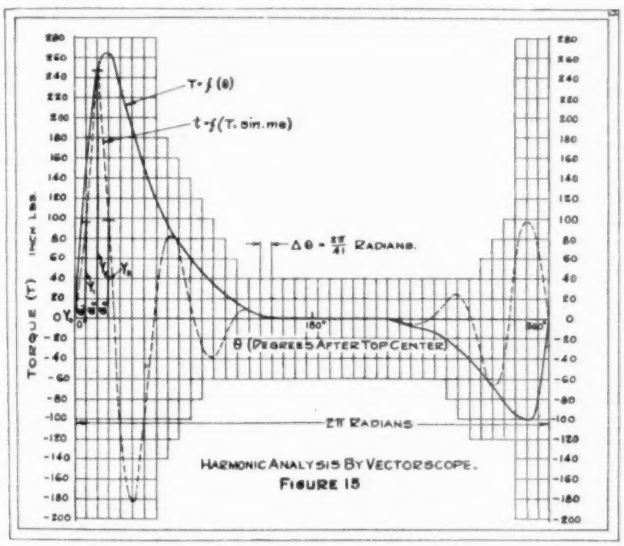

FIG. 15 HARMONIC ANALYSIS BY THE VECTORSCOPE

not important. However, in adapting the Vectorscope as a harmonic analyzer, the following method of obtaining areas is desirable.

The abscissa of the original function is divided to give r equally spaced ordinates at $(r - 1)$ equally spaced intervals of $\Delta\theta$. The ordinates at each point are multiplied by the appropriate sine or cosine value giving a new series of ordinates on the curves $t = f(T \sin m\theta)$ and $t = f(T \cos m\theta)$. See Fig. 15. The first elementary area a_1, assumed to be a trapezoid, may be closely approximated by $(Y_0/2 + Y_1/2)\,\Delta\theta$.

Adding up all of the elementary areas a_1, a_2, a_3, ... gives the net area of the curve, representing the value of the integrals of Equations [16] and [17].

The total area under the curve is therefore

$$\int_0^{2\pi} T \sin m\theta \, d\theta = \left(\frac{Y_0}{2} + \frac{Y_1}{2}\right)\Delta\theta + \left(\frac{Y_1}{2} + \frac{Y_2}{2}\right)\Delta\theta + \ldots . \left(\frac{Y_{r-1}}{2} + \frac{Y_r}{2}\right)\Delta\theta$$

$$A_m = \frac{1}{\pi}\int_0^{2\pi} T \sin m\theta \, d\theta = \frac{\Delta\theta}{\pi}\left(\frac{Y_0}{2} + Y_1 + Y_2 + \ldots . \frac{Y_r}{2}\right)$$

$$A_m = \frac{\Delta\theta}{\pi}\left[\frac{T_0}{2}\sin 0 + T_1 \sin (m\,\Delta\theta) + T_2 \sin (m\,2\,\Delta\theta) + \ldots . T_{r-1} \sin \{m(r-1)\,\Delta\theta\} + \frac{T_r}{2}\sin 2\pi\right] \ldots [18]$$

The first and last terms are zero. Similarly

$$B_m = \frac{\Delta\theta}{\pi}\left[\frac{T_0}{2}\cos 0 + T_1 \cos(m\,\Delta\theta) + T_2 \cos(m\,2\,\Delta\theta) + \ldots . T_{r-1} \cos\{m(r-1)\,\Delta\theta\} + \frac{T_r}{2}\cos 2\pi\right] \ldots . [19]$$

It will be noted that Equations [18] and [19] for A_m and B_m are of the form which can be evaluated by the Vectorscope.

The present arrangement of the Vectorscope requires that the original curve be divided into 41 equal intervals, that is, $\Delta\theta = 2\pi/41$ radians.

The use of 41 intervals, which is a prime number, avoids the possibility of the piling up on any one peg of several Vectorscope weights for certain harmonics. The disk for harmonic analysis has 42 basic pegs and 42 additional pegs diametrically opposite these to take care of negative ordinates.

The modus operandi for making the harmonic analysis is as follows: Prepare 42 Vectorscope weights corresponding to the ordinates of the curve to be analyzed, except the first and last weights which should represent only half the ordinate. Mark the weights for ordinate identification, including a definite indication of negative ordinates. Adjust the Vectorscope in the usual manner to give a suitable scale. A_0 is merely the algebraic sum of the ordinates multiplied by $1/2\pi$, and the use of the Vectorscope will not be required. To obtain A_1 and B_1 as well as their resultant and its phase, place the weights in order on the basic pegs; w_1 on peg 1, w_2 on peg 2, and so on. After the weights are distributed, the deflection of the spot of light on the screen will indicate directly the sine and cosine coefficients as well as the resultant coefficient and its phase, except for multiplication by $\Delta\theta/\pi$ which may however be incorporated into the scale reading, if so desired.

The second harmonic is obtained by redistributing the weights, placing w_1 on the first basic peg, w_3 on the third basic peg (2 peg angles apart), w_5 on the fifth peg, and so on, until all weights have been distributed.

Thus any harmonic, say the mth one, may be obtained by distributing the weights in succession, counting off m peg intervals each time.

Analyses up to the twelfth harmonic have been carried out for trial curves, indicating differences of about 2 per cent for the sixth harmonic and about 15 per cent for the twelfth harmonic, when compared with a chart method which is described by Lewis.[5]

Greater accuracy will, of course, attend the use of a larger number of ordinates, but the use of 42 ordinates should give results of sufficient accuracy for most purposes and types of curve.

SUMMARY

The Vectorscope is a simple and rugged instrument that requires little attention as regards adjustment and care. Any degree of fineness and accuracy may be built into it as dictated by the use intended. A diagram of a somewhat refined model suitable for desk use is shown in Fig. 16.

It is believed that this instrument will prove useful to the designer of internal-combustion engines in handling the problems of engine balance, torsional vibration, and harmonic analysis. Other uses may suggest themselves with further study and use of the device. Where extensive studies of firing order are

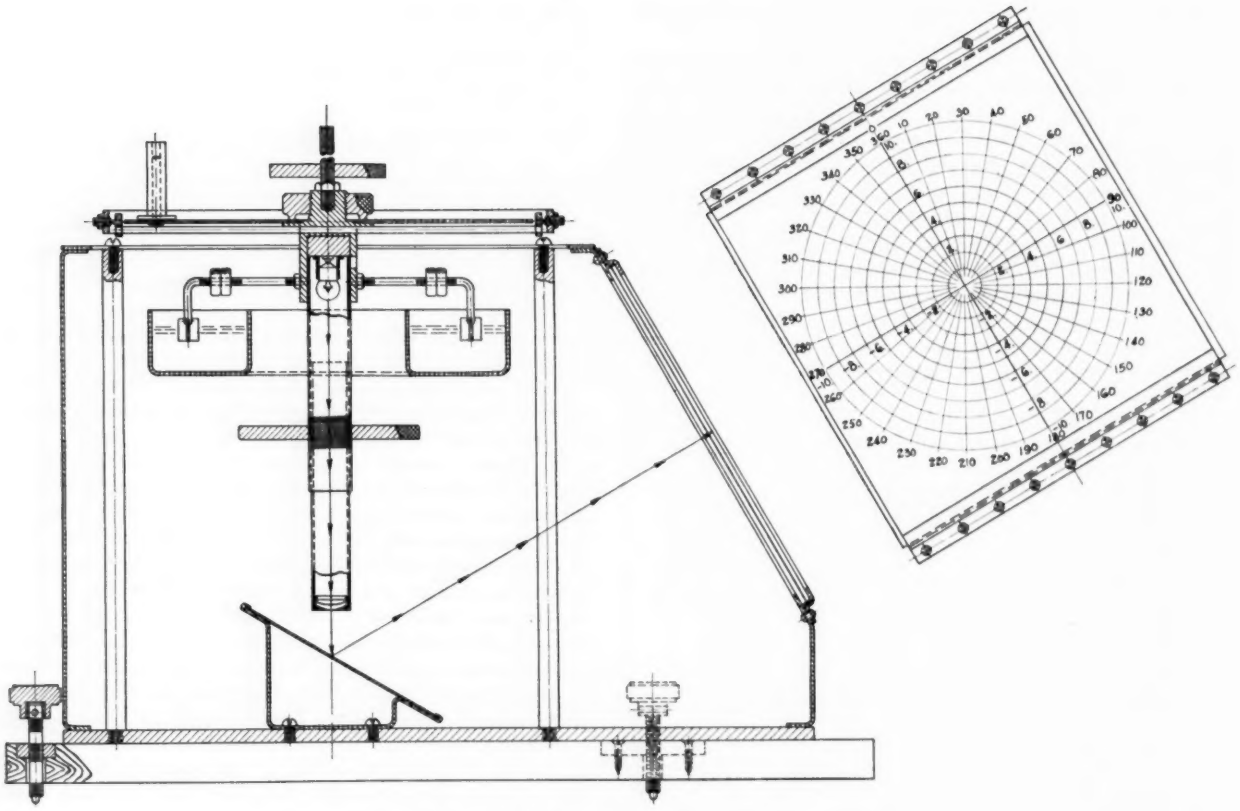

FIG. 16 A DESK-MODEL VECTORSCOPE

necessary, a considerable amount of labor may be saved. The use of the instrument is reduced to a mechanical manipulation, requiring little experience and may thus be delegated to younger members of an organization.

If considered desirable, the instrument or a bank of instruments could be used in making a complete study of all firing orders, for engines up to say nine cylinders, and listing the characteristics of engine balance and torsional vibration. For more than nine cylinders the amount of work involved for an investigation of all possible firing orders would be prohibitive. However, the brief experience of the author in using the instrument indicates that one soon recognizes the direction to shift the various weights to give small disk deflections. The sequence of the weights on the disk indicates the firing order. It is thus possible, for any configuration of cylinders, to arrive quickly at some good firing orders without investigating the whole range.

ACKNOWLEDGMENT

The author is indebted to John Dietmeier and Milton J. Berg of the Diesel-engine technical staff of the New York Navy Yard for many helpful suggestions in the design of the instrument and in preparing the present paper.

Discussion

A. D. ANDRIOLA.[6] The superiority of the Vectorscope over analytical solutions for the three types of problems discussed by the author appears chiefly as a time-saving feature. This advantage is predominant where the vectors involved are of different magnitudes as, for example, the average elastic curve met with in torsional-vibration problems. Where used for firing-order investigation for various numbers of cylinders or for harmonic analysis, a reduction in total time is not readily seen. In both of these problems, especially the latter, the matter of summation represents the appreciably smaller proportion of the work involved.

Incidentally, the instrument is subject to the same limitations that exist in analytical methods. Beyond nine cylinders the amount of work involved for a complete investigation of the range is great and almost prohibitive. Below this number of cylinders much information has been published but as yet is not complete. In this respect the instrument may prove very useful.

The writer does not feel that analysis should be discarded in favor of a mechanical device when the advantages are not too marked. This, of course, has not been implied in any manner by Mr. Dashefsky. Instead, they should be employed to supplement each other. This procedure is very desirable where complex work is involved since a check of principal results by two independent methods practically eliminates all chance for error.

Undoubtedly since the presentation of the paper the author had further opportunity to experiment with the Vectorscope. His remarks on a comparison with analytical methods for both speed and accuracy and as regards applications other than those considered in the original paper would be appreciated.

K. J. DEJUHASZ.[7] Determination of engine balance and torsional vibrations has been justifiably regarded as a bugbear of Diesel-engine design. It involves difficult and lengthy calculations in which it is easy to commit serious errors which are diffi-

[6] Electric Boat Company, Groton, Conn. Jun. A.S.M.E.

[7] Associate Professor of Engineering Research, The Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

cult to detect. Graphical construction alleviates these difficulties to an important extent. Even this method, however, involves a prohibitive amount of labor, if all the great number of possible crank arrangements in multicylinder engines are to be investigated.

The Vectorscope described by the author is an invention which appears to supply the practicable solution to this complex problem. The correctness of its principle is fully proved and its arrangement and design have reached a thoroughly practicable stage.

In the present arrangement the value of the vector is changed by changing the weight and keeping its radius constant. The other alternative of keeping the weight constant and varying the radius appears to have some desirable features. Furthermore, a combination of these two methods could be used. The author has undoubtedly considered these alternatives so it would be of interest to learn the reasons for the adoption of the present choice.

Stacking the weights on the pegs introduces a slight change of the actual lever arm when the disk is tipped. While the error from this source is small, it could be fully eliminated by suspending the weights on hooks located in the plane of the virtual pivot of suspension.

The importance of being able rapidly and accurately to determine engine balance is attested to by the fact that in Europe a mechanical device has also been developed to simplify the work.[8] This however embodies a linkage arrangement. It is intended to provide balancing for the first harmonics only, and it does not appear to possess the adaptability and the accuracy of the Vectorscope.

It is interesting to speculate upon the possible further developments of this instrument. It appears to be possible to shift the weights (or, in general, to alter the relative orientation of the vectors) automatically, according to a predetermined program. Thereby the full investigation of multicylindered engines would become a practicable proposition and much drudgery would be eliminated. Far-fetched as this possibility may seem, one has to bear in mind that numerous complicated and costly mechanical calculators have been built in recent times and found useful, such as mechanical harmonic analyzers and integrators, including the apparatus at the Massachusetts Institute of Technology and at the University of Pennsylvania for solving differential equations; the apparatus developed at the University of Pennsylvania for solving algebraic equations; the wave analyzers for the prediction of tides; the automatic devices developed for the study of light spectra and of the composition of the human voice (Bell Telephone Laboratories).

Even in its present simple form, however, there can be no doubt of the usefulness of the Vectorscope for calculation, and, also, as an instructional aid serving to facilitate for a student the understanding of the complex problems of engine dynamics. The Vectorscope reflects credit on all the men associated in its development. It can be listed as one of the numerous important contributions of the United States Navy to the advancement of Diesel-engine design.

F. M. Lewis.[9] There exists a considerable error in the Vectorscope in its present form. This is due to the location of the weights, representing the vectors to be added, in a position above the plane of the gimbal supports. The correct moment of a weight is $w_1 r \sin \theta_1 + w_1 h_1 \sin \phi v$, where h_1 is the distance of the center of gravity of w_1 above the plane of the gimbals. The effect of the weights being added above the plane of the gimbals is to increase the sensitivity of the instrument, i.e., virtually to decrease R.

It would appear necessary to modify the instrument in such a way that this error is not introduced. A suggested method is to provide a disk with radial holes drilled in it, in which rods can be slid in and out. The rods could be suitably scaled. Some difficulty arises in locating the gimbals in the same plane but it is not insuperable.

It is pointed out that considerable study has already been given to the problem of balance and torsional vibration in engines up to nine cylinders. Even the Vectorscope appears to be too tedious a means for a complete investigation above that number.

The use of the instrument for harmonic analysis is very interesting and, with 41 ordinates, a high degree of accuracy should be attained, if the instrument is modified to correct the error previously mentioned. The complication of negative ordinates can be avoided by the arbitrary choice of an axis below the lowest point of the curve. This influences none of the coefficients except the constant term.

Philip Mallozzi.[10] Vector summation of forces, moments, and component amplitudes of vibrations constitutes a large portion of the task involved in a complete analysis of Diesel-engine installations. It is now admitted by engineers that serious study of the vibration problem must be made before mating a Diesel engine with other parts of the drive.

In choosing a suitable firing order for an engine having more than seven cylinders, to make a complete investigation in order to arrive at a desirable compromise between engine balance and torsional vibration is a lengthy task if the usual graphical or tabulation methods of summing vectors are used. To this end the author's Vectorscope is invaluable as a time-saving device. In operating the instrument, it can be seen at a glance how to move the vector weights in order to arrive at firing orders that will give smaller deflections of the indicator.

In summing up vectors graphically or analytically, unavoidable graphical or arithmetical errors obtain. Similarly, in summing up vectors by means of a mechanical instrument, such as the one presented in this paper, unavoidable small instrument errors are present. The predominant errors are as follows:

1 If the motion of rod No. 9 is sufficiently large, the liquid used to dampen the motion of the rod gives rise to a buoyancy component which tends slightly to increase the resultant vector.

2 If the vector weights No. 13 are sufficiently tall, the center of gravity of the system comprised of disk and vector weights will rise. This condition will tend slightly to change the true resultant moment, which moment is not accounted for in the author's Equations [1] to [6].

The foregoing comments have been made for the purpose of emphasis on the limitations of the instrument. However, in either of the two cases, the error can be made negligible for all practical applications of the Vectorscope. The error indicated in case No. 1 can be reduced by lightening and properly shaping the damper plates. The error indicated in case No. 2 can be reduced by making the disk sufficiently large and by making the vector weights low.

In Fig. 14 the author shows that the engine cylinders, which have large values of the amplitude factor $\Sigma \beta$, also have large moments about cylinder No. 1, thus yielding similar vector diagrams for the same harmonics of either unbalance moments or orders of vibration. In this connection it is desired to point out that this condition exists only for that mode of vibration which has the node at, or slightly remote from, cylinder No. 1.

L. M. PORTER.[11] The writer will discuss mainly the instrument's application to the investigation of the rocking moments produced by the inertia forces.

In discussing Equation [7] for the inertia force in each cylinder, would it not be clearer if the fact were mentioned that this equation gives the inertia force in pounds per pound of reciprocating weight? The reciprocating weight has been omitted from the equation.

The author states in his paper that the same force exists at each cylinder and, therefore, the moment of any cylinder about crank No. 1 is proportional to its distance from the reference point, taken at the center line of No. 1 cylinder. Would it not clarify the discussion to point out that it is the maximum force in any one cylinder which is constant? The instantaneous values of course are functions of the crank angle, the primary forces varying as cos θ and the secondary forces varying as cos 2θ. It is the instrument itself that resolves the maximum force in any one cylinder into a vertical component, which is proportional to the instantaneous value in the cylinder, and gives the resultant of the components multiplied by their respective lever arms. However, since there are no horizontal components of the inertia forces in an in-line engine, would it not be advisable to point out that only the vertical component of the resultant shown by the instrument should be considered in the final analysis? The diagrams shown in Figs. 7 and 8 will have a resultant horizontal component. The statement on page 406 is therefore somewhat confusing, that "the vector sum and the direction of the resultant are indicated directly on the screen." Why not leave out the direction in the present case? The horizontal component may be automatically taken care of in Figs. 7 and 8 by placing a second set of weights on the pegs in mirror similarity to the first set. This of course will double the vertical component but a suitable adjustment of the counterweight (10) will take care of this.

In Table 1 the author lists the possible number of firing orders for engines with a different number of cylinders, after stating previously that the number of firing orders is given by the expression $(n - 1)!/2$. It would appear that, in the case of a two-stroke-cycle in-line engine, there are twice as many firing orders as those listed in Table 1. In this type of engine the cranks must necessarily be evenly spaced to give an evenly spaced order of firing impulses. Each cylinder will fire as the crank passes through every top-center position. Since it is possible to twist the cranks into any desired location, it is evident that a three-cylinder engine may fire 1–2–3 or 1–3–2 instead of in only one order as given in Table 1. Similarly, for a four-cylinder two-stroke-cycle in-line engine with cranks spaced 90 deg, there are six possible orders instead of three, i.e., 1–2–3–4; 1–2–4–3; 1–3–2–4; 1–3–4–2; 1–4–2–3; 1–4–3–2; and so on for the other engines.

In the case of the 12-cylinder 90-deg V-type engine shown in Figs. 10 and 11, for the direction of rotation and spacing of cranks shown, it would appear that cylinder $3R$, and not $2R$, will fire after $1L$, inasmuch as $3R$ will be the next crank passing through its top-center position. In choosing a basic firing order for this engine, would it not have been better to use the conventional six-cylinder firing order of 1–5–3–6–2–4 instead of 1–5–3–6–4–2? The latter sequence has cylinders 2 and 1 in any one bank firing successively. It is well known that this arrangement does not produce the best manifolding conditions where the exhaust of one cylinder may directly impede the exhaust gases leaving an adjacent cylinder.

In closing, there appear to be some inconsistencies in connection with the seven-cylinder in-line engine. The firing order given on page 408 is not apparent from the diagram shown in Fig. 12, and the successively firing cylinders will again cause exhaust interference. It is also not clear whether the author is still referring to a two-stroke cycle or has changed to a four-stroke cycle. The expression for the crank displacement between successively firing cylinders given on page 407, $\theta = 720/7$ deg, would indicate that he has a four-stroke cycle in mind.

[11] Assistant Professor of Machine Design, New York University, College of Engineering, New York, N. Y.

T. C. RATHBONE.[12] The Vectorscope as described has been developed to aid in the analysis of engine balance and torsional-oscillation characteristics, where much labor is involved in the handling of vector quantities.

This apparatus would also appear to be valuable for the solution of rotor unbalance on the usual turbine generator installations having three or four bearings and three or four corrector-weight locations. The rotor-balancing problem is developed analytically in a current paper by J. G. Baker.[13]

A unit of unbalance at each location produces "unit vectors," defining the vibration at each bearing. For four bearings and four corrector locations, there are therefore sixteen unit vectors. The problem is to cancel the initial unbalance at all bearings by adjustment of the magnitude and azimuth of all the mutually interdependent unit vectors.

It would seem that four Vectorscopes, geared together, should aid materially in reducing the labor necessary to determine the group relations which affect only a single chosen bearing.

PAUL SHIRLEY.[14] There does not seem to be much that can be added to the subject matter of this paper. The explanations are clearly given. The Vectorscope should prove to be a time saver in solving the problems mentioned in the paper.

However, it might be added that the Vectorscope can be used for analysis and development of side-thrust couples and forces which are, in my opinion, just as important as the rotating and reciprocating forces and couples in arriving at good dynamic balance of engines.

P. E. SCHWEIZER.[15] The significance of the Vectorscope lies in two directions:

First, in the field of immediate demand its usefulness may be demonstrated by means of the instrument's ability to indicate the resultant vectors directly.

The determination of a suitable firing order, on account of torsional vibration and balance, has thus far been a matter of adjusting crank positions arbitrarily and calculating the results. With the Vectorscope, the minimum value of harmonic-torque input or unbalanced forces or moments may now be obtained quickly for a given set of cranks and Vectorscope weights, by means of the condition of least declination of the Vectorscope disk.

Thus, defying even the simplifying qualities of the graphic arts, the use of the Vectorscope becomes a matter of playing with weights and crank positions.

Second, if we afford ourselves a moment of leisure and review records of the past, it seems as if history again demonstrates a decided tendency toward repetition: first pebbles, then lines in the sand, and after that the flight over the runway of numbers and letters toward the higher spheres of present-day mathematics, with its complexity in form of both insolvable integrals and differential equations. Does not perhaps the Vectorscope,

[15] Consulting Engineer, Diesel Engine Division, American Locomotive Company, Auburn, N. Y. Mem. A.S.M.E.

in principle at least, represent a milestone in mathematical history in the form of pebbles, but of a higher order?

Seven years ago, the location of the $5^1/_2$ order critical of torsional vibration promised to become detrimental at the speed of operation for which the unit, an eight-cylinder four-cycle engine, was sold.

Since the unit was a stock engine, it was of course not possible to raise the natural frequency in order to effect relocation of the critical sufficiently removed from the normal rating. To lower the frequency was not deemed advisable on account of increased forced vibration, likely to be encountered due to the combined effect of the $4^1/_2$ and 4 orders.

Therefore, the only alternative that remained was a change in firing order. This meant changing the relative position of the cranks arbitrarily, after which the process was solved by the slide rule. Doing this for different settings, resulted in the firing order: (*a*) 1–2–3–5–8–7–6–4–1. Checking up the question of balance for this firing order gave the result of complete balance, both for the forces and moments.

The crankshaft was ordered and the engine tested. Tests covered torsiographic measurements and comparison with those taken from a similar installation with firing order: (*b*) 1–3–2–5–8–6–7–4–1, which firing could be altered to the standard firing order: (*c*) 1–6–2–5–8–3–7–4–1 by a simple interchange of cams and fuel pipes.

The records indicate a reduction of 70 per cent over the $5^1/_2$-order amplitude due to firing order (*c*) with everything else, except the relative crank position, being identical.

It would be interesting to know whether the Vectorscope can produce a still more favorable ratio. In any case, the writer was satisfied with the results obtained and several engines are operating successfully with firing order (*a*).

Relative to the question of balance, a surprise was in store, however. Despite the fact that calculations indicated complete balance, the engine proved rough on the test floor. This consisted of two usual cast-iron flanged beams about 30 in. high and reinforced very little sideways. The engine, on the other hand, being of the individual-cylinder type, proved quite elastic in the combined base and frame sections.

Since firing order (*a*) results in the firing of two four-cylinder groups alternately, the platform, fastened to the individual cylinders, had a decided tendency toward twisting itself in the middle.

This incident demonstrated clearly that, aside from torsional vibrations and balance, torque reaction forces do exist and must also be considered in all instances in which the polar moment of inertia of frame and base combination is of small numerical value, and such is intended to be mounted on a relatively flexible foundation.

Since the engine referred to was to be mounted on a rigid concrete foundation, it was concluded that the disturbances cited would not be present in the field.

This example applied to the Vectorscope means that those who are going to use it should also consider, beside torsional vibration and balance, the foundation, the well-beaten path, and tradition of the trade.

Author's Closure

The author does not agree with Mr. Andriola that the reduction in time, when using the Vectorscope for firing-order investigations and harmonic analyses, is not marked. The study of firing orders usually involves a set of vectors of fixed magnitude and varying orientation. The Vectorscope appears particularly well adapted to this type of vector addition because, once the set of weights representing the vectors has been adjusted, each shift in position of the weights immediately yields the resultant of a complete vector diagram.

With regard to the second type of problem, harmonic analysis, it is the author's opinion that the Vectorscope will find broad application. The existing tabular methods for making an harmonic analysis lack accuracy for the higher harmonics, unless a great number of ordinates is used. The use of many ordinates involves a considerable increase in work. Furthermore, these schematic tabulations require extreme concentration as regards the algebraic signs involved. It is very easy indeed for errors to creep in. In this respect, the Vectorscope seems to have a decided advantage. After having made up the weights, representing the ordinates of the curve under analysis, the remaining procedure is entirely mechanical. The probability of error is considerably less than with the tabular solution.

The author is now constructing a Vectorscope of large dimensions, incorporating improved mechanical arrangements. In the near future he will be in a better position to make further studies of the instrument and its application to various problems.

The discussion of Professor DeJuhasz is most interesting. The objection to the arrangement of weights is noted. It has been recognized that the present arrangement introduces an error. However, the arrangement is simple and seems to afford the maximum of accessibility when shifting weights. By using weights of larger diameter, in order to reduce the height of the stacks, in combination with a larger Vectorscope disk, this error should be reduced to the point of being negligible. The suggested arrangement of combining weights, which can be shifted radially with variable weights at fixed radius, appears entirely feasible and is being considered in an arrangement now being designed.

Referring to comments by Professor Lewis, as stated above in response to Professor DeJuhasz, the location of weights above the plane of the gimbals admittedly introduces an error. In the model used for demonstration, the stacks are rather tall, compared with the disk, which is only 6 in. in diameter. An instrument intended for actual use should be larger than this, and the weights should be arranged to have their centers of gravity as close as possible to the plane of the gimbals. The radially extended rods suggested by Professor Lewis would seem to complicate the mechanical arrangement of the instrument unnecessarily. In the author's opinion it would be better to accept a slight error rather than sacrifice the mechanical simplicity. This phase of the instrument's design is being considered and improved arrangements have been devised. The author is grateful to Professor Lewis for his suggestion regarding the elimination of negative ordinates, when making harmonic analyses. This simplifies the disk as well as the distribution of weights in the process of making the analysis.

The comments of Mr. Mallozzi indicate an error introduced by the buoyancy effect of the damper. It is essential that the ratio of submerged surface to volume of the damping vanes be made large. The error due to this cause may further be reduced by using a lighter damping fluid. Use of an oil instead of mercury would reduce the buoyancy component in the ratio of approximately 1 to 15, and result in a negligible buoyancy effect.

Professor Porter's discussion regarding the force expressed by Equation [7] is well taken. The force as expressed is for 1 lb of reciprocating weight. The discusser also points out that the respective maximums of primary and secondary harmonics are used in calculating the resultant forces and moments. Discussion of these fundamentals was not deemed necessary in the paper, since it was assumed that the reader would have a knowledge of them. Rather, the object of the paper was to explain the principle and application of the instrument. There is one point upon which Professor Porter seems to have a wrong impression. In interpreting the meaning of "horizontal" and "vertical" components, he states that the moments due to reciprocating forces have no horizontal component. This is correct. Apparently, he has

overlooked the fact that the horizontal and vertical components, referred to as being indicated directly on the screen, are the two coordinate components of the resultant vector, and have no reference to their direction relative to vertical and horizontal planes of the engine. The angle of the resultant vector is merely the phase relation of the maximum value of the resultant with respect to the top dead center of the reference cylinder, No. 1, in this instance. The direction of the resultant vector is therefore quite important and it cannot be omitted from consideration as suggested. In view of the above, the complication of compensating weights, etc., suggested by Professor Porter is unnecessary.

Professor Porter questions the expression giving the number of possible firing orders. He offers proof by examples of 3- and 4-cylinder two-cycle engines, to show that there are twice as many firing orders as indicated by the formula. The two firing orders for the 3-cylinder engine are equivalents. Any vector quantities determined from these firing orders will be fully equivalent; i.e., the resultant vectors will be equal in magnitude and will differ only in direction. The vector diagrams, per se, are mirror images of each other. Likewise for the 4-cylinder engine, the following pairs of firing order are equivalent:

1–2–3–4 and 1–4–3–2
1–2–4–3 and 1–3–4–2
1–3–2–4 and 1–4–2–3

The number of firing orders is thus consistent with the formula. Another interpretation for this equivalence is that an engine having a firing order as listed at the left, upon reversing its direction of rotation, assumes the firing order indicated on the right.

Any specific firing orders mentioned in this paper were chosen merely to illustrate the various problems as related to their study with the Vectorscope. No particular effort has been made to indicate desirable firing orders with regard to engine balance, manifolding, or to any other characteristic influenced by firing order.

The author appreciates Mr. Rathbone's suggested application of the Vectorscope to dynamic-balancing problems. A study of Mr. Rathbone's paper,[16] and that of J. G. Baker,[13] referred to in Mr. Rathbone's discussion, indicates that a bank of Vectorscopes should expedite the solution of this vector problem. A study by the author indicates that gearing of the Vectorscopes involves a more or less elaborate mechanical arrangement. A somewhat less automatic arrangement utilizing a bank of manually coordinated Vectorscopes is now being worked out.

The author tenders his thanks to Messrs. Schweizer and Shirley for their comments.

In general it may be stated that inherent instrumental errors may by proper design be quite completely eliminated. The geometry of the instrument itself is correct, so that readings do accurately indicate vector sums. It is believed that instruments of any required accuracy can be constructed by observing the various precautions brought out in the discussion of this paper. An instrument now being built by the author does in fact circumvent many of these sources of error. The accuracy should be as good as that ordinarily to be expected from careful graphical solutions and probably well consistent with most engineering requirements.

Use of the instrument is not limited to any particular type of problem. Application of the instrument may be made to any problem which may be resolved into, or expressed as, a vector summation.

Use of the Vectorscope is advocated not merely as a time-saving device. It is believed that experienced calculators will be enabled to undertake problems previously slighted or only partially solved because of the large amount of labor involved. Furthermore, certain phases of calculation can be delegated to relatively inexperienced calculators and reliable results will be obtained.

Problems and Trends in Centrifugal-Machine Applications

By JOSEPH S. PECKER,[1] PHILADELPHIA, PA.

The paper deals with the factors that govern the design and choice of a centrifugal machine for some specific application so that a prospective user or purchaser may appreciate the scope of the problems involved in the construction of a machine that would meet his requirements.

The article describes the various types of machines that are available and specifically calls attention to the newer types of development not generally known. The author surveys the trends in centrifugal-machine development and endeavors to indicate to manufacturers, prospective inventors, developers, and users of these machines the direction in which the art may be extended and expanded by the judicious choice and application of new materials, drives, and methods of construction, as a means of securing maximum production with required safety.

Historical

CENTRIFUGAL machines for the separation of liquids from solids were used a thousand years ago in the purifying of tung oil. The first "reduction to practice" however appears to be a British patent to Seyrig in 1838 which discloses the general principles as used in centrifugals today. A patent was issued to Hurd in the United States in 1844, to Brooman in France in 1852, and to Langen in Germany in 1878.

The first filtering type of centrifugal for the clarification of sugar crystals was developed by David Weston about 1852 and the manufacture of this machine by the American Tool and Machine Company dates to approximately 1864.

Although the first cream separator appears to have been invented in France in 1876, the first nonfiltering cream separator, invented in the United States by Carl De Laval in 1878, proved successful in practical application in the United States. Cream separators were manufactured in the United States by P. M. Sharples approximately in 1887.

For some thirty years the principal applications of centrifugal machines were for cream separators, clarification of sugar crystals, and laundry driers. It is only since approximately 1915 that the use of centrifugals has been extended to a wider variety of industrial applications. There are now over four hundred such applications in the chemical, industrial, petroleum, and food industries.

It is estimated that the total value of centrifugal machines manufactured and sold in the United States within the last few years, has amounted to approximately fifteen million dollars. The greatest percentage of these centrifugals, nevertheless, are still being used as cream separators and clarifiers for sugar crystals.

Uses of Centrifugal Machines

Practically all industries at one process stage or another deal with the separation of liquids from solids, purification of crystals, recovery of by-products, the concentration and thickening of slurries, or the disposal of waste. The centrifugal machine is not a panacea for all dewatering problems. Under certain conditions, the settling tank is still the most practical and efficient method, as exemplified in papermaking and mining.

In some instances, nevertheless, centrifugal machines perform the complete dehydration process. In the main, however, centrifugal machines may be used advantageously for the removal of the bulk of the liquid or where stratification of the liquid will separate a mixture into its component parts and thus complete the separating operation, as in cream separators. Where solids must be dehydrated to nearly 100 per cent, centrifugal machines may be used as an auxiliary process with thermal drying equipment to complete the operation.

In many cases the evolution of the centrifugal machine has supplemented other equipment such as bag filters, plate-and-frame filters, and suction-leaf filters. In many applications it has surpassed the rotary-drum vacuum filter and, on the other hand, there are many applications in which the vacuum filter has proved superior to the centrifugal.

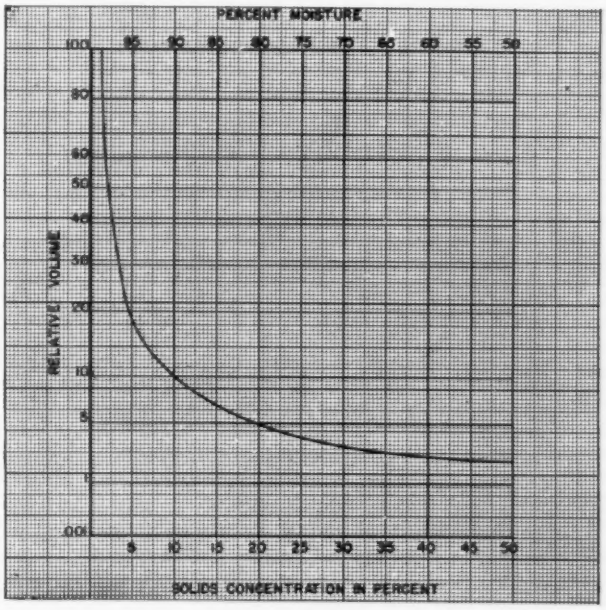

Fig. 1 Relative Sludge Volume

Where the solids in a slurry are but a small percentage of the water to be extracted, a centrifugal may be applied economically. However, although the surplus or free water can be extracted quickly, there is a point of dehydration beyond which it becomes uneconomical to use a centrifugal. A study of Fig. 1, will illustrate this point. The chart has been prepared for one special slurry and is not applicable to all slurries although generally the curve will be similar. It will be noted that a slurry with approximately 98 per cent moisture will lose its free moisture rapidly and

[1] Consulting Mechanical Engineer. Mem. A.S.M.E.

Contributed by the Process Industries Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cause a concentration of the solids down to approximately 75 per cent moisture. Beyond that the curve levels off and it will require considerable time for the centrifugal to extract 5 or 10 per cent more of the water. It is, therefore, obvious that an efficient still, evaporator, or drier may complete a dehydration process much more economically than a centrifugal.

If, however, the dewatered material is a waste product that must be disposed of by combustion, as for example in sewage disposal, it may prove more economical to retain the sludge in the centrifugal until the moisture content is such that the dewatered

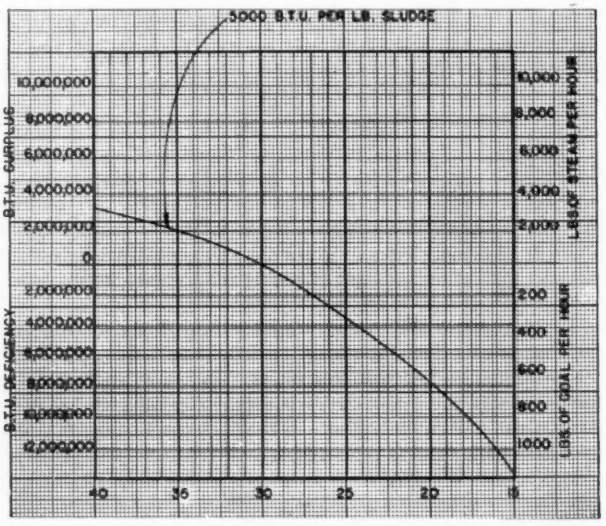

FIG. 2 EFFECT OF MOISTURE ON THE BURNING OF DEWATERED CAKE

cake will support its own combustion. This is illustrated in Fig. 2.

THE SEPARATING EFFECT

Centrifugal machines will separate any two solids when there is at least 3 per cent difference in specific gravity of the constituent parts, providing that the constituent parts are not in solution with each other. When a slurry or sludge is allowed to settle in an ordinary tank, the large particles will drop rapidly to the bottom, the lighter particles will float in suspension, and the still lighter particles, such as oil or grease, will remain on top of the water. Obviously then any materials which will separate by gravity will be separated by centrifugal machines. Materials in the state of emulsion or in extremely fine subdivision, and in some instances in colloidal suspension, that ordinarily would not be separated by gravity, although retained in a tank for an indefinite time, can be separated by a centrifugal machine.

In an ordinary tank, the rate of settling is based on Stokes' formula which may be stated as

$$V = (2/9)G\,[(s - s^1)/e]r^2$$

where V = velocity of settling
G = acceleration due to gravity
s = specific gravity of the particles
s^1 = specific gravity of the liquid
e = viscosity of the liquid
r = radius of the particle

An analysis of the formula will indicate the following outstanding characteristics:

1 If, by pretreatment prior to dewatering by a centrifugal machine, the particles can be made to coalesce by chemical treatment or other means to increase particle size, separating action will be improved.

2 If the viscosity of the fluid can be reduced, as for example by temperature increase as is now being applied in practice in sugar refineries (Stevens hot mingle), separation will be immediately speeded up.

3 If the force of gravity is increased, it is apparent that separation will increase in direct proportion and, inasmuch as gravity can be increased several thousand times in a centrifugal, the intrinsic value of a centrifugal becomes apparent.

Where the increase of temperature is impractical, the reduction of the effect of viscosity can be obtained by decreasing the depth of the liquid. If a slurry is allowed to settle in a tank of some specific depth, say 10 in., the liquids will separate at a rate of increase in almost direct proportion to the depth and if depth is decreased to 2 in. it is obvious that the settling effect will be multiplied by 5. Thus in a centrifugal machine developing an intensity equal to 2000 times gravity, where the solids are being forced through a depth of liquid averaging 10 in., if the depth of the liquid in the centrifuge could be decreased to 2 in. and the same centrifugal intensity applied for the same length of time as in the former case, the effect of centrifugal intensity would be equal to 10,000 times gravity.

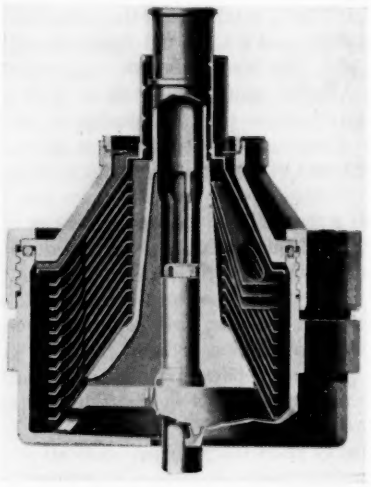

FIG. 3 CONE TYPE OF CENTRIFUGAL MACHINE

This phenomenon has been ingeniously developed in the De Laval and Sharples cream separators and oil clarifiers by the utilization of a series of cones which decrease the depth of the liquid through which a solid is acted upon while under the influence of centrifugal force. This type of centrifugal is illustrated in Fig. 3.

It is furthermore apparent that the longer the time gravity or the multiplication of gravity acts on a solid to be dewatered, the more complete will be the separation. It is, therefore, obvious that in a continuous-flow solid-bowl centrifugal, the longer the material is retained in the basket while subjected to centrifugal action, the more thorough and complete will be the separation. From this fact springs the implication that the larger the basket through which a material must pass, subjected to the same centrifugal intensity, the more complete will be the separation or the greater the production obtained.

The formula for centrifugal force is $F = KN^2R$ where F is the number of times the force of gravity is developed, N equals rpm, R is the mean radius of the material in the centrifugal, in inches, and K equals 0.0000284. It will be noted that the force of

gravity increases as the square of the speed and directly as the diameter of the basket. It is obvious, of course, that it is impossible to increase the speed of any size basket indiscriminately. The choice of speeds and diameters is a compromise depending on the extent to which force need be applied on the material to be dewatered. When that speed is known, the size of the basket that will give the greatest production can be readily determined.

Factors Influencing Choice of a Centrifugal

The outstanding object of a centrifugal machine therefore is:

1 The removal of surplus liquids from materials.
2 The separation or stratification of solids mixed with liquids.
3 The separation of materials of different specific gravities, either liquids from liquids or liquids from solids.

The choice of a centrifugal machine to perform any one or more of these conditions must meet with the following economic and operating factors:

1 The maximum degree of moisture reduction in any one pass through the centrifugal.
2 The degree of purification of the effluent.
3 The quantity output per day as compared to other processes.
4 The labor involved in operating one or several machines.
5 The economy of operation, bearing especially on the power consumed, serviceability, and maintenance.
6 Plant space required as compared to other equipment available for the same operation.
7 The processes preceding and following the centrifugal dewatering operation.
8 The flexibility of control of the machine especially in cyclical types of operation.
9 The method of feeding the material to the machine, the removal of the dewatered cake from the centrifugal, and the conveying of the clarified liquids and cake from the machine.

In addition to these factors, the acidity of the slurry, the grease content, and the particular affinity of water or liquid to the solids in which they are mixed, all contribute to the problem of selecting the proper type of centrifuge to do the work desired successfully and economically.

The ingenious designs of various manufacturers, based on the conditions as outlined, have made available to industry a choice of an infinite variety and types of machines to meet almost any conditions.

Types of Machines

Categorically, there are essentially two different types of centrifugals, namely, the solid-bowl or basket type and the filtering type.

In the solid-bowl type, the constituent materials in the slurry or sludge separate and stratify in accordance with their relative specific gravities, similar to the action which may be noted in a normal gravity settling tank.

The filtering centrifugal is one where the periphery of the basket is perforated. These perforations may take varying forms. They may be relatively large holes as in laundry machinery where the surplus water may freely pass through; the restricting effect of the walls of the basket is all that is needed to hold the large bundles of wash within the bowl.

On the other hand, filtering centrifugals may have these perforations covered with some filtering medium such as wire mesh or wire cloth, as in coal drying, or fine slots several thousandths of an inch wide, either cut into plates or built up with a series of thin plates mounted around the complete periphery of the basket.

Generally, the filtering medium is built similar to the filter surface of a vacuum filter, that is, with large holes in the basket, wire mesh next to the basket, and a fine-mesh cloth possessing high durability and wear against which the solids on the inside of the basket are deposited. Thus, the liquid surface of the material being dewatered is forced through the slots or through the filtering cloth. This type of centrifugal may be used for fine crystalline materials, and organic or fibrous slurries.

Centrifugals may be mounted on both vertical and horizontal axes. Generally centrifugals operating at high speeds are suspended on vertical axes because of the gyroscopic stability of a centrifugal mounted vertically and the facilities of feeding the material to the basket and of discharging of the clarified liquids. The driving, however, of a vertical machine becomes somewhat more difficult than a horizontal one. Larger and slower-running centrifugals are usually mounted horizontally.

Centrifugal machines both of the solid-bowl and filter types, horizontal or vertical, are manufactured to perform the dehydration in cycles, as a continuous operation, or a combination of both.

The continuous type of centrifugal performs the operation of feeding, dehydrating, and the removal of solids at a predetermined speed, usually sufficiently high to perform the dehydration satisfactorily.

With the batch machine the material is fed to the machine either when the basket is rotating at top speed or during the process of accelerating the speed, the feed is cut off and the material is centrifuged for a specific length of time. The basket is then decelerated to a lower speed, in several instances almost to a stop and the material is plowed out of the basket either by an operator who manipulates a paddle or by the operation of a plow mounted on the centrifugal and operated manually. This cycle is then repeated.

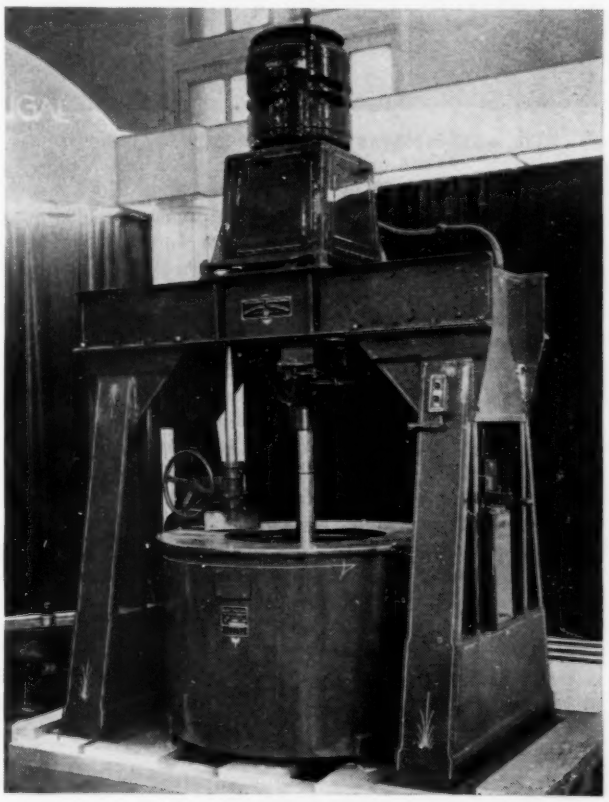

Fig. 4 A Typical Batch-Type Centrifugal

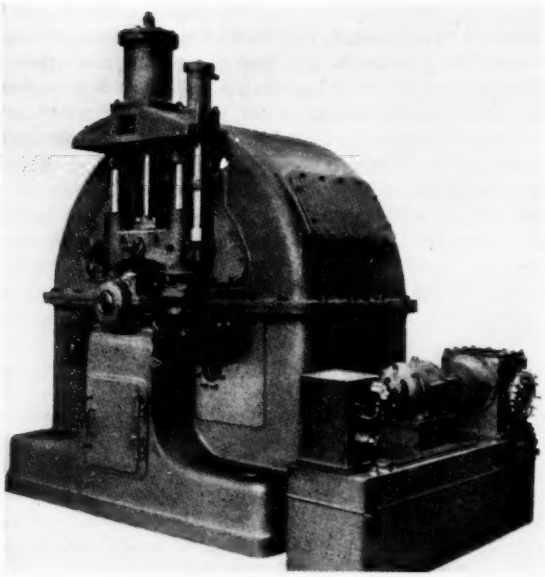

FIG. 5 LARGE-DIAMETER BATCH-TYPE MACHINE

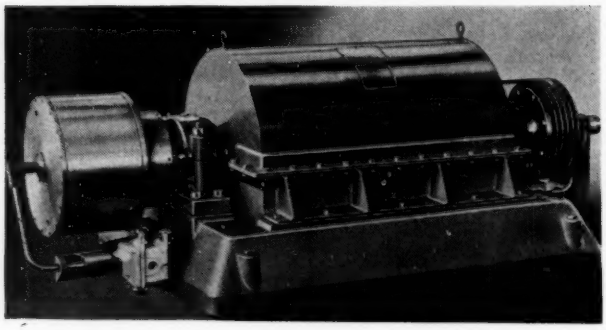

FIG. 6 HORIZONTAL CONTINUOUS-TYPE CENTRIFUGAL

On the other hand, there are batch machines which operate automatically, that is, the material is fed to the machine automatically, the solids are dehydrated, the centrifugal is decelerated, the dehydrated solids are discharged by a plow mechanically operated or by the automatic dropping of the bottom of the centrifugal, and the complete cyclical operation is repeated without the need of an operator.

A typical batch type of machine is illustrated in Fig. 4. Machines of this type are manufactured by such outstanding concerns as American Tool & Machine Company, Rochester Engineering and Centrifugal Corp., Western States Machine Company Bird Machine Company, Tolhurst Machine Company, and others.

Large-diameter batch centrifugals with perforate or imperforate baskets, operating at a continuous speed both for the dehydration and the discharge of the solids, are exemplified in the illustration Fig. 5. These machines periodically unload and reload themselves by means of a hydraulic mechanism which can be made fully automatic. The two outstanding types in this class of machine are being manufactured by Sharples Company and Baker-Perkins Company. In several instances these bulk centrifugals have their perforations not only on the periphery of the basket but also in the top and bottom plates, thus adding to the filtering area.

The continuous automatic centrifugal, where material is fed to the machine as long as the machine is operated and the dehydrated solids and the extracted liquids are continuously discharged,

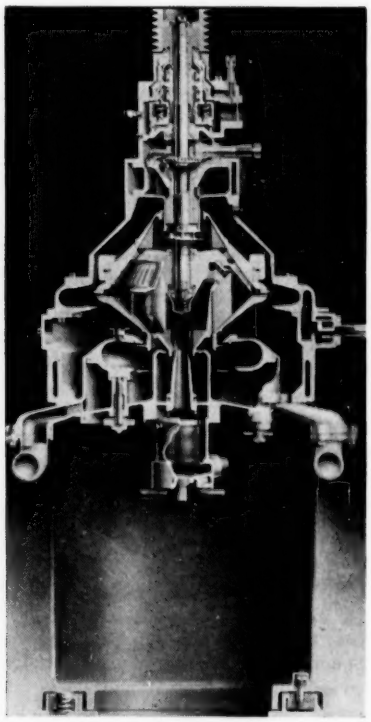

FIG. 7 VERTICAL CONTINUOUS-TYPE MACHINE WITH AUTOMATIC CONTROL OF SEPARATION

is illustrated in Figs. 6 and 7. The Bird horizontal screw type of centrifugal, as illustrated in Fig. 6, is undoubtedly the most advanced design of this kind today.

TRENDS IN DEVELOPMENT

The development of centrifugal machines is characterized by the following trends:

(*a*) *Automatic Control of the Degree of Separation.* Fig. 7 illustrates a machine of this class manufactured by the Merco Centrifugal Company. This machine is employed in various industries; in the starch industry for separating starch from gluten, and in the petroleum field for desanding and conditioning rotary-drilling mud.

The principle of operation is rather simple; the feed, after passing through a screen to remove large débris, enters the rotor at the top and immediately comes under the influence of centrifugal force. Heavy components of the feed are projected to the periphery of the rotor while the "clean" carrying fluid passes out of the rotor over the weir near the center. The solids concentrated in part of the fluid pass out of the rotor at the periphery through a series of nozzles. A large part of this discharge drops to the bottom of the housing where it is picked up by the rotor and returned to the periphery. This return furnishes means for further concentrating the solids and flushing the entrance to the nozzles. The remainder of the discharge from the nozzles passes through a specific-gravity device which regulates the density or concentration of the discharge. Once the gravity device is regulated, only material of the desired concentration can leave the machine. The cycle is continuous and operation automatic.

Another machine in this category, Fig. 8, is one manufactured by Centrifugals, Inc., which has been applied for the separation, classification, thickening, and clarification of materials. In this machine, the discharge of the solids that are dewatered is controlled by the solids themselves as they fill up the valve and cause it to open automatically for their discharge. A similar

machine has been developed by the De Laval Company who have also installed a special valve in conjunction with their standard type of oil clarifier. This machine has been recently applied in the thickening of activated sludge in the sewage-disposal field.

(*b*) *Flexibility in Operation of the Machine.* The advance in flexibility of operation, especially with regard to speeds, acceleration, deceleration, and cyclical control, is exemplified by the Roberts centrifugal which employs a new driving arrangement in which six machines are connected to a 250-hp motor and driven individually by spiral bevel gears from a constant-speed horizontal line shaft to which each centrifugal is connected at the appropriate time by means of a water-cooled friction clutch. A system of forced oil circulation and a water-cooled brake are provided. See Fig. 9.

It has been found that with the clutch shoes set to slip at 70 hp, the basket attains the speed of 1500 rpm in 45 sec; thus the

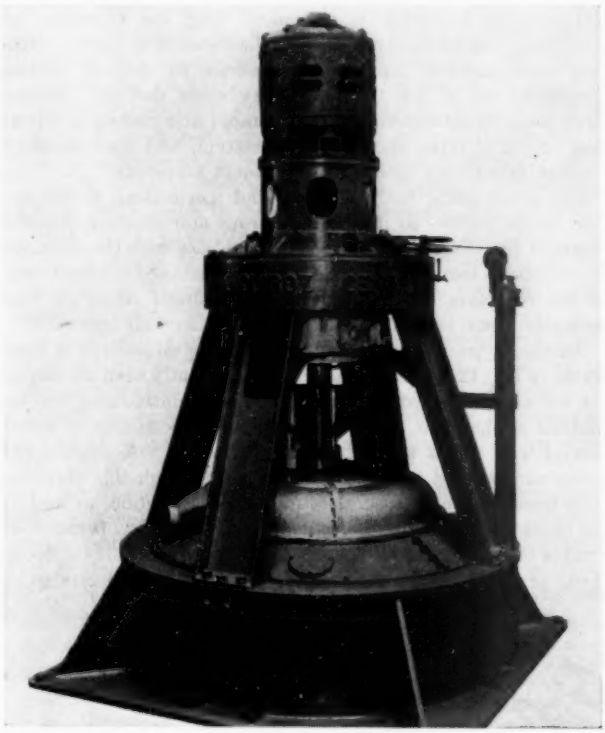

FIG. 8 VERTICAL CONTINUOUS MACHINE WITH AUTOMATIC CONTROL OF SOLIDS DISCHARGE

flywheel effect of all machines in operation contributes to the decrease in power consumption and the increase in speed with which each machine can be accelerated and decelerated through its cyclical operation.

Still another development in the method of driving a centrifugal machine is shown in Fig. 10 by the illustration of a machine manufactured by the American Centrifugal Corporation. This shows two motors mounted on a horizontal base, one used for the high or purging speed and the other for the low or basket-cleaning speed. Interconnected between these two motors is a free-wheeling coupling so that when the high-speed motor is de-energized and the low-speed motor energized, the latter continues driving the basket without the need of transferring the power from one motor to the other by a shifting clutch.

The American Tool and Machine Company has utilized the same principle in a rather ingenious arrangement as illustrated in Fig. 11. Units are available to any manufacturer.

Centrifugals manufactured by the Rochester Engineering and Centrifugal Corporation have been equipped with four-speed

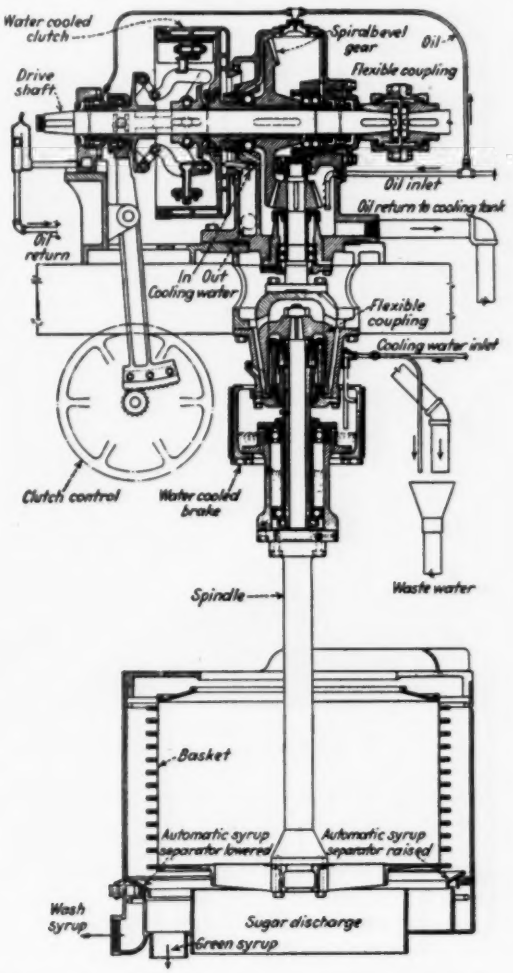

FIG. 9 UNIT WITH WATER-COOLED CLUTCH AND BRAKE

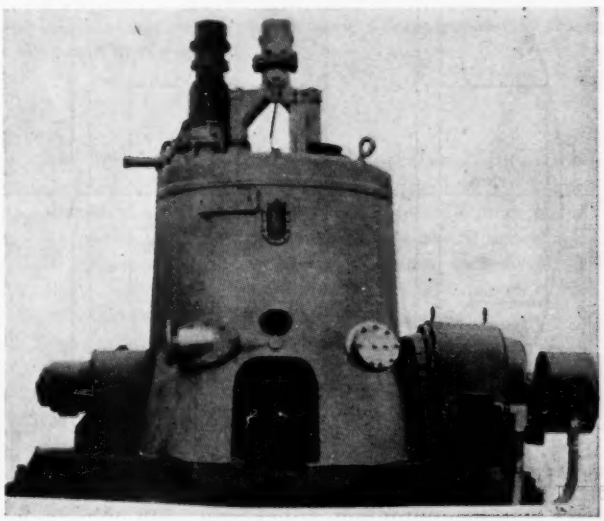

FIG. 10 UNIT WITH HIGH- AND LOW-SPEED MOTORS AND FREE-WHEELING COUPLING

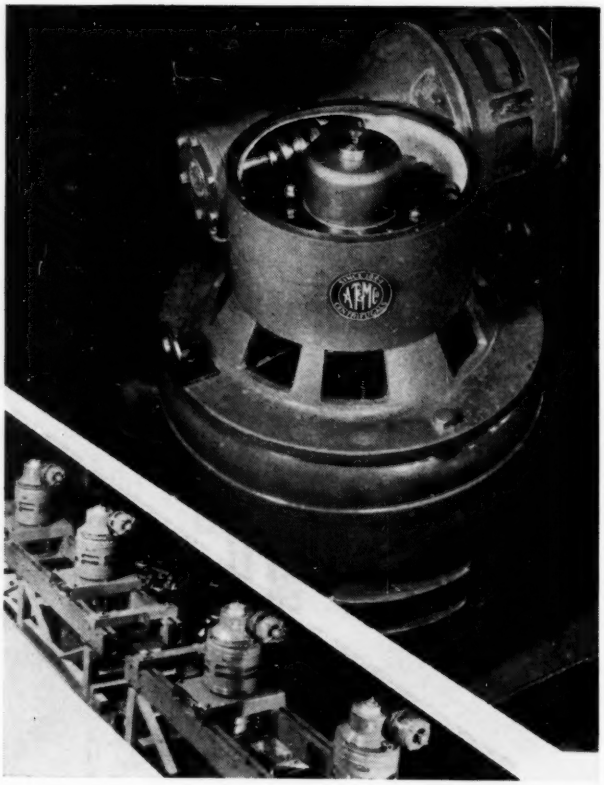

FIG. 11 TWO-SPEED FREE-WHEELING DRIVES

motors, providing, as an example, synchronous speeds of 1200, 900, 600, and 450 rpm. In addition to these four speeds, a low-speed gear ratio of 30 to 1 has been incorporated so that the machine can readily be operated at speeds of 15, 20, 30, or 40 rpm for unloading the basket. Thus, the full power of the motor may be used for high-speed centrifuging and increased torque is available at the lower speeds through the gearing arrangement.

With this flexibility of speeds, certain materials which cannot be handled by arbitrary speeds can be dehydrated efficiently. For instance, some materials of a flaky crystalline structure cannot be handled in a filter-type centrifugal basket in the average way because loading the machine while the basket is operating at top speed would cause an impounding or impacting of the crystalline materials, building up an impervious wall that would prevent the escape of the liquid.

In order to handle such a material satisfactorily, therefore, it would be necessary to load the basket at a relatively much lower speed than would be used for the handling of crystalline materials having a rhomboid or other similar shape. Thus with multiple speeds, as described, the machine could be loaded at 450 rpm, operated for a minute or two at 600 or 900 rpm to give a wringing action, and then brought up to 1200 rpm for final dehydration, after which it could be dropped to any one of the low speeds for unloading.

The unusual conditions associated with the operation of centrifugal machines, especially those subjected to batch operation have impelled motor manufacturers to develop motors specifically suited for the ideal duty cycle desired. Motors have been manufactured to provide rapid and smooth acceleration or, as is often the case, deceleration, and high constant torques at varying speed with minimum amperage.

The refinements, both electrical and mechanical, in the design of the motors to meet the rigorous and exacting requirements of centrifugal extractors have kept pace with the demands of centrifugal manufacturers and have contributed tremendously to the reduction of stresses in the centrifugal machines that normally would reduce the factor of safety in their operation.

Another type of drive which is now being considered is illustrated in Fig. 12. This drive, which has recently been developed for automotive purposes and is now being introduced for industrial applications, appears to possess a flexibility of speed control well suited to centrifugal application. A single-speed motor can be used to drive a centrifugal through this variable-ratio transmission, and acceleration and deceleration, as well as the operating speed, can be controlled through the operation of a valve controlling an oil pump which in turn controls the speed of one of the gears in a differential transmission as illustrated.

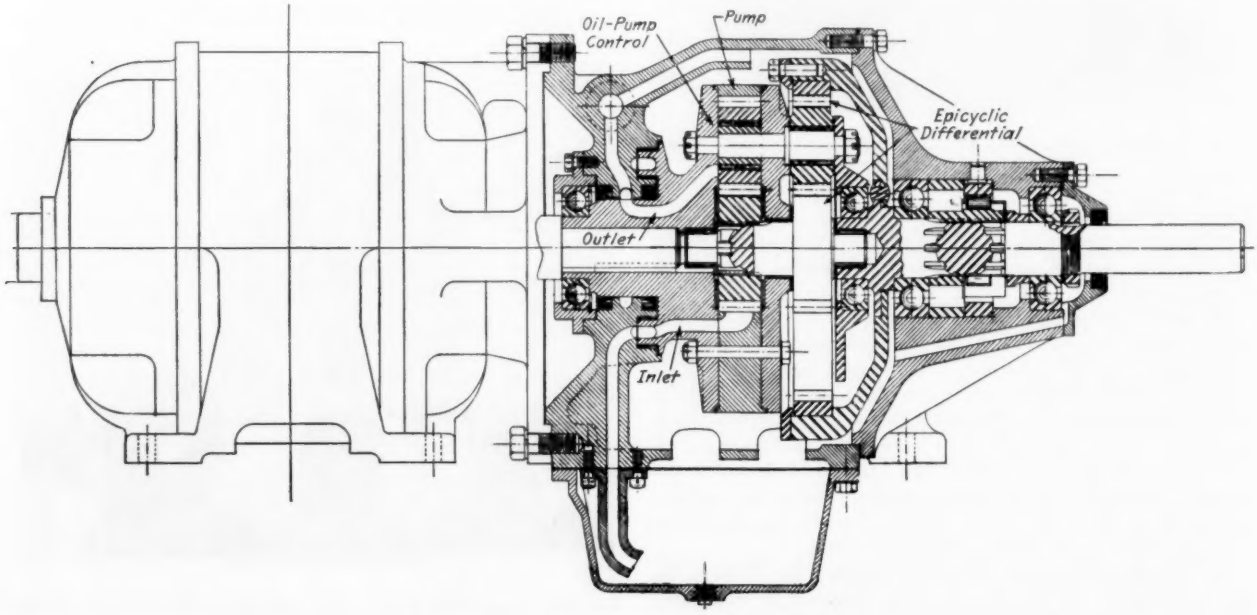

FIG. 12 SZEKELY VARIABLE-SPEED TRANSMISSION

(*c*) *Increase of Size of Centrifugal* with attendant increase of speeds and the use of noncorrosive materials and alloy steels to obtain the former with a high degree of safety.

While it is true that, in the early stages of centrifugal development, a number of baskets burst, this invariably could be traced to amateurish attempts on the part of inventors to build centrifugals without consideration of the safety factors involved in the operation of centrifugal machines.

Today centrifugal machines may be operated with considerable safety at a surface speed of approximately five miles per minute. Centrifugal machines have been built in diameters of from less than 1 in. for laboratory use to 80 in. for industrial use, and with speeds of from a few rpm to 160,000 rpm for laboratory centrifugals in which the force of gravity is increased more than a million times.

The design of a centrifugal machine to operate with safety is today a precise engineering function. For instance, in Fig. 13, there is illustrated a type of chart which may be developed for any specific size of centrifugal with a basket wall of a specific thickness and operating at varying speeds with some specific charge in the machine. The chart is for an impervious basket in which the stresses imposed on the walls are due both to the weight of the material from which the basket is made and the internal pressure developed by the material inside of the basket.

It will be noted that a curve can be drawn to indicate that, with a certain factor of safety or say a stress of 2700 psi, the particular type of basket of varying diameter can be operated only at the speeds shown. For example, a basket of 41½ in. diam operating at 2000 rpm will impose the same stress as a 49-in. basket operating at approximately 1600 rpm.

A parallel line outside of the shaded area can be drawn representing stresses of material equal to 37,000 psi. This line may be represented as a maximum stress that may be imposed on the material in question. Thus graphically can the diameters and speeds of a machine of some specific construction be chosen with safety.

The metallurgical advances within the last few years dealing with stainless alloy steels, high-tensile alloy steels, heat-treatment, rustproofing, and welding have contributed immeasurably to the increase of speed with adequate factors of safety.

The development of pierce forgings, high-tensile aluminum alloys, monel metal, and rubberizing processes has furthermore contributed toward increase of speeds of the machines with commensurate factors of safety by minimizing the deteriorating effect of corrosion.

Improvements in basket suspension, the construction of modern foundations, the use of cork or rubber in shear for supporting machines, methods of mounting ball bearings, dynamically balanced baskets, the use of spiral heat-treated gears, the design of shafts with critical speeds beyond the range of operating speeds, and improvements in drives, have contributed to the elimination of noise, vibration, and unknown stresses that are normally inherent in the operation of centrifugal machines, especially the cyclical types of machine. Thus by decreasing the factors which contribute to the unknown stresses, speeds of machines and factors of safety can be simultaneously increased.

Future Development

The rapid development in modern industry dealing with the careful and exacting preparation of foods, the advance in the art of plastics and synthetic materials, the increase in the use of paper and paper products, the need for more economical operation of the mining and metallurgical industries, and the construction of sewage-disposal plants, marks an era in which the use of the centrifugal machine is becoming increasingly important as a dewatering medium whereby the force of gravity can be multiplied many times.

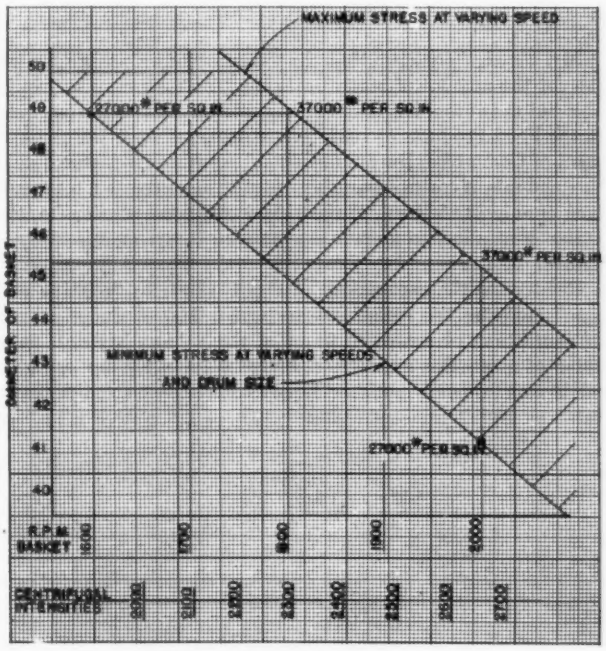

Fig. 13 Basket Speeds and Diameters for a Fixed Range of Allowable Stresses

The role of prophet is dangerous, but it is the author's opinion that the centrifugals of today are entirely too small and too slow, and that, with the judicious application of the materials and engineering knowledge available plus a little imaginative and ingenious daring on the part of engineers engaged in this field, the centrifugal art can be advanced to a degree where it might nearly supersede every other type of dehydrating equipment except the last-stage thermal drying units.

Acknowledgment

The author wishes to acknowledge with thanks the cooperation of the various manufacturers and the engineers associated with these manufacturers, in supplying necessary information and illustrations and materially assisting in the compilation of the data submitted in the paper.

Discussion

A. E. Flowers.[2] The author states that the value of centrifugal machines sold in the United States in the last few years has amounted to about $15,000,000. This estimate must be far too small for the annual value of one class of centrifuges alone, the small farm-model cream separator, is at least that much. If all classes of centrifuges are included the annual business in centrifuges would be two or three times this amount.

The author should give a further explanation of the values plotted and the meaning of the curve Fig. 1, in both the legends and titles on the chart and also in the explanatory paragraph.

In the discussion of Separating Effect, no mention is made of Brownian and other movement, limitations on settling, or of the effect of critical forces and velocities on settling rates and quantity of centrifuged solids.

---

[2] Engineer, in charge of Development, De Laval Separator Company, Poughkeepsie, N. Y. Mem. A.S.M.E.

Author's Closure

Mr. Flowers' criticism that the valuation of $15,000,000 is too low for the amount of centrifugals manufactured may be justifiable but the author has taken this figure from an article appearing in the Food Products of 1937. As a matter of fact, the Department of Commerce, Bureau of Census, reports that the manufacture and sale of cream separators in 1937 amounted to a total volume of only $3,850,000. If the $15,000,000 total is incorrect, the author is at a loss to know where to turn to get more authentic figures.

Relative to the explanation of Fig. 1, the term "relative volume" indicates the volume (water and solids) of sludge at any concentration, expressed in terms of the volume having a base value of 100. For example, a sludge volume having one part solids and 99 parts liquid or 1 per cent concentration is designated as 100, 2 per cent concentration as a "relative value" of 50, 5 per cent as a relative value of 20, 10 per cent as a relative value of 10.

The use of this figure quickly gives the volume of any sludge concentration in terms of other concentrations. For example, a sludge of 2 per cent concentration has a relative volume of 50 as compared to one of 10 per cent concentration having a relative volume of 10. It is plain thereby that the latter has one fifth of the volume of the sludge having a 2 per cent concentration.

In discussing separating effect, mention of the Brownian and other movements was purposely omitted as it was not the purpose of the paper to go into a highly technical discussion of the innumerable theoretical factors that must be considered in the development of a centrifugal machine. All data given were of the simplest character in order to lay the basis for the discussion of the problems and trends in centrifugal-machine application. The paper was designed to stay more on the practical than the theoretical side.

Motive-Power Characteristics and Lightweight Equipment

By R. EKSERGIAN,[1] PHILADELPHIA, PA.

A common basis of units and ratings for the analysis of different types of locomotive power units is discussed. On the basis of these units a performance comparison of steam, Diesel-electric, and straight-electric locomotives is made. The characteristics of locomotive performance are expressed in terms of rated power and tractive force at rated speed. Consideration is given to the variation in power and tractive force in terms of a power-speed function and the tractive-force amplification relative to its rated value. The power and weight ratios of locomotive to train at different power-weight ratios for the locomotive itself are also discussed. Finally, the adhesion conditions and adhesion-weight ratio to total locomotive weight are shown to depend upon the rated speed, the tractive-force amplification and the power-weight ratio of the locomotive. The effect of power characteristics on grades and double heading are discussed. In the conclusion flexibility of ratings and economic considerations are discussed.

THE OBJECT of this paper is a preliminary survey, by a common method, of power ratings and performance characteristics of various types of power units, together with an evaluation of power savings effected by lightweight equipment, both in the train as well as in the locomotive. In order to express various characteristics of power units for performance analysis, it is necessary to reduce such characteristics to a common basis of units and ratings. With a given weight of train, and power-plant weight, definite horsepower capacity is necessary in order to meet a definite schedule.

Since both inertia and total train resistance increase with the tonnage of the train, the power required for a given performance likewise increases with the total train weight. To obtain high speeds with rapid acceleration, it is necessary either to increase the horsepower capacity of the power plant or reduce the weight of the train itself. We are confronted with a very difficult problem in increasing performance ratings with orthodox equipment. To increase the performance of the train from $2^1/_2$ hp per ton to a performance rate of 4 hp per ton, with a train at present utilizing 3000 hp, would require a power plant of nearly 5000 hp capacity. It is obvious, therefore, that to maintain the same power capacity and effect corresponding increase in performance requires considerable weight reduction of train equipment. On the other hand, where a performance schedule is satisfactory, weight reduction is obviously effective in reducing the power demand for the train. In either case, it is obvious that weight reduction has its primary effect in reducing the horsepower requirements of the power plant. Therefore, any consideration of weight reduction also requires corresponding consideration, with harmony and coordination, in the adaptation of consistent power-plant units in order to obtain full advantages of light weight.

With increasing performance demands, the weight efficiency of the power plant itself becomes an important factor. At very high power ratings, weight efficiency in the power plant becomes equally important as weight efficiency in the train itself.

Much ambiguity has arisen in the rating of locomotives. In some cases, the horsepower capacity of the unit is stated in the terms of the engine horsepower and other cases in terms of horsepower developed at the rail. Steam locomotives are frequently rated on their drawbar horsepower, and sometimes their indicated horsepower. In the following analysis, the horsepower rating of a locomotive will be considered as that developed at the rail only, so that when power ratings are stated in terms of engine horsepower, as in Diesel equipment, transmission efficiencies must be taken into consideration. Likewise, horsepower ratings in terms of drawbar horsepower for steam locomotives require corresponding corrections to rail horsepower at the driver.

Rated Horsepower

The power available for traction at the rail varies in a given speed range with different types of power units. In a steam locomotive, the cylinders, drivers, and boiler are proportioned for a given normal power output corresponding to its operating or rated speed, roughly at two thirds of maximum speed. At other speeds, either in the overspeed or underspeed zone, the power developed is reduced to a percentage of the rated output. In a self-contained Diesel-electric locomotive, the power rating depends upon the normal power rating of the engine and the transmission efficiency and occurs at a rated speed roughly 40 per cent of the maximum speed, at which the motors develop their continuous rated torque. This occurs practically at maximum rail output. Diesel-electric locomotives maintain nearly constant power over a wide overspeed range.

Characteristics of straight-electric locomotives differ essentially from that of electric drives with self-contained power plants. First, the available power is relatively unlimited, and second, the supply of power is at constant voltage. Due to this feature, electric locomotives have considerable amplification of power over their continuous ratings. This amplification of power is effected by overloading the motors and sustaining full starting tractive force to a speed limited by line voltage.

On the basis of the power variation against speed, the actual power at the rail is xH_{PR}, where H_{PR} is the rated horsepower and x is the ratio of the actual horsepower developed at V mph to the rated horsepower at rated speed V_R. The tractive force in terms of the rated output is

$$Z = \frac{375xH_{PR}}{V} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where $x = f(V/V_R)$ = the power-speed function.

The train speed is obviously correlated with the revolutions

[1] Consulting Engineer, Edward G. Budd Mfg. Co. Mem. A.S.M.E.

Contributed by the Railroad Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of the drivers per minute through the wheel diameter and gear ratios.

Performance Characteristics

If all locomotives had exactly the same variation in power over a given speed range, then the performance could be completely determined by its rated power. Due to the variation in power against speed with different types of power units, it is obvious that for a given horsepower per ton, based on its rated value, different schedules will be obtained. For a given schedule, the rated power must be greater for a locomotive with poor power-speed characteristics.

The motion of the train, including the locomotive, is governed by the relation

$$Z - R \pm 20WG = 2000\left(\frac{kW}{g}\right)a \quad \ldots\ldots [2]$$

where a = acceleration, ft per sec per sec; A = acceleration, mph per sec; R = total train resistance, lb; W = weight of train including locomotive, tons; G = gradient, per cent; k = allowance factor for rotational inertia of rotating parts, as wheels, motors, and axles; $r = R/W$ = train resistance, lb per ton.

It is more convenient to express these components on a unit basis per ton, so that Equation [2] reduces to

$$Z_t = r \pm 20G + 91kA, \text{ where } Z_t = \frac{Z}{W}$$

With $k = 1.1$

$$Z_t = r \pm 20G + 100A \quad \ldots\ldots [3]$$

Thus

$$Z_t = \frac{375}{V}\left[\frac{xH_{PR}}{W}\right] = \frac{375}{V}x(H_{PR})_t \quad \ldots\ldots [4]$$

and

$(H_{PR})_t$ = rated horsepower per ton = power rating

From this relation, it is obvious that the performance of a train depends primarily on the available power per ton of total train weight and the variation of this power throughout the speed range. Further, the tractive force falls off with increasing speed. At low speeds, since Z is large and r is small, the greater part of the tractive force is utilized in overcoming the inertia resistance $100A$ of the train. With increasing speeds Z drops and r rapidly increases, with resulting reduction in acceleration. At the maximum or balance speed, $A = 0$, so that the tractive force then just balances the train resistance.

The resistance per ton varies with different types of equipment, as well as with the condition of track and roadbed. The resistance per ton r is usually divided into (1) journal and rolling resistance, (2) flange resistance which is proportional to the speed, (3) air resistance which depends on the geometrical configuration of the train and the speed. Since the air-resistance component increases nearly as the square of the speed, it becomes of importance at the higher speeds. The air resistance itself can be divided into head and tail resistance, and side skin friction and turbulence, this latter being the greater part of the air resistance, particularly with long trains.[2]

Over an average operating schedule, with stops, grades, and slowdowns, these variations in train resistance play a relatively small part compared with acceleration and grade resistance.[3] For this reason since the latter, as well as a large component of the train resistance itself, are directly proportional to the weight of the train, the general performace is governed primarily by the available tractive force per ton over a given speed range.

The effect of auxiliary power for train equipment is either a reduction of available power for traction, when taken from the power plant, or an apparent increase of train resistance with axle-driven generator equipment. With steam air-conditioning and training heating, the steam available for traction is reduced.

When power is taken from car-axle drives, it directly reduces the locomotive power for traction so that q_pH_{PR} is the effective rated power for train performance, and $(1 - q_p)H_{PR}$ is utilized for auxiliary power. Let P_A = auxiliary power at rail per car, W_c = weight of car in tons, and W_t = weight of train not including locomotive. W = total weight of train, tons.

Then

$$(1 - q_p)H_{PR} = \frac{P_A}{W_c}W_t \quad \ldots\ldots [5]$$

Therefore

$$q_p = 1 - \frac{P_A}{W_c}\frac{W_t}{W(H_{PR})_t} \quad \ldots\ldots [6]$$

With $(H_{PR})_t = 3$, $P_A/W_c = 0.6$ for 60-ton cars and $W_t/W = 0.7$, then $q_p = 0.86$.

Power and Weight Proportions of Locomotive to Train Weight

To estimate the power requirements of a locomotive for a given train schedule requires not only its power rating, but also a correction for accounting for the variation in power at other than its rated speed. Let H_{PR} = rated horsepower per ton of train weight developed at driver; W_p = weight of power unit, tons; W_t = weight of train, tons; thus, $W = W_p + W_t$ = total train weight including locomotive.

Let q account for different power characteristics with allowance for train auxiliaries. The power requirement for meeting a given schedule is defined as performance rating, which is

$$\frac{qH_{PR}}{W_p + W_t} = h_{pt} \quad \ldots\ldots [7][4]$$

Therefore

$$h_{pt} = q(H_{PR})_t \quad \ldots\ldots [7a]$$

where $q = q_Rq_p$ is divided into q_R for comparing different power-speed functions and q_p for train auxiliaries. For example, assume a typical schedule requires 4 hp per ton power rating for a steam locomotive. With more favorable power-speed characteristics, assume a Diesel-electric requires 3.5 hp per ton for the same schedule. Then q_R accounts for the ratio of these ratings. Referring to the steam locomotive as a standard with $q_R = 1$ then q_R for the Diesel is 4/3.5. With the Diesel as a standard, then q_R for the steam locomotive is 3.5/4.

Weight Ratio. A very important constant in locomotive design is the ratio of the weight of the total locomotive in pounds divided by the rated horsepower at the drivers. This ratio will be defined as the weight ratio, the units of which are pounds per rated horse-

[2] For further discussion of train and air resistance see "Air Resistance of Railroad Equipment," by A. I. Lipetz, Trans. A.S.M.E., vol. 59, 1937, paper RR-59-4, p. 617. Also: "Design of Light-Weight Trains," by R. Eksergian, Trans. A.S.M.E., vol. 56, 1934, paper RR-56-4, p. 667.

[3] Variation in train resistance per ton where the air-resistance component is large, due to trains operating at high sustained speeds, is discussed later in connection with Equation [7].

[4] The term q can also account for deviations in train resistance for different train consists where air resistance is of importance at high sustained speeds.

power. In the case of steam locomotives, weight ratios are frequently given in terms of the locomotive without tender. In comparison with other types of power, as with Diesel-electric units, it is necessary to include the tender weight. When the weight ratio of the steam locomotive is stated in terms of the locomotive itself, then the weight ratio, as a power plant which includes tender, is increased by the ratio of tender weight to locomotive weight.

Let E = weight ratio of locomotive without tender, K = ratio of tender weight to locomotive weight, W_L = weight of locomotive alone, W_D = weight of tender, and $W_L + W_D = W_P$ = total weight of power unit. With the weights expressed in tons, then

$$\left.\begin{aligned} E &= \frac{2000W_L}{H_{PR}} \\ E(1+K) &= \frac{2000W_P}{H_{PR}} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

The relation can be equally applied to Diesel or electric locomotives where in this case $K = 0$. A steam locomotive weighing 120 lb per hp with a tender weighing 75 per cent of the locomotive itself, is increased to 210 lb per hp for the total power plant. Tender weights will include two-thirds maximum fuel and water capacity.

Since the performance rating is equal to the total horsepower at the rail divided by the weight of the power plant and train in tons, while the weight ratio is expressed in terms of the weight of the power plant in pounds divided by the horsepower developed at the rail, it can be shown on combining these relations that

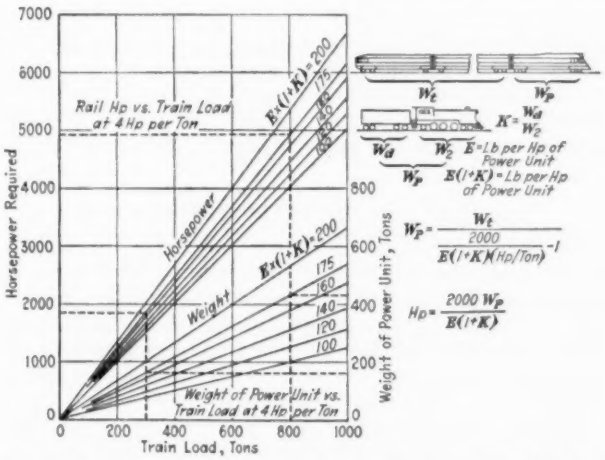

FIG. 1 RAIL HORSEPOWER AND WEIGHT OF POWER UNIT VS. TRAIN LOAD FOR A RATING OF 4 HP PER TON

the weight of the power plant increases directly as the train weight and inversely as a function depending upon the weight ratio of the power unit. Likewise, the horsepower developed by the locomotive is proportional to the train weight and the power rating required, and inversely as a function of the weight ratio of the power unit.

That is, combining Equations [7] and [8]

$$W_P = \frac{W_t}{\dfrac{2000q}{E(1+K)h_{pt}} - 1} \quad \ldots\ldots\ldots\ldots [9]^5$$

and

$$H_{PR} = \frac{2000W_P}{E(1+K)} = \frac{2000W_t h_{pt}}{2000q - E(1+K)h_{pt}} \quad \ldots\ldots [10]^5$$

[5] The term h_{pt} can be replaced by $(H_{PR})_t$ by putting $q = 1$.

Referring to Fig. 1, these relations are plotted for a relatively high power rating of 4 hp per ton, at various weight ratios against train load. Similar relations can be obtained for different power ratings. Since the size, weight, and power of a locomotive increase in direct proportion to the weight of the train for a given performance requirement, it is obvious that a reduction in train weight is most effective in reducing size of power unit. Thus, at a power rating of 4 hp per ton power rating, a 10-car train with 85-ton cars, requires, with a locomotive weighing 174 lb per hp, 5250 hp. With a like train of 10 cars weighing 45 tons each, the power is reduced to 2800 hp. In the former, double-head power would be needed with tremendous increase of operating cost.

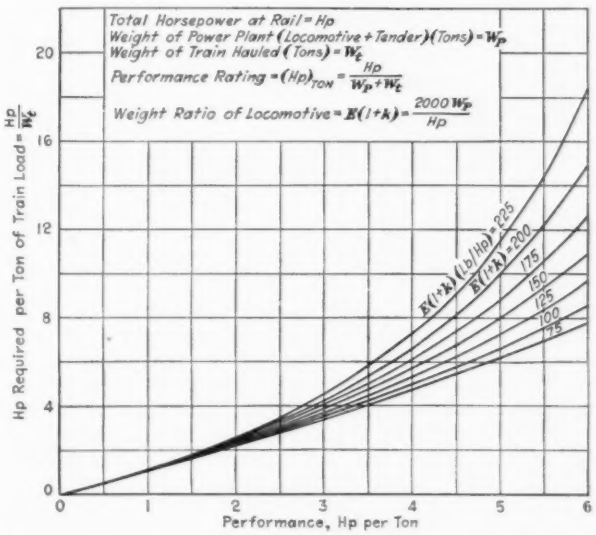

FIG. 2 TRAIN POWER REQUIREMENTS AT VARIOUS LOCOMOTIVE-WEIGHT RATIOS

While the motive power required increases directly with the train weight, it also is very much affected by the weight ratio of the power unit itself.

The locomotive power required to haul a ton of train load, from Equation [10], is

$$\frac{H_{PR}}{W_t} = \frac{2000h_{pt}}{2000q - E(1+K)h_{pt}} \quad \ldots\ldots\ldots [11]^5$$

Fig. 2 shows the effect of weight ratio of the power unit to the power required to haul a ton of train load for different performance ratings, neglecting train auxiliary power. A series of curves at various weight ratios of the locomotive are plotted, showing the horsepower required per ton of train hauled, at various performance ratings. It is to be particularly noted that the weight ratio of the power plant is relatively unimportant at low performance ratings.[6] This is almost obvious, since in considering a long freight train the effect of weight efficiency of the locomotive would have very little reaction on its performance as a whole.[6] On the other hand, as we increase toward the higher performance ratings, the power required increases considerably per ton of train hauled. In the higher power range, the weight ratio of the power plant becomes of great importance. Thus, at a performance rating of 5 hp per ton, a change from 225 to 175 lb per hp in the weight ratio of a locomotive amounts to a saving of $2^1/_2$ hp for each ton of train load

[6] Obviously, a ton of weight saved on a locomotive always means an increase of 1 ton in payload, regardless of the size of train load.

hauled. With an 850-ton train, the savings through reducing the power-unit weight from 225 to 175 lb per hp exceeds 2000 hp.

For a given train load, a given power-plant weight is necessary. The power required to pull a ton of train weight increases with its performance rating, and is also a function of the ratio of power-plant weight to train weight. Obviously, the lower the ratio of the power-plant weight to the train weight, the less is the amplification of the horsepower required per ton of train hauled at a given performance rate. Further, the ratio of weight of power plant to weight of train depends upon the weight ratio of the locomotive itself.

From Equation [9], the ratio of power-unit weight to train weight is given by the expression

$$\frac{W_P}{W_t} = \frac{E(1 + K)h_{pt}}{2000q - E(1 + K)h_{pt}} \quad \ldots\ldots\ldots [12]^5$$

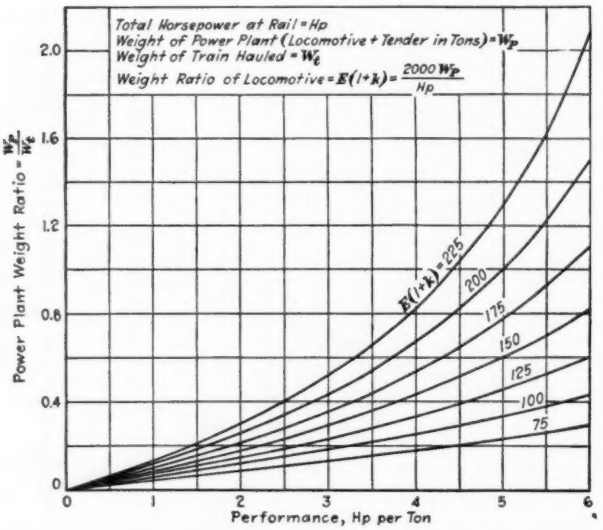

FIG. 3 RATIO OF LOCOMOTIVE WEIGHT TO WEIGHT OF TRAIN HAULED

Referring to Fig. 3, the ratio of weight of power plant to train weight hauled is plotted against the performance rating at different weight ratios of the power unit. These curves make obvious the tremendous increase of power plant to train weight in the higher performance power zone. Thus, a locomotive weighing 200 lb per hp, with a low performance requirement at say 2 hp per ton, has a weight of only 25 per cent of the train weight. On the other hand, for high-speed performance at 4 hp per ton the locomotive will weigh two thirds of the train weight. Should it be desirable to increase the power capacity to a performance rate of 6 hp per ton, as for high-speed suburban service, the locomotive weight becomes 50 per cent greater than the train load itself. Obviously, this is nearly all locomotive. This condition in the high-power-rating zone can be greatly relieved by reducing the power-plant weight ratio. Thus, if the power plant is reduced to 100 lb per hp at a power rating of 6 hp per ton, the weight of the power plant to the train weight reduces to 43 per cent. This shows why distributed electric power using electric motors throughout, as in multiunit electric trains, is the only present means of obtaining very high performance ratios. It is very difficult to reduce the weight efficiency of a self-contained power unit to anything comparable to distributed power with electrification.

Obviously, a ton of weight reduction of the locomotive is as effective as a ton of weight saving in the train hauled, since in either case the power required is equally reduced by the same horsepower-per-ton rating.

At the lower performance ratings, as with a long freight train, reducing the weight of the locomotive, no matter how much, has little effect in reducing the total weight of the train and locomotive. In this case a small percentage in the reduction of the train hauled is far more effective than a large percentage in weight reduction of the locomotive. As the performance rating increases, however, the weight of the power plant becomes a far more important factor, therefore, its weight reduction becomes increasingly important. As an example, let us compare a percentage weight reduction of 25 per cent, first, on the locomotive by reducing its weight by 25 per cent, then on the train by reducing its weight by 25 per cent.

Let the original weight ratio for the locomotive alone be E = 200 lb per hp, while W_t = original weight of train alone. With a 25 per cent reduction on the locomotive side $E = 0.75 \times 200$ = 150 lb per hp. With a 25 per cent reduction on the train side $W_t' = 0.75W_t$. The locomotive power requirements for different performance ratings, (1) by reducing locomotive weight by 25 per cent, and (2) by reducing train load by 25 per cent, separately, are as given in Table 1.

From Table 1 it should be noted that around 5 hp per ton, or

TABLE 1 LOCOMOTIVE POWER REQUIREMENTS FOR DIFFERENT PERFORMANCE RATINGS

Performance rating HP_R, hp per ton of train weight	Original horsepower per ton of train weight W_t	Horsepower required per ton of train weight W_t	
		By reducing locomotive weight 25 per cent	By reducing train weight 25 per cent
1.5	1.75	1.69	1.32
2.0	2.50	2.36	1.87
3.0	4.35	3.93	3.26
4.0	6.70	5.72	5.00
5.0	10.00	8.00	7.50

over, reducing the power-plant weight is practically as effective as reducing the train weight. On the other hand, at lower performance ratings, the gain is greater by reducing the train load.

PERFORMANCE CHARACTERISTICS OF LOCOMOTIVES

The performance of a locomotive is governed by the variation of the power in its speed range relative to its rated power at rated speed. The ratio of the power developed at any speed V mph, to the rated power at rated speed V_R mph has been defined as the power-speed function x. It can also be regarded as the performance efficiency. It measures the efficiency of power developed at various speeds relative to the rated output.

Different types of locomotives have definite power and tractive-force characteristics. The tractive force is limited by the characteristics of the transmission and the power capacity of the unit. In a steam locomotive the low-speed tractive force with late cutoff is roughly double that of the tractive force at rated speed with early cutoff. With a given steam supply, the cutoff at a given speed is fairly definite, since the cylinders are based on proportions necessary for developing rated horsepower at rated speed V_R. With Diesel-electric locomotives, the tractive-force variation depends upon the characteristics of the electric drive. The rated power occurs when the motors run at their continuous rating. Below the rated speed at which the motors develop their continuous torque, the motors are overloaded, resulting in considerable torque amplification at the lower speeds. The starting torque is based on the allowable overload current relative to its continuous-current rating. The variation of the transmission efficiency against speed with constant engine output, relative to the continuous current efficiency at rated speed, is the performance efficiency of the drive.

With straight-electric locomotives and external power, the

rated output corresponds to the continuous rating of the motors at their rated speed. The starting torque corresponds to the allowable overload torque of the motors. This torque can be sustained to a speed dependent on line voltage. Beyond this speed the motors operate on their constant-voltage characteristics with decreasing torque at increasing speeds. The overspeed range, beyond the rated speed, is further extended by weakening of the motor fields. At the speed corresponding to the motor-field change, the current loading is increased with increased torque and power output. Beyond this overspeed-field change, the motors operate on their constant-voltage weakened field characteristics.

Direct steam-turbine drives have starting torques roughly double their rated torques at rated speed. The torque decreases linearly with increasing speed. The power output, therefore, varies as a parabola with the rated power and torque at a speed corresponding to the peak of the parabola. The reciprocating-steam-locomotive drive has very similar characteristics.

With hydraulic drives, the torque converter has characteristics on the output end exactly similar to the direct steam-turbine drive. To extend the speed range, a change-over to a hydraulic coupling is effected. The speed change is then obtained through the slip of the coupling. Torque amplification with reduced speeds takes place with the converter, but no torque amplification can be effected through the coupling.

The characteristics of all locomotive drives are referred to the rated output H_{PR} at rated speed V_R. Therefore, the rated tractive force is

$$Z_R = \frac{375H_{PR}}{V_R} \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

The power at any other speed V is xH_{PR}, where x is the power-speed function or the performance efficiency and the corresponding tractive force, at V mph, is

$$Z = \frac{375xH_{PR}}{V} \quad \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

The tractive-force amplification is defined as the ratio of the tractive force at V mph to the rated tractive force at V_R mph, that is, the tractive-force amplification is

$$\phi = Z/Z_R \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

On substituting Equations [11] and [12] in Equation [13] we have

$$x = (V/V_R)\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

which shows the relation of the speed-performance efficiency with torque amplification at V mph. Thus, with a steam locomotive with a drag speed around 0.25 of the rated speed and tractive-force amplification around 2, the power output relative to its rated value is $x = 0.5$. With Diesel-electric, $\phi = 3$ when $V/V_R = 0.25$, so that $x = 0.75$.

The performance speed range is limited by the maximum allowable speed of the locomotive, V_{max}. It is not to be confused with actual peak speeds with a given train load. It is rather the limiting overspeed allowance above the rated speed consistent with not too much falling off in the power curve against speed and with mechanical limitations of the drive itself. For instance, in steam locomotives, where the rated speed occurs around 200 to 250 rpm, the overspeed range should not much exceed the diameter speed of 336 rpm. Further increase of speed will also cause a very rapid falling off in power with poor operating efficiency.

The maximum performance speed V_{max} is definitely related with the rated speed V_R for different types of locomotives. Let $\gamma_R = V_R/V_{max}$ = the ratio of rated to maximum-performance speed. For steam locomotives γ_R varies from 0.6 to 0.7. For Diesel-electric locomotives γ_R varies from 0.35 to 0.45. For straight-electric locomotives γ_R varies from 0.5 to 0.6. Direct steam-turbine drives have values for γ_R similar to steam locomotives. For hydraulic drives with converter and coupling, $\gamma_R = 0.45$ approximately for the rated output and torque of the converter.

From Equation [16] it will be noted that low values of V_R, and therefore γ_R, result in increased performance efficiencies x, in the low-speed range, so that every effort should be made to increase the overspeed range in order to lower γ_R. The more favorable overspeed characteristics of the electric drive with Diesel locomotives permit lower values of γ_R.

The tractive force can be expressed directly in terms of the tractive-force amplification ϕ by the relation

$$Z = \frac{375\phi H_{PR}}{V_R} = \frac{375\phi H_{PR}}{\gamma_R V_{max}} \quad \ldots\ldots\ldots\ldots [17]$$

By definition $\phi = 1$ at rated speed. In the low-speed range, ϕ is greater than 1, and represents a torque amplification. In the overspeed range ϕ is a fraction.

The drive, through its limitations in tractive-force amplification ϕ at a given speed V, must be consistent with the power capacity and really sets the efficiency of power performance in relation to its rated capacity. In other words, the variation of ϕ is a characteristic of the drive, or, more broadly, that of a given type of locomotive. Thus, in a steam locomotive the tractive-force variation not only depends upon the reciprocating drive, but the boiler capacity as well. However, with a relatively fixed steam supply, the performance characteristics are then more dependent upon the cylinder characteristics. In a direct steam-turbine drive, with a constant steam supply, the characteristics of tractive-force variation are entirely dependent upon the variable-speed characteristics of the turbine. For a Diesel-electric locomotive, with constant engine output, the tractive-force variation and the performance at rail output are also dependent upon the characteristics of the electric transmission. In a straight-electric locomotive the performance characteristics are dependent upon the characteristics of the motors.

From Equation [15], however, while ϕ represents the characteristics of the drive, or, more broadly, that of the locomotive itself,[7] the actual tractive-force variation is also dependent upon the selection of the rated speed $V_R = \gamma_R V_{max}$. The tractive force can be raised in the low-speed range for a given tractive-force variation ϕ relative to its rated value (a characteristic of the drive) by lowering the rated speed ratio γ_R. With parabolic power characteristics, this implies poorer characteristics and a greater dropping of the tractive force in the overspeed range. A problem in locomotive design is to improve the overspeed characteristics to a more constant rail output, thus extending the overspeed range and lowering the rated speed in order to raise the tractive force in the low-speed range.

When the speed V of a locomotive is expressed in terms of the maximum performance speed V_{max}, and if $\gamma = V/V_{max}$ = speed ratio, then, from Equation [14] $x = \gamma\phi/\gamma_R$.

Starting Tractive Force

At very low speeds in the drag-speed range the tractive force depends primarily on the characteristics of the drive rather than the power capacity of the locomotive.[8] Thus, at speeds up to

[7] In a steam locomotive, the cutoff must be adjusted to the steam supply at a given speed and this corresponds to a given firing rate.

[8] See discussion on "Adhesion Limitations."

roughly one quarter rated speed, the tractive force of a steam locomotive is limited by cylinder proportions, because at drag speeds the boiler capacity is in excess of the steam demand of the cylinders. With a Diesel-electric locomotive the tractive force is limited by the allowable overload torque on the motors consistent with heating and commutation limitations. The torque reaction at the generator does not load the engine to its capacity so that the limitation in starting tractive force is the overload capacity of the motors.

The starting tractive force can be sustained through a given speed range $\gamma_D V_R$ known as the drag-speed range. Above this speed the tractive force also becomes limited by the power capacity of the unit. In a steam locomotive not only cylinder characteristics but boiler capacity must be considered. With Diesel-electric locomotives the tractive force depends upon the efficiency of the drive with full loading on the engine. The slight falling off in tractive force in the drag-speed range is a limitation of the drive itself as, for example, wire drawing in reciprocating-engine cylinders or motor characteristics.

The starting-tractive-force amplification ϕ_i is defined as the ratio of starting tractive force Z_i to rated tractive force Z_R at rated speed V_R. That is

$$\phi_i = Z_i/Z_R \quad \ldots\ldots [18]$$

where $Z_R = (375H_{PR})/V_R$; therefore

$$Z_i = \frac{375\phi_i H_{PR}}{V_R} = \frac{375\phi_i H_{PR}}{\gamma_R V_{\max}} \quad \ldots\ldots [19]$$

For reciprocating steam locomotives and direct steam-turbine

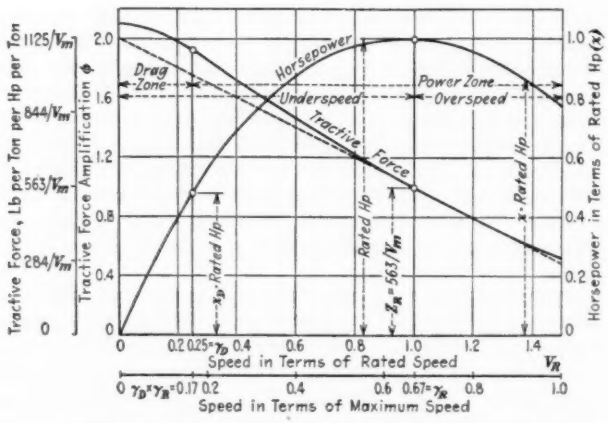

FIG. 4 STEAM-LOCOMOTIVE PERFORMANCE CURVES

drives, $\phi_i = 2$ to 2.3, with $\gamma_R = 0.6$ to 0.7. With Diesel-electric drives $\phi_i = 3$ to 4, with $\gamma_R = 0.35$ to 0.45.

The starting tractive force not only depends upon ϕ_i, but is also influenced considerably by the choice of γ_R. With fixed values of ϕ_i for a given type of drive, the only way to increase the starting tractive force Z_i is either by lowering the rated speed ratio γ_R (or V_R) or by increasing the rated output of the locomotive, except by the use of auxiliary booster engines that go out of action at the end of the drag-speed range. To lower the rated-speed ratio requires longer overspeed characteristics with improved performance characteristics in this range.

The starting tractive force must be consistent with the power capacity of the locomotive at the end of the drag speed. If the time in the drag-speed range is too small, not much benefit in over-all performance is obtained by the use of too high a starting tractive force. Usually it is desirable to maintain the starting tractive force, without too much falling off, up to approximately one quarter or one fifth of the rated speed. At the end of the drag speed, $V_D = \gamma_D V_R = \gamma_D \gamma_R V_{\max}$, where $\gamma_D = 0.2$ to 0.25 and the performance efficiency is x_D. Hence, the tractive force at end of drag speed V_D is

$$\left.\begin{aligned} Z_D = Z_i \text{ (approx)} &= \frac{375 x_D H_{PR}}{\gamma_D V_R} \\ \text{or } Z_i &= \frac{375 x_D H_{PR}}{\gamma_D \gamma_R V_{\max}} \text{ (approx)} \end{aligned}\right\} \quad \ldots\ldots [20]$$

Also the tractive-force amplification is related to the performance efficiency at drag speed V_D by the relation

$$\phi_D = \phi_i \text{ (approx)} = \frac{x_D V_R}{V_D} = \frac{x_D}{\gamma_D} \quad \ldots\ldots [21]$$

Thus, with $\gamma_D = 0.25$ and $x_D = 0.5$, $\phi_i = 2$. With a higher power speed ratio $x_D = 0.75$, then $\phi_i = 3$, approximately. Since

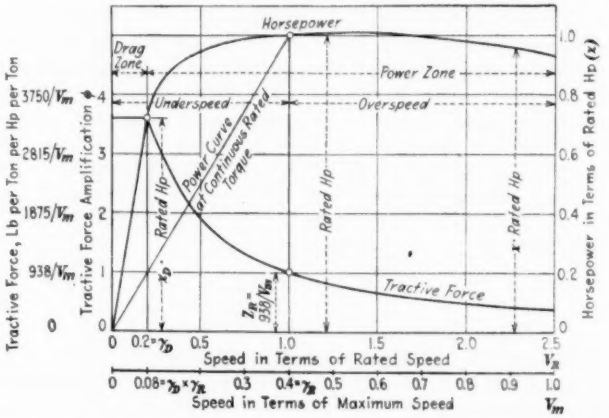

FIG. 5 PERFORMANCE CURVES OF A DIESEL-ELECTRIC LOCOMOTIVE

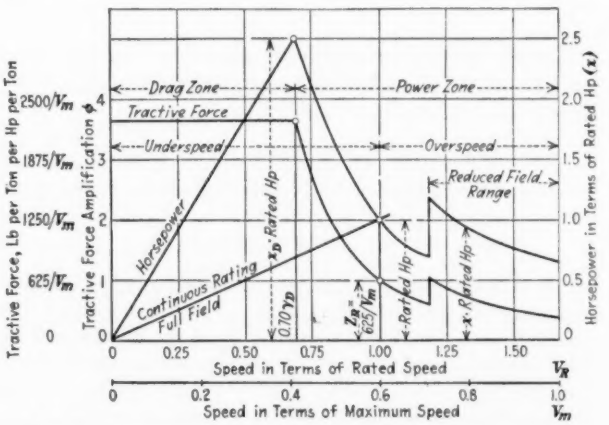

FIG. 6 PERFORMANCE CURVES OF AN ELECTRIC LOCOMOTIVE

x_D is not likely to exceed 0.8, even with the most ideal drive, the maximum tractive-force amplification should not exceed $\phi_i = 4$.

From Equations [17] and [18], the starting tractive force is definitely related with the speed-performance range of the locomotive. To maintain a high starting tractive force with a low power rating, as in switcher service, the performance range must be low. To increase the starting tractive force for high-speed road locomotives, with γ_R fixed for a given type, the power capacity of the unit must be increased. Auxiliary booster engines permit larger values of γ_R with increased starting tractive force.

In Figs. 4, 5, and 6 typical power and tractive-force relations

against speed are plotted showing typical characteristics for steam, Diesel-electric, and straight-electric locomotives.[9] The speeds are plotted in terms of rated speed V_R and maximum performance speed V_m. With unit horsepower at rated speed, the ratio of actual to rated power x, at various speed ratios in the performance range are shown. The tractive-force variation is measured either in terms of tractive-force amplification ϕ relative to the rated tractive force or directly in terms of tractive force per ton. The tractive force per ton is given by the relation

$$Z_t = \frac{375x}{\gamma}\left[\frac{(H_{PR})_t}{V_m}\right] = \frac{375\phi}{\gamma_R}\left[\frac{(H_{PR})_t}{V_m}\right] \quad \ldots\ldots [22]$$

where $\gamma = V/V_m$ = speed ratio and $\gamma_R = V_R/V_m$ = rated-speed ratio.

The tractive-force scale in pounds per ton is measured in $(H_{PR})_t/V_m$.

Fig. 4 shows the variation of power and tractive force against speed for a typical steam locomotive. The rated speed occurs at a speed two thirds of the maximum performance speed V_m. Therefore, the overspeed range is 1.5 times the rated speed V_R The ratio of actual to rated horsepower at maximum speed V_m is 0.78. The drag speed is 0.25 V_R or 0.17 V_m and the power ratio is 0.48. The starting tractive force amplification is ϕ = 2.1. The rated tractive force, in pounds per ton is

$$(Z_R)_t = \frac{375}{0.66}\,\frac{(H_{PR})_t}{V_m} = 563\,\frac{(H_{PR})_t}{V_m} \quad \ldots\ldots [23]$$

and the starting tractive force, in pounds per ton, is

$$(Z_i)_t = \frac{375 \times 2.1}{0.66}\,\frac{(H_{PR})_t}{V_m} = 1180\,\frac{(H_{PR})_t}{V_m} \quad \ldots\ldots [24]$$

Thus at a power rating of 3 hp per ton and a performance speed range to 85 mph, the starting tractive force is 42 lb per ton.

Steam-locomotive characteristics do not differ greatly from a linear variation at which the starting tractive force is approximately twice the rated tractive force. Therefore, the power curve approximates a parabola with the rated values at the peak of the parabola.

Fig. 5 shows typical power and tractive-force characteristics of a Diesel-electric locomotive. The rating of the locomotive is taken at the continuous rating of the motors. The inclined line shows the power variation of the product of rated tractive force and speed plotted against speed. Obviously, the intersection of this line with the power curve corresponds to the rated output. The rated-speed ratio is $\gamma_R = 0.4$, so that the overspeed range is 2.5 V_R. With electric transmissions in Diesel locomotives the maximum output slightly exceeds the continuous current power rating, so that, for maximum output, $x = 1.01$. The starting tractive-force amplification $\phi = 3.6$. The rated tractive force is increased by the lowering of the rated-speed ratio to $\gamma_R = 0.4$. For this case, the rated tractive force, in pounds per ton, is

$$(Z_R)_t = \frac{375}{0.4}\,\frac{(H_{PR})_t}{V_m} = 938\,\frac{(H_{PR})_t}{V_m} \quad \ldots\ldots [25]$$

and the starting tractive force, in pounds per ton, is

$$(Z_i)_t = \frac{375 \times 3.6}{0.4}\,\frac{(H_{PR})_t}{V_m} = 3370\,\frac{(H_{PR})_t}{V_m} \quad \ldots\ldots [26]$$

It should be noted that at a speed ratio $\gamma = 0.66$ the tractive force agrees with that of the steam locomotive. Below and above this speed, the Diesel-electric locomotive has superior tractive-force and power characteristics. However, it is important to emphasize that the comparisons are based on the rated output at the rail.

In the steam locomotive, the ratio of the rail output to cylinder indicated output at rated speed exceeds 90 per cent. In the Diesel-electric transmission, the efficiency of transmission, i.e., the ratio of rail output to engine output, at rated speed, varies from 75 to 80 per cent. Since the analysis is based on rail output, further corrections for efficiency allowance must be made when considering engine outputs.

Fig. 6 shows basic characteristics of straight-electric locomotives. The distinctive characteristic of this type of power unit is a large power amplification over its continuous-current rating. The ratio of maximum power to continuous-current rated power reaches a power amplification[10] $x = 2.5$ at a speed ratio relative to the performance range at $\gamma_P = 0.41$. The continuous-current output has a rated-speed ratio $\gamma_R = 0.59$. The changeover to reduced speed occurs roughly when $\gamma = 0.7$. The starting tractive force is sustained to maximum output with $\gamma_P = 0.41$. The starting tractive-force amplification[10] $\phi = 3.65$, relative to the rated tractive force at continuous-current rating. This, of course, agrees with Diesel-electric starting tractive-force amplification since in both cases the limitation is based on the motor capacity. The rated tractive force in pounds per ton, is

$$(Z_R)_t = \frac{375}{0.59}\,\frac{(H_{PR})_t}{V_m} = 630\,\frac{(H_{PR})_t}{V_m} \quad \ldots\ldots [27]$$

and the starting tractive force, in pounds per ton, is

$$(Z_i)_t = \frac{3.65 \times 375}{0.59}\,\frac{(H_{PR})_t}{V_m} = 2200\,\frac{(H_{PR})_t}{V_m} \quad \ldots\ldots [28]$$

Electric locomotives have large power amplification in the low speeds; therefore, they are well adapted for rapid acceleration from slowdowns. If the greater part of the schedule be in the slow-speed range, then the performance rating will considerably exceed the continuous-power rating. For high speeds, however, the performance rating is less than the continuous-current rating, so that the latter is more nearly the true rating of the locomotive.

Fig. 7 shows the characteristics of a typical hydraulic-turbo-transmission. The characteristics shown approximate those of the Voith turbo two-stage transmission. The transmission is assumed to operate at the normal rated speed of a nearly constant-torque Diesel engine. In the first stage, the transmission operates on the converter stage where torque amplification is effected between the engine (with impeller) and the turbine rotor through reaction stationary vanes. With constant engine torque at rated speed, the flow rate at different turbine speeds does not vary much. Therefore, the output characteristics of the converter are practically those of a direct turbine drive at nearly constant flow rate. The output torque and corresponding tractive force varies nearly linearly with an approach to a parabolic power-output curve. The characteristics in the converter range closely resemble those of the reciprocating steam locomotive. In order to extend the speed range, a hydraulic coupling (without torque amplification) comes into action at approximately 0.68 V_m, where V_m = maximum speed range. The converter performance efficiency at this speed is $x = 0.87$. At a rated speed of 0.45 V_m, the over-all efficiency is 83 per cent, so that the

[9] For a different treatment of these relations see the report of the committee on Economics of Railway Locatio.1, Proceedings of The American Railway Engineering Association, vol. 39, 1938, pp. 440–484.

[10] In average operation, the power amplification in electric locomotives is frequently less than 2. Tractive-force amplification ranges from 2.5 to 3.

over-all efficiency of the converter at the coupling entrance is 72 per cent. The efficiency of the coupling at entrance is around 96 per cent, which corresponds to 4 per cent slip.

The changeover from converter to coupling requires a sudden reduction in engine speed. Let Φ_P = primary or engine torque and ω_P = engine speed. Let Φ_S = secondary or output torque and ω_S = secondary speed. Let ϵ_R = transmission efficiency at rated output speed. Let $\epsilon = x\epsilon_R$ = over-all efficiency of converter and $1 - S$ = efficiency of coupling, with slip S. Then, at changeover speed where ω_{PR} = rated engine speed

$$\epsilon\Phi_P\omega_{PR} = \Phi_S\omega_S \quad \ldots\ldots [29]$$

for the converter; since, at this change-over speed, $\Phi_P = \Phi_S$ nearly, $\omega_{PR} = \omega_S/\epsilon$. With the coupling engaging, and since

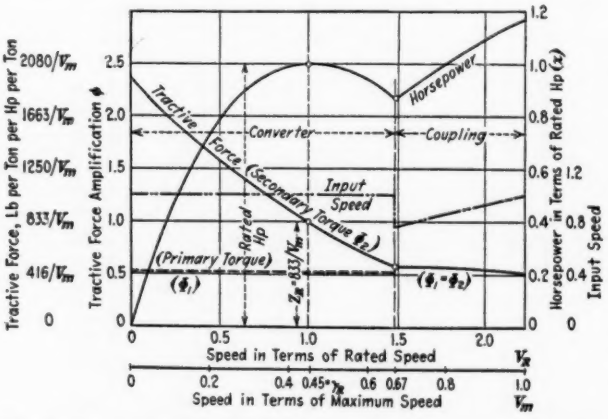

FIG. 7 PERFORMANCE CURVES OF A DIESEL-ELECTRIC LOCOMOTIVE WITH HYDRAULIC TRANSMISSION

necessarily $\Phi_P = \Phi_S$, then $\omega_{P_1} = \omega_S/(1 - S)$. Hence, the drop in engine speed is

$$\omega_{PR} - \omega_{P_1} = \left[1 - \frac{\epsilon}{(1 - S)}\right]\omega_{PR}$$

Therefore, referring to Fig. 7

$$\omega_{PR} - \omega_{P_1} = 0.25\omega_{PR} \quad \ldots\ldots [30]$$

In the second-stage operation with coupling, the engine speed increases from 0.75 ω_{PR} to its rated speed ω_{PR}. Neglecting the small slip, the engine speed increases directly with the speed of the train, with practically constant engine torque transmitted through the coupling. Thus, the power curve rises very nearly as a linear function with increasing train speed. The limiting speed occurs when $S = 0$.

The overspeed can be extended by a second coupling, the intermediate coupling having a mechanical gear for torque amplification and the second coupling a direct drive for torque amplification.

ANALYTICAL RELATIONS

Tractive-force speed relations lie between two extremes:

(1) The first relation is that where tractive force varies as a linear function of the speed, which corresponds to a parabolic power curve against speed. In this case, given the rated tractive force Z_R at rated speed V_R, then the starting tractive force is $Z_i = \phi_i Z_R$, and the tractive force and power, respectively, at speed V, are

$$\left.\begin{aligned} Z &= Z_i - mV \\ P &= (Z_i - mV)V \end{aligned}\right\} \quad \ldots\ldots [31]$$

where

$$m = \frac{Z_i - Z_R}{V_R} = (\phi_i - 1)\frac{Z_R}{V_R} \quad \ldots\ldots [32]$$

At maximum power, corresponding to the power rating, $V = V_R$ so that

$$\frac{dP}{dV} = Z_i - 2mV_R = 0$$

Therefore

$$m = \frac{Z_i}{2V_R} \quad \ldots\ldots [33]$$

and $\phi_i = 2$, so that $Z_i = 2Z_R$.

The tractive-force speed equation in terms of rated power is

$$Z = \frac{375H_{PR}}{V_R}\left(2 - \frac{V}{V_R}\right) \quad \ldots\ldots [34]$$

so that by lowering the rated speed, the tractive force is increased.

(2) The second relation is that where tractive force varies inversely as the speed, which corresponds to a constant-power curve independent of speed (except during starting-tractive-effort drag-speed zones).

ADHESION REQUIREMENTS

The adhesion weight on drivers must be consistent with the starting tractive force. The factor of adhesion must allow for variation in tractive force per revolution; that is to say, the limiting friction force corresponds to the peak tractive force, so that the mean tractive force requires a lower mean friction coefficient. Therefore, in conjunction with adhesion limitations, an important ratio is that of maximum to mean tractive force exerted at the drivers per revolution. This ratio is approximately 1.23 for two-cylinder steam locomotives with ordinary rod obliquities. With three-cylinder locomotives having cranks 120 deg apart, this ratio is reduced to 1.08. On the basis of a peak friction coefficient of 0.3, the mean value for two-cylinder locomotives is 0.245. The ratio of necessary weight on the drivers at the rail to tractive force limited by friction, i.e., the factor of adhesion, is 4.1. In other words, the weight on drivers must exceed four times the starting tractive force.

With electric motors, the effect of weight transfer is an important factor; since the motors are in series, the total tractive force is limited by the most slippery driver.

The ratio of weight on drivers to the total weight of the locomotive is defined as the adhesion-weight ratio. It determines the necessary driving wheel base to the total wheel base of the locomotive, as well as the necessary weight distribution for these component parts. Therefore, the starting tractive force is limited by the product of the adhesion-weight ratio and the total weight of the locomotive. On the other hand, the starting tractive force is proportional to the rated horsepower times the tractive-force amplification and divided by the rated speed. The weight of the power unit can be expressed in terms of the rated power and the power-weight ratio. On combining these relations we can obtain the limiting adhesion-weight ratio in terms of the rated speed, the tractive-force amplification, and the weight efficiency.

Let W_A = weight on drivers, lb; W_P = weight of power unit, lb; $E(1 + K)$ = weight ratio, lb per rated horsepower; H_{PR} = rated horsepower; V_R = rated speed, mph; ϕ_i = starting tractive-force amplification; and $\mu = 1/F_A$ = mean friction coefficient, where A = factor of adhesion, then the adhesion-weight ratio is

$$C = \frac{W_A}{W_P} \quad \ldots\ldots [35]$$

where

$$W_P = E(1 + K)H_{PR} \quad [36]$$

Therefore, the starting tractive force in terms of the adhesion limit is

$$Z_i = \mu W_A = \mu C W_P \quad [37]$$

Therefore

$$Z_i = \mu C E(1 + K)H_{PR} \quad [38]$$

But this tractive force must be consistent with the tractive force limited by the tractive-force amplification of the drive, that is, with

$$Z_i = \frac{375\phi_i H_{PR}}{V_R} \quad [39]$$

On equating expressions [38] and [39]

$$C = \frac{375}{\mu(V_R/\phi_i)} \frac{1}{E(1 + K)} \quad [40]$$

Thus, the adhesion-weight ratio varies inversely as the weight efficiency of the power unit and also inversely as the ratio of rated speed to tractive-force amplification. In terms of the rated-speed ratio $\gamma_R = V_R/V_m$ and the factor of adhesion $F_A = 1/\mu$

$$C = \frac{375F_A\phi_i}{\gamma_R E(1 + K)V_m} \quad [41]$$

which shows that the weight on the drivers to the total locomotive weight increases directly with the tractive-force amplification and inversely with the rated-speed ratio, the weight efficiency and the speed range V_m of the locomotive. Thus the operating speed range V_m has a major influence on the necessary weight on drivers. High-speed locomotives with a large operating range require less weight on drivers than locomotives in freight service which have a lower operating speed range. In switching service V_m is inherently small, so the entire weight of the locomotive is required for adhesion.

Referring to Fig. 8, the adhesion-weight ratio is plotted against weight efficiencies of the locomotive at various ratios of rated speed to starting tractive-force amplification. The mean friction coefficient is taken at 0.25. For other values of friction coefficients, it is only necessary to multiply the adhesion-weight ratio by 0.25 divided by the assumed mean coefficient of friction. The lower chart shows rated speed V_R plotted against starting tractive-force amplification ϕ_i at various values of the ratio of rated speed to starting tractive-force amplification.

Low values of V_R/ϕ_i, say from $12^1/_2$ to $17^1/_4$, correspond to low rated speeds V_R and high starting tractive-force amplifications ϕ_i. High rated speeds, in general, have large values of V_R/ϕ_i. With weight ratios $E(1 + K)$ as low as 100 lb per hp, and a low value of V_R/ϕ_i around 15, the adhesion-weight ratio $C = 1$, so that the entire weight of the locomotive is necessary for adhesion. For another example, consider a slow-speed freight locomotive with 59-in. drivers, which at 200 rpm corresponds to a rated speed at 35 mph. Let $\phi_i = 2.3$, then $V_R/\phi_i = 15.2$. Assuming $E(1 + K) = 210$ lb per hp, then by interpolation, the adhesion-weight ratio $C = 0.47$. With a tender-weight ratio $K = 0.75$, the corresponding weight ratio of the locomotive above is 120 lb per hp. Then the adhesion-weight ratio with respect to this freight-locomotive is 0.82.

On the other hand, with a high-speed passenger locomotive with 80-in. drivers and a rated speed at 60 mph with $\phi_i = 2.3$, then $V_R/\phi_i = 26.2$. Considering the locomotive power-weight ratio without tender at 120 lb, then the adhesion-weight ratio by interpolation is 48 per cent. Obviously, with a higher factor of adhesion the adhesion-weight ratio on drivers is increased.

Corresponding running gears would indicate a locomotive of the Santa Fe type for the former and an Atlantic-type locomotive for the latter.

Adhesion Limitations. More logically, the adhesion-weight ratio should be sufficient for the starting tractive force based on the limiting tractive-force amplification of the drive. On the other hand, particularly with high-speed units, tracking limitations of the running gear must be considered, which with rigid wheel bases require adequate guiding trucks. Further limitations are due to allowable wheel-base lengths and weight distribution with limiting axle loads. For these reasons the adhesion-weight ratio may be limited, so that the starting tractive force then becomes limited rather by adhesion than by tractive-force amplification.

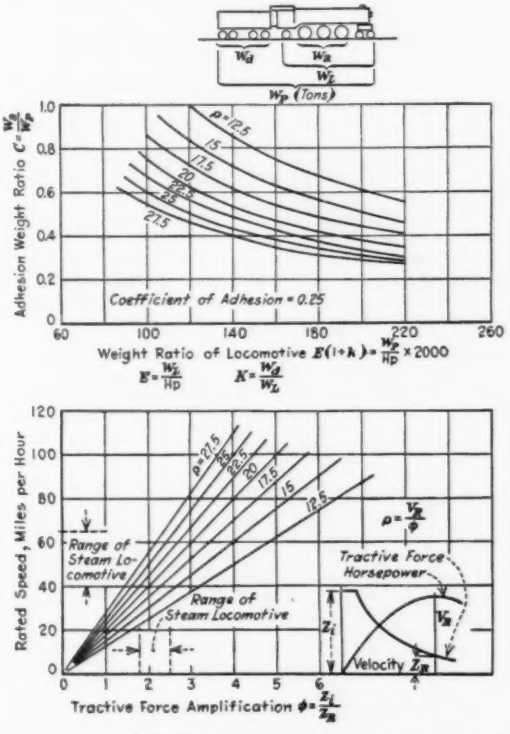

FIG. 8 ADHESION-WEIGHT RATIOS PLOTTED AGAINST WEIGHT RATIOS

The number of driving axles in a locomotive is dependent on the total horsepower required and the limiting power concentration per unit driver. This, in turn, depends upon the allowable axle loading and the ratio of rated speed to tractive-force amplification. With a limiting axle loading A the maximum power is

$$H_{PA} = \frac{\mu A}{375}\left[\frac{V_R}{\phi_i}\right] \quad [42]$$

where μ is the mean friction coefficient.

Referring to Fig. 9, the maximum power concentration per axle is shown plotted against allowable rail axle loadings at various ratios of rated speed to tractive-force amplification and with a factor of adhesion equal to 4. The lower auxiliary plot gives V_R/ϕ_i for a given rated speed and tractive-force amplification.

Axle loadings vary from 40,000 to 80,000 lb; the latter re-

quiring extremely heavy rail. Normal axle loadings range between 50,000 to 65,000 lb. Steam locomotives with high rated speeds have large power ratings per driver.

With a factor of adhesion of 4.2, $\mu = 0.24$. With a rated speed at 60 mph and a torque amplification at 2.3, then $V_R/\phi_i = 26$. With a limiting axle loading at 63,000 lb, then the limiting power per axle is 1050 hp. For a 3000-hp locomotive, three driving axles are needed. For a freight locomotive, with rated speed at 200 rpm and 69-in. wheels, $V_R = (200/336) \times 69 = 41$ mph. With $\phi_i = 2.3$ and $A = 63{,}000$ lb, $\mu = 0.24$; then

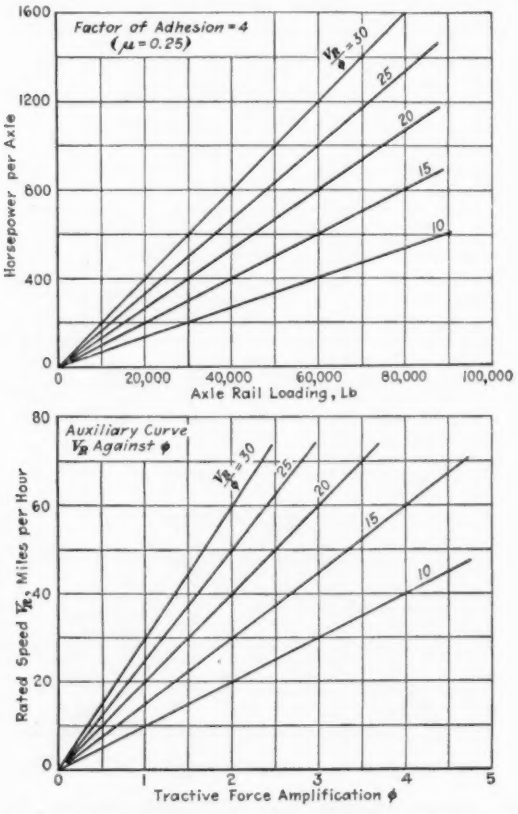

FIG. 9 MAXIMUM PERMISSIBLE HORSEPOWER PER AXLE FOR DIFFERENT AXLE LOADINGS

the limiting power per driver is 710 hp. For a 3000-hp rating, at least four drivers are necessary.

For an electric drive with $V_R = 37.5$ mph and $\phi_i = 3$, $\mu = 0.25$ and $A = 55{,}000$ lb; then, the limiting power per axle is 460 hp. For a 3000-hp locomotive at least six axles are required.

Wheel diameters D should preferably not be less than $A/1350$.

Ordinarily, the wheel diameter is fixed by the allowable revolutions per minute N_R at rated speed V_R. That is

$$D = \frac{336}{N_R} V_R \quad \ldots\ldots\ldots\ldots\ldots\ldots [43]$$

where the driving-wheel diameter is expressed in inches.

In steam locomotives, N_R ranges from 200 to 250 rpm. With electric drives, $N_R = N_m/\alpha$, where α = gear ratio and N_m rated rpm of rotor armature.

Besides these factors, constructional limitations due to boiler and allowable rigid wheel base and space limitations in motor trucks very often fix the limiting wheel diameter. Thus, in steam locomotives, maximum wheel diameters, due to boiler limitations, are limited to from 80- to 84-in. diameter. Mountain-type locomotives are limited to smaller diameters due to limiting rigid wheel bases.

POWER REQUIREMENTS FOR GRADES

Power requirements on grades usually require special consideration, particularly with low power ratings. Also, since the operating speed on a grade is low relative to the rated speed, the power developed is some fraction of the rated power. In other words, the speed-performance efficiency of the power curve must be taken into consideration in connection with the operating grade speed for estimating the required rated power.

As a simple illustration, consider a 2 per cent grade which corresponds to a grade resistance of 40 lb per ton with an additional allowance of 10 lb per ton for train and other resistances. With an operating grade speed of 30 mph, the actual power requirements at the rail is $(50 \times 30)/375 = 4$ hp per ton.

With a speed-performance efficiency of 75 per cent at 30 mph, the rated power is increased to 5.33 hp per ton. Thus, even with high power-performance ratings, heavy grades usually require additional power, so that a new formulation of power relations must be evaluated.

Obviously without additional power, the operating speed on a grade must be consistent with the tractive-force-speed characteristics of the locomotive and the balancing grade plus train resistance. Thus, it is only necessary to add to the train-resistance curves against speed the grade resistance of $20G$. Where these curves intersect the tractive force, expressed in pounds per ton of total train plus locomotive, is the balance speed corresponding to the particular grade.

With additional power, the power characteristics of the booster locomotive usually is different from that of the main power unit. Therefore, this, along with its weight efficiency, must be considered.

When a given speed up a specified grade is required, the power requirements of the booster locomotive become fixed. If Z_1 and Z_2 are the tractive forces of the main and the booster locomotives, respectively, W_{P1} and W_{P2} = the corresponding weights of the power units, and R_V = the train resistance at V mph; then, for a train weight W_t

$$Z_1 + Z_2 = (20G + R_V)(W_{P1} + W_{P2} + W_t) \ldots\ldots [44]$$

But we note

$$\left.\begin{aligned} Z_1 &= \frac{375\phi_1 H_{PR1}}{V_{R1}} \\ Z_2 &= \frac{375\phi_2 H_{PR2}}{V_{R2}} \end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots [45]$$

where H_{PR1} is the rated horsepower of the main locomotive, H_{PR2} is the rated horsepower of the booster locomotive, and $E_1(1 + K_1)$ and $E_2(1 + K_2)$ are their respective weight efficiencies in pounds per horsepower. Also ϕ_1 and ϕ_2 are the tractive-force amplifications at V mph relative to their rated speed V_{R1} and V_{R2}, respectively. Hence

$$\frac{375\phi_1 H_{PR1}}{V_{R1}} + \frac{375\phi_2 H_{PR2}}{V_{R2}} = (20G + R_V)\left[\frac{E_1(1 + K_1)H_{PR1}}{2000} + \frac{E_2(1 + K_2)H_{PR2}}{2000} + W_t\right] \ldots\ldots [46]$$

Since $\phi_1 = x_1 V_{R1}/V$ and $\phi_2 = x_2 V_{R2}/V$. Then

$$x_1 H_{PR1} + x_2 H_{PR2} = \frac{(20G + R_V)}{375}\left[\frac{E_1(1 + K_1)H_{PR1}}{2000} + \frac{E_2(1 + K_2)H_{PR2}}{2000} + W_t\right] V \ldots\ldots [47]$$

expressed in horsepower, which is obviously the power equation.

The power requirement of the booster locomotive, given the main-locomotive power rating, is

$$H_{PR_2} = \frac{(20G + R_V)W_t - \left[\frac{375\phi_1}{V_{R_1}} - (20G + R_V)\frac{E_1(1 + K_1)}{2000}\right]H_{PR_1}}{375\,\frac{\phi_2}{V_{R_2}} - (20G + R_V)\,\frac{E_2(1 + K_2)}{2000}} \quad \ldots\ldots [48]$$

As an example, consider a train load $W_t = 1000$ tons on a 2 per cent grade, pulled by a main locomotive for which $H_{PR_1} = 3000$ hp with its rated speed at 60 mph and a weight efficiency $E(1 + K) = 220$ lb per hp. Let the booster locomotive have a rated speed $V_{R_2} = 35$ mph and let its weight efficiency $E(1 + K) = 200$ lb per hp.

What rated horsepower is required for the booster locomotive so that the double-headed train makes the grade at 20 mph? Assume the train resistance at this speed to be approximately 8 lb per ton.

At a speed ratio of 20/60 $V_{R_1} = 0.33V_{R_1}$, the tractive-force amplification of the main locomotive is $\phi_1 = 1.80$. At a speed ratio 20/35 $V_{R_2} = 0.57V_{R_2}$, the tractive-force amplification for the booster locomotive is $\phi_2 = 1.5$. From Equation [48]. $H_{PR_2} = 2650$ hp.

Conclusions

It is important to emphasize that all types of locomotives have more or less flexibility in rating, both as to rated speed and to corresponding power developed. Thus, in a steam locomotive, various rates of firing result in different evaporation rates. Methods of operation, for example, operating at various cutoffs, will give different road characteristics. Likewise, Diesel engines can increase their output by overspeeding, supercharging, or by increased fuel injection at a given engine speed. Steam-turbine units can augment their torques by increasing the flow rates and overloading the boilers. Therefore, the rating of a locomotive at best can be considered only as an approximation.

Certain types of locomotives are further considerably influenced in their performance ratings by modes of operation, as well as extraneous weather conditions. With electric drives, the ratings of motors are dependent upon their heat ratings so that under heavy loading at low speeds, the motors may be overloaded for a long time duration, thus requiring a reduction of performance rating for a given service. Finally, it is important to emphasize that the power-performance efficiencies at very low and at very high speeds, where these efficiencies are frequently poor, are difficult to estimate accurately due, in general, to possible overloading capacity of the power unit to meet special conditions in these ranges.

In a final analysis, the adoption of one type of power unit over another depends upon its economic justification. A fairly universal adoption of one type of power unit may have a far-reaching effect on the mode of operation of a railroad, as in electrification. On the other hand, with mixed power and self-contained units, as with steam, Diesel, and turbine locomotives where a certain degree of interchangeability must exist, it is possible to draw immediate comparisons over typical operating schedules under common maintenance conditions and hostelry.

Since the performance of a horsepower is only slightly affected by the type of power unit, a primary factor is the cost per horsepower mile. Obviously, this simply amounts to the cost per horsepower per annum divided by the mileage availability of the unit per annum. Increasing costs of superior-performing power units can only be justified to the extent of their increased availability and to where in the modes of operation of a railroad, such as in schedules, such availability can be utilized.

The primary costs attributed to the locomotive itself are (1) fixed charges, including allowance for depreciation and obsolescence, (2) maintenance charges, and (3) fuel and operating costs. These charges are for a locomotive of given rated horsepower. The charges added together per annum and then divided by the mileage availability of the unit per annum and the rated horsepower can be expressed as the cost per 1000 horsepower miles.

Thus, higher fixed charges for improved designs can be sustained provided they react in greater mileage availability per annum, with lower maintenance, fuel, and operating costs.

An immediate effect of weight savings on the locomotive or train side, is either a reduction in horsepower miles and corresponding costs or an increase of train capacity and pay load for a given schedule.

Acknowledgments

The author is greatly indebted to L. K. Silleox and A. F. Stuebing for important suggestions and revisions; to H. B. Oatley, C. E. Barba, and to W. J. Hargest for reviewing the paper; and to Colonel E. J. W. Ragsdale and R. H. Horton for also reviewing the paper and making several suggestions.

The author is particularly grateful to Dr. C. A. Adams for his contribution and discussion of various concepts in the paper.

Credit is due to R. E. Ebenbach for aiding the author in the preparation of the paper, and to H. de Fritsch in connection with the electric calculations.

Discussion

Lawford H. Fry.[11] The author states that this paper is a preliminary survey, and his statement of purpose shows that it covers a very wide territory. Study of the paper shows that the survey is in the nature of a sketch map, rather than a careful triangulation. This should be emphasized before someone unfamiliar with the territory tries to use the paper to plot a course.

The author proposes to describe by one common method the operating characteristics of locomotives of all species, steam, Diesel-electric, turbo-geared, and line-fed electric. All classes of service from drag-freight to ultra-high speed are to be covered. The project is extremely ambitious and would have been more successful if the analysis had been more incisive. The author writes: "To obtain high speeds with rapid acceleration it is necessary either to increase the horsepower or reduce the weight of the train. We are confronted with a very difficult problem in increasing performance ratings with orthodox equipment. . . . It is obvious, therefore, that to maintain the same power capacity and to effect corresponding increase in performance requires considerable weight reduction of train equipment."

It is hard to agree that this is obvious. No mention is made of the possibility of reducing train resistance or of increasing locomotive efficiency. Even aside from this, the statement is incomplete. The author looks at only one side of the problem and thus throws his analysis out of balance. It may, as he says, be difficult to increase locomotive performance, but it is certainly not easy to reduce train weight while keeping pace with increasing demands for comfort and safety.

It is unfortunate that the paper does not present a background of basic facts from which the conclusions are derived. Figs. 4, 5, 6, and 7 are given to represent the tractive effort and horsepower characteristics of steam, Diesel-electric, line-fed electric, and Diesel-hydraulic locomotives. A single plot is offered to

[11] Railway Engineer, Edgewater Steel Company, Pittsburgh, Pa. Mem. A.S.M.E.

cover all types of locomotives of each of the species. No information is given as to the type or size of the locomotives on which the curves are based, nor any indication as to the original sources of the curves. These four plots, Figs. 4 to 6, seem a slender foundation for a complete theory of locomotive performance.

Also, much more searching analysis is required if any effective use is to be made of the so-called rated horsepower, rated speed, and rated tractive effort on which the various plots are based.

Some thirty years ago the term rated tractive effort was introduced to designate the cylinder tractive effort computed for a mean effective pressure of 85 per cent of the boiler pressure. This was intended to represent the maximum tractive effort available at the rim of the drivers at slow speed. The term has been quite extensively used in this connection, but the rated tractive effort of the present paper is something entirely different. It seems unfortunate that a well-established term should be given a new significance. For each species of locomotive a rated speed is chosen, and the horsepower and tractive effort at this speed are designated as "rated." The rated horsepower is used as a basis for developing equations to describe operating characteristics. The drawback to this is that the author does not provide any clear-cut definition for rated horsepower and rated speed. In describing Figs. 4 to 6, the rated speed, which sets the value of the rated horsepower, is located by a different rule in each case. In Fig. 4, steam, the rated speed is $^2/_3$ of the maximum operating speed, which is assumed to be 336 rpm; in Figs. 5 and 6, Diesel-electric and line-fed electric, the rated speed is the speed at the continuous current rating of the motors.

These rather indefinite rules for the value of the rated speed, which are given in descriptions of the illustrations do not agree with those given under the subheading, "rated horsepower." When the conclusion is reached, the author says in effect, it is important to emphasize the fact that, for all types of locomotives, the rating as to speed and horsepower is more or less flexible and can at best be considered only as an approximation.

After this statement it seems legitimate to ask whether it was worth while to develop forty complicated equations on the uncertain basis of the rated horsepower.

Before answering this question, the equations themselves should be considered. Equation [3] represents the tractive effort required to overcome train resistance and acceleration,[12] while Equation [4] is an arbitrary grouping of symbols intended to represent the tractive effort made available by the locomotive. From examination of these two expressions, the author concludes: "It is obvious that train performance depends primarily on the available power per ton of total train weight;" and "over an average operating schedule. . . . these variations in train resistance (due to speed and to differences in equipment[13]) play a relatively small part compared with acceleration and grade resistance." It does not seem obvious to the writer that consideration of speed is unnecessary in estimating train resistance. Also, a question must be asked as to the meaning of "average operating schedule." How is it possible to average drag-freight and superspeed runs? The same question comes up in connection with Equation [7] for performance rating. The author assumes that a typical schedule requires 4 hp per ton for steam and 3.5 hp per ton for Diesel-electric power. "Typical schedule" is not defined, and no information is given as to how the horsepower values are obtained.

Equation [10], which forms the basis for Fig. 1, rates critical attention. The left-hand side is composed of the single symbol H_{pr}, the rated horsepower, which supposedly has a constant value for a given locomotive. On the right-hand side the numerator is the product of W_t, the weight of the train, and the so-called performance rating, h_{pt}, which is the horsepower available at a given speed and therefore varies with the speed. The variable in the numerator must be eliminated if the two sides are to be harmonious. This is done by having a similar variable in the denominator. With the variable, V, removed from numerator and denominator on the right-hand side, Equation [10] assumes a more logical form. It is then seen to be not a real equation, but an identity expressing the arithmetic fact that if values are given for train weight, locomotive weight, and horsepower, these establish values for horsepower per ton of total train and for locomotive weight per horsepower.

Fig. 1, which is plotted from Equation [10], is merely an abacus to facilitate the arithmetical computation of the relations between the foregoing quantities. In discussing the conclusions to be drawn the author says: "Since size, weight, and power of a locomotive increase in direct proportion to the weight of the train for a given performance, it is obvious that a reduction in train weight is most effective in reducing size of power unit." Omission of any consideration of locomotive efficiency and of train resistance makes this statement inadequate, to say the least.

Figs. 4, 5, 6, and 7 are discussed generally, a good deal of attention being given to the Diesel hydraulic-turbo-coupled locomotive, although this does not seem to be of any great practical importance or to have any special bearing on the main theme of the paper. Most of the discussion is very sketchy, with occasional numerical values supplied, but with no statement of origin to support such values. In many cases values are given in such broad terms as to be meaningless. To say that axle loads vary from 40,000 to 80,000 lb, with normal loads between 50,000 and 65,000 lb, does not assist the expert nor enlighten the ignorant. Under the subhead "Power Requirements for Grades," the author introduces calculations for helper locomotives. The practical value of this is not apparent, as it is not common practice to design special locomotives for helper service.

In publishing the paper the author should make clear that it is a preliminary survey; that Figs. 4 to 6 are merely illustrative, and that any values given are not absolute and may be greatly modified in practice.

Unless this is done, the paper contains elements of danger. The author would not go wrong in applying his principles and equations, nor would any other experienced locomotive engineer, but if the paper is broadcast in its present form, there is always the possibility that it may be misused.

It would be quite possible by using the present equations and selecting numerical data to arrive at some very remarkable conclusions which might be put forward as being based on the authority of The American Society of Mechanical Engineers, and the reputation of Dr. Eksergian. This contingency should be avoided.

E. E. KIMBALL.[14] The author has referred to a similar study of the characteristics of steam, electric, and Diesel-electric locomotives, described in a report of the Committee on the Economics of Railway Location of the American Railway Engineering ing Association. It may be helpful briefly to outline some of this work.

The object of the study was to develop a method for comparing the characteristics of the principal types and classes of locomotives used by the railroads of this country, in order to determine their effect upon the economics of railway location and operation.

[12] In developing Equation [3], the author estimates the rotative inertia as 10 per cent of the longitudinal. This is very high, being twice the value frequently used.

[13] Parenthetical statement by the writer.

[14] Schenectady, N. Y. Chairman, Subcommittee No. 1, Economics of Railway Location and Operation, American Railway Engineering Association.

The work of the committee largely parallels that of the author, except that it is intended to apply to specific examples rather than to a preliminary survey of a much wider field.

Fundamentally the object of any locomotive is to furnish power to propel trains over a railroad. For this reason it is necessary to consider what there is about different types of locomotives which limit their power.

Usually the power is limited in three ways:

(*a*) The amount of power which can be used is limited by the adhesion between the drivers and the rails and varies with the speed as represented by the line *OA* in Figs. 10 and 11, based on a constant coefficient of adhesion (25 per cent for steam and 30 per cent for Diesel-electric types, as explained later).

(*b*) In the case of a steam locomotive, the amount of power which is available depends upon the amount of steam the boiler is capable of generating, which is equivalent to a certain amount of horsepower delivered to the cylinders and which can be represented by the horizontal line *B'C'* in Fig. 10, designated maximum boiler capacity.

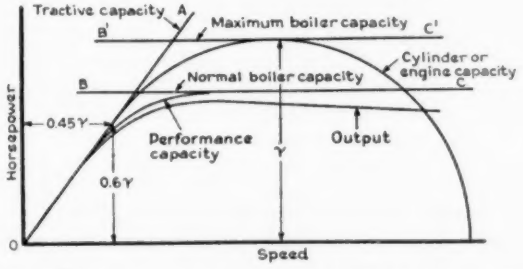

FIG. 10 DIAGRAM ILLUSTRATING TRACTIVE CAPACITY, BOILER CAPACITY AND ENGINE CAPACITY OF STEAM LOCOMOTIVES

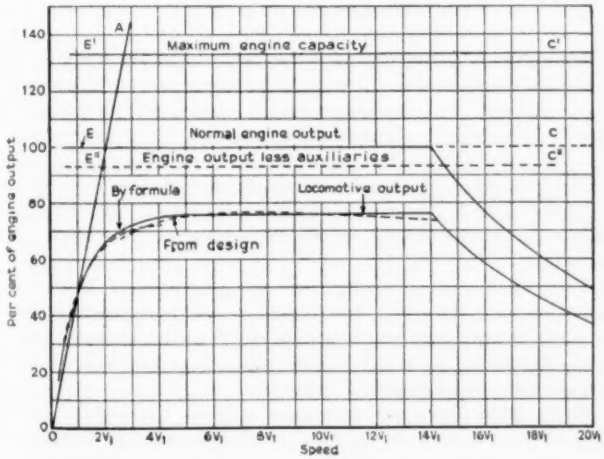

FIG. 11 TYPICAL HORSEPOWER CURVES OF OIL-ELECTRIC LOCOMOTIVES

(*c*) In order to have a locomotive, which can work up to the adhesion limit of its drivers and which can use all the steam that the boiler can generate, it is necessary to design the engine with sufficient capacity to do both.

That is, if the characteristics of the engine can be represented by a circle, then the limiting characteristics of the locomotive can be obtained by drawing a circle, tangent to the lines *OA* and *B'C'*, Fig. 10.

A circle may not represent the characteristics of the engine but it can be used for purposes of discussion. In the low-speed range, the amount of steam which can be used is primarily limited by the number of strokes per minute. As the speed increases, it is possible to use more and more steam and to develop more and more horsepower but, with full cutoff and increasing amounts of steam, the branch-pipe pressure decreases and the back pressure increases, which react to limit the amount of steam and the horsepower which can be developed with full cutoff.

By shortening the cutoff, the steam is used more economically and for a while it is assumed possible to use more steam than when

FIG. 12

operating with full cutoff. Hence, the horsepower continues to increase until the cutoff is shortened to such an extent that the amount of steam, which can be admitted to the cylinders, is limited by the time that the valves remain open. At higher speeds less and less steam is admitted, which means less and less horsepower input and less demand on the boiler.

Aside from these assumptions, Fry has shown that the boiler efficiency decreases as the firing rate increases, consequently it is impractical to operate steam-locomotive boilers at maximum capacity. In fact it can be shown that $^3/_4$ of the maximum capacity can be obtained if the firing rate is limited to $^1/_2$ the maximum. The committee chose this value to represent the normal capacity of the locomotive and based its estimates on a constant firing rate and boiler evaporation, as indicated by the line *BC* in Fig. 10.

On this assumption it is necessary to base the engine performance on a constant supply of steam, which is shown by the curve designated performance capacity.

The horsepower output at the driving axles of the locomotive is obtained by subtracting the power required to overcome the

Compiled 1937 by AREA Committees XVI and XXI

friction in the machinery, based on 20 lb per ton on drivers, from the indicated-horsepower input to the cylinders.

In the case of Diesel-electric locomotives, it is customary to assume the overload capacity of the electrical equipment is sufficient to develop tractive efforts equivalent to 30 per cent of the weight on drivers instead of 25 per cent assumed for steam locomotives. The line *OA*, Fig. 11, is drawn on this basis.

The power available on a Diesel-electric locomotive is limited by the horsepower capacity of the power unit. The maximum engine capacity is represented by the horizontal line *E'C'*, Fig 11. In the case of electric drive it is necessary to reduce the standard rating of Diesel engines, because in these cases it is possible to operate them continuously at maximum capacity, which would be injurious to the engines and cause high maintenance. For this reason the normal output of the engine is based on a much lower rating and is held constant by automatic devices embodied in the control as indicated by the horizontal line *EC*, Fig. 11.

In some cases the main engine supplies power for operating auxiliaries, air compressors, fans, battery charging, etc., consequently it is necessary to deduct this power from the output of the engine to obtain the amount of power available for traction.

Since the characteristics and capacities of the component parts of the equipment are or can be tested on the stand before assembling on the locomotive, it is possible to calculate the characteristics of Diesel-electric locomotives very accurately from design data.

The committee making this study developed an empirical formula which closely approximates the horsepowers obtained from design data and has used this formula as the basis for a special work sheet Fig. 12 (form G), for calculating the speed, tractive-effort, and horsepower-output curves of typical Diesel-electric locomotives. The first four columns of the form apply to what may be termed the speed range covered by normal gearing. If a different speed range is desired, it is necessary to change the motor gearing and adjust the speed and tractive efforts accordingly based on the horsepower outputs from column (k).

Form B, Fig. 13, is the corresponding work sheet developed for calculating the speed, tractive-effort, and horsepower curves of typical steam locomotives and is based on an empirical formula derived in a manner similar to that used in deriving the equation for Diesel-electric locomotives.

Steam locomotives are sometimes rated on the basis of road tests and sometimes on the basis of their average performance in service. In order to obtain a rational rating for steam locomotives, the committee assumed that the weight, tracking qualities and capacity depended upon the wheel arrangement or locomotive classification and compiled Table 1 based on an analysis of about 250 different designs of locomotives. This table shows the normal horsepower capacities per ton on drivers (75 per cent of maximum), corresponding to the ratio of the weight on drivers to weight of the engine, the types of locomotives available, and also the ratio of the weight on drivers to the weight of engine and tender for use in preliminary estimates.

In the final analysis or in the case of individual locomotives, it may be necessary to adjust the horsepowers in order to agree with actual design data.

Sample work sheets covering various types of electric loco-

motives together with examples showing their application will be found in the committee's report which will be submitted to the American Railway Engineering Association during its convention in March, 1939.

SIDNEY WITHINGTON.[15] Any attempt to compare power characteristics of locomotives of widely varying types on a common basis of units and ratings is indeed interesting and courageous. As the author very logically concludes, "the rating of a locomotive at best can be considered only an approximation," and there are many variables which make accurate comparison of rating data among different types exceedingly difficult.

It is suggested that, in the discussion of the characteristics of the electric locomotives, the alternating-current single-phase equipment be included, as well as the direct-current equipment. With the voltage-control methods available, the tractive-effort and horsepower characteristics of the alternating-current motor are more flexible and quite definitely more favorable, especially at the higher speeds, than those of the direct-current motor equipment.

Mention is made of the overload capacity of electric motors and the sustaining of full starting tractive force with electric locomotives. This characteristic should be recognized in the diagram, Fig. 6, in which it would seem the slope, at low speeds, of the horsepower curve should be approximately equivalent to that of the Diesel equipment given in Fig. 5, whether the electric locomotives are of the alternating-current or the direct-current type.

The limitation of the electric-motor capacity being a temperature limitation, the horsepower rating of electric locomotives can be assumed to be somewhat higher in winter than in summer, and this is favorable, since train resistance normally is higher in winter than in summer. The horsepower rating characteristic tendency is opposite in steam locomotives where cold weather tends to increase radiation losses and therefore to decrease horsepower rating at a time when increase is desirable. Furthermore, the quantity of steam required for train heating in cold weather also tends to reduce the traction rating of steam equipment at such times. With electric and Diesel locomotives the steam supply for steam air-conditioning and for train heating is usually independent of the traction equipment.

The statement in the paper that "motive power required increases directly with train weight" is open to some qualification, for there are several items of train resistance which are independent of the train weight. The resistance per ton weight of train is greater for light than for heavy trains, other things being equal.

Mention is made in this paper of the varying adhesion characteristics with different types of locomotives. It might be pointed out that, where the driving axles are not coupled, there is a tendency for the forward drivers to lift on account of the moment due to heavy drawbar pull and rail reaction. This would obviously increase the tendency of the leading driving wheels to slip and thus reduce the tractive effort of the locomotive. Coupling the driving axles by side rods of course eliminates this tendency.

While the primary costs attributed to locomotives, reduced to a mileage basis, may theoretically be based upon the "mileage available," this may not be the whole story, for the actual annual mileage may be limited, and usually is limited in practice, not by mileage available, but by traffic requirements.

AUTHOR'S CLOSURE

It is apparent that Mr. Fry has misinterpreted the author's purpose. The object of the paper was a coordination by a common basis of units and ratings for the analysis of different types of power units.

The paper is by no means a sketch map as Mr. Fry would infer, but, to the contrary, it represents a careful study of basic design limitations. Certains criticisms are very difficult to answer. For instance, his objections, "that a more searching analysis is required if any use is to be made of the so-called rated horsepower, rated speed, and rated tractive force," seem inconsistent with the actual deductions made from their use throughout the paper. The various plots, Figs. 4 to 7, inclusive, show characteristics of basic types of locomotives explicitly using these ratings. A major purpose of these plots was to show just how the various ratings were to be interpreted on a quantitative basis. Obviously, the plots do not represent the exact characteristics for all types of designs, but they can be interpreted as sufficiently typical to illustrate the method of arriving at the basic design parameters for any actual locomotive.

In stating that a steam locomotive, a Diesel-electric locomotive, and an electric locomotive have distinctive and unique characteristics appears fully as justified; as for instance, in stating characteristics of induction motors, Diesel engines, power, and torque-speed characteristics of turbines. While individual designs vary, the general characteristics are still maintained. One object of the paper was to coordinate these characteristics of locomotive power units to a common basis of comparison for train performance.

Attempts at generalizations are not usually accepted at the outset by those accustomed only to working on detail and specific designs, due to the great difficulty in presenting such generalizations to cover all details. But the advantage of generalization is very great in that it requires concentration on the fundamental limitations of a design and clearly points to the essential factors that result in a balanced design.

The author feels that the entire problem of motive power on the railways has been considered from too narrow a point of view, and that greater progress can be made with competing types of locomotive when it is more clearly realized that there are certain generalizations and limitations applicable to all types of power unit. One object of this paper was to point out the nature of these limitations and their specific applications to given classes of locomotive.

Mr. Fry's objection that the author, does not provide a clear-cut definition of rated horsepower which the author uses as a basis for developing equations for operating characteristics, clearly shows the difficulties that are immediately met in attempting generalizations. Possibly Mr. Fry raises this objection due to the particular difficulty of giving an exact power rating of a steam locomotive. For a long time steam locomotives were rated on their starting tractive force alone, but it has been appreciated for some time that the power capacity of the locomotive in its operating-speed range has even greater significance. This latter point of view was definitely introduced by the late Mr. Cole of the American Locomotive Company and revised to a rational basis by Dr. Lipetz as a method for the rating of steam locomotives.

The outstanding feature of these methods in power rating was to correlate boiler performance with cylinder performance at either a definite piston speed or number of revolutions per minute of the drivers, which amounts to a definite power output at a given speed. The author has maintained this point of view.

The power output of a locomotive varies with speed at any given firing rate. At a fairly definite operating speed, the output and the over-all efficiency reach a maximum. If this maximum efficiency is definitely limited, the locomotive then has a definite power rating and a corresponding rated speed. The over-all effi-

[15] Electrical Engineer, New York, New Haven and Hartford Railroad Company, New Haven, Conn. Mem. A.S.M.E.

ciency can be divided into two components, that due to boiler and that due to cylinders. With the cylinder efficiency fairly fixed at the rated speed, the boiler efficiency must have a definite value corresponding to a definite firing rate. Therefore in stating the rated output of a steam locomotive it is necessary to qualify this with a definite over-all thermal efficiency corresponding to that specified or desired in normal operation.

Mr. Fry refers to Equation [10] as rating critical attention. Evidently his misunderstanding of this equation is due to his misinterpretation of the symbol h_{pt}. The symbol h_{pt} for performance rating is not stated as "the horsepower available at a given speed and therefore varies with the speed." The definition of h_{pt} is actually stated as a numerical coefficient q multiplied by the rated horsepower per ton $(H_{PR})_t$ including both train weight and locomotive, and q is a correction factor for different power characteristics with allowance for train auxiliaries. Obviously the performance of a locomotive over a given schedule depends not only upon its rated power but also on the actual power developed at speeds other than its rated speeds which occur in a given schedule. Therefore, in comparing locomotives relative to their performance over some given schedule, a locomotive with unfavorable power-speed characteristics requires a higher rated power than a locomotive of more constant horsepower characteristics. For this reason a correction factor q is necessary to apply to the rated power when comparing locomotives of different power characteristics to account for the same performance in any given schedule. The correction factor, therefore, depends not only on the particular locomotive power characteristics but also on the nature of the schedule to be met. The author assumes, only as an example, that a typical schedule may require a rating of 4 hp per ton for steam and 3.5 hp per ton for Diesel-electric locomotives. The symbol q is a ratio, so that h_{pt} maintains the unit of horsepower per ton. The variable V for speed is not included or implied. Further consideration will show that Equation [10] has more significance than an identity since the rated power is stated in terms of basic parameters, which are (1) the weight of the train to be hauled, (2) the performance rating h_{pt}, and (3) the weight-power ratio $E\ (1 + k)$. It is hoped that Mr. Fry's apparent confusion of units in Equation [10] will be clarified by these remarks.

In the analysis of train performance, it is important to note that the power is measured at the drivers, so that over-all efficiencies are not considered directly. The power developed at the drivers is analogous to the brake output of an engine or motor. From a performance aspect, the effect of over-all efficiencies is to modify the weight efficiency of the locomotive $E(1 + k)$ which has been taken as a basic parameter in the analysis. The effect of variation of efficiency with speed is taken into consideration by the power-speed function. Except for balanced top speeds, possible reductions in train resistance due to better streamlining are of small order compared with inertia resistance to acceleration and grade resistance that usually occur in operating schedules. Even the balanced speed, where the tractive force balances the total train resistance, i.e., the particular speed at which the curve of tractive force crosses the train-resistance curve, is more influenced by variation of the tractive force and therefore the horsepower per ton available than by any possible reduction in train resistance. Therefore the author cannot sustain Mr. Fry's objection raised in his second and third paragraphs.

In conclusion the author is in agreement that actual performance data would be helpful in clarifying the presentation on ratings.

Mr. Kimball's discussion is of particular interest in that the work of Subcommittee No. 1, Economics of Railway Location and Operation,[9] American Railway Engineering Association parallels the author's work in certain phases of the paper. While the units and ratios for comparison differ, the agreement for estimated performance is close.

For example, in Mr. Kimball's discussion it is interesting to compare Fig. 13, for calculating the horsepower output of typical steam locomotives, and item 8, that is $V_1 = 0.396 \times$ horsepower per ton on drivers, with the author's discussion pertaining to Fig. 4. V_1 corresponds to the limit speed in the drag zone, where $V_1 = \gamma_D V_R$ according to the author's symbols. In a first approximation the author has assumed for steam locomotives, $\gamma_D = 0.25$, that is $^1/_4$ of the rated speed V_R.

With the starting tractive force sustained to the end of drag speed, then $Z_i = \mu A$ where $\mu = 0.25$ = the coefficient of friction, and A = weight on drivers in pounds. But $Z_i = \phi Z_R$ where ϕ varies from 2 to 2.3. Assume that $\phi = 2.1$. Then

$$\text{horsepower} = \frac{Z_R V_R}{375} = \frac{Z_i}{\phi} \times \frac{4V_1}{375}$$

$$\therefore \text{horsepower} = \frac{\mu A_t \times 2000}{\phi} \frac{4V_1}{375} \text{ and}$$

$$\frac{1}{V} = \frac{375\phi}{4\mu \times 2000} \frac{\text{horsepower}}{A_t}$$

With $\phi = 2.1$ and $\mu = 0.25$, $V_1 = 0.393 \times$ (horsepower per ton of weight on drivers).

With the Diesel-electric locomotive, the author uses $\gamma_D = 0.2$, so that the rated speed is 5 V_1. Mr. Kimball uses $\mu = 0.3$ for this type due to uniform torque. The torque amplification ϕ, therefore, on the basis $V_1 = 0.395 \times \text{hp}/A_t$, is $\phi = 3.16$.

This is somewhat less than the value used by the author. With high-speed road locomotives 3.5 is not excessive due to the short time period of overload current, whereas in switcher service ϕ may be as low as 2.5. A value around $\phi = 3.0$ appears a nominal average value for starting tractive amplification for Diesel locomotives relative to their continuous rated output.

Mr. Kimball gives the speed range V_m of steam locomotives as approximately $6V_1$. With $V_1 = 0.25V_R$, then $V_m = 1.5V_R$, which agrees with that used by the author in Fig. 4. It is to be noted that the ratio of power to rated power is estimated, at the end of the drag-speed range $V_1 = 0.25\ V_R$, at 0.528, which is in close agreement with the author's value in Fig. 4.

Referring to Fig. 12 for performance of Diesel-electric locomotives, the speed range is $14V_1$. In the author's Fig. 5, the speed range $V_m = 2.5V_R$. With a drag speed $V_1 = 0.2\ V_R$, then $V_m = 5 \times 2.5V_1$, a value somewhat less than used by Mr. Kimball.

Next consider Table 1 for obtaining approximate horsepower capacities for typical steam locomotives based on horsepower per ton on drivers. To obtain the actual horsepower it is necessary to consider the percentage of weight on drivers. In the author's analysis he has disregarded *types* of steam locomotives and has used the weight ratio (weight per horsepower E) of the locomotive with an additional term K to account for the tender weight relative to the locomotive weight. A basic ratio E independent of the type of steam locomotive can be further justified by referring in Mr. Kimball's table to the values, hp/A_t = horsepower per ton on drivers and C = ratio of weight on drivers to weight of engine. In Table 2 are listed the first and third columns of Mr. Kimball's Table 1, together with values of E, $E(1 + k)$, and K for different types of locomotives.

From these values, E = weight-power ratio for the locomotive alone appears fairly constant and independent of the type. Tender-weight ratios are approximately three quarters of the engine weight while $E\ (1 + k)$ = over-all weight-power ratio, range from 175 to 200 lb per hp.

The rating of a steam locomotive depends upon a normal firing

TABLE 2

C	HP/A_i	Type	E	$E(1+k)$	K
0.45	39.2	4-4-4	114	204	0.78
0.54	35.4	4-6-4	105	186	0.77
0.62	32.0	4-8-4	101	177	0.75
0.70	28.6	2-10-4	100	174	0.74
0.77	25.7	2-10-2	101	176	0.74
0.84	22.7	2-10-2	105	182	0.73
0.92	19.4	2-10-0	113	195	0.73
1.00	16.0		125	218	0.75
0.69	25.3	4-6 + 6-4	114	175	0.54
0.75	23.5	2-6 + 6-4	114	180	0.58
0.80	22.0	2-8 + 8-4	114	184	0.61
0.90	19.0	2-8 + 8-2	117	197	0.67

rate. Mr. Fry assumes the boiler efficiency to vary as a straight line against firing rate, and arrives at a parabolic curve for the evaporative capacity. These assumptions are justified from numerous tests. If x = firing rate, then the efficiency $E_B = (c - mx)/100$, the evaporation is $E = K[(cx - mx^2)/100]$, and $dE/dx = 0$; $x_{max} = c/2m$.

$$\therefore \frac{E}{E_{max}} = \frac{cx - mx^2}{c^2/4m}$$

If the normal firing rate is $x = kx_{max} = kc/2m$ then, $E = (2-k)\,kE_{max}$.

With $k = 0.5$, then $E = 0.75\,E_{max}$. If $k = 0.66$ then $E = 0.89\,E_{max}$. This shows that firing rates exceeding 50 per cent of the maximum rapidly approach the maximum evaporative capacity of the boiler. For this reason Mr. Kimball's committee's choice of a firing rate at 50 per cent of maximum corresponding to 75 per cent of maximum boiler capacity appears to be a good design value for the normal rating of a boiler.

On the basis of normal evaporation of the boiler, the performance of a locomotive then depends upon the cylinder efficiency, measured by the steam consumption per horsepower = hour h. The value of h varies with cutoff and speed, reaching a minimum at around 20 or 25 per cent cutoff. Since hp $= E/h$ and E is maintained nearly constant at the higher speeds, while h decreases to a minimum at rated speed, therefore the output reaches a maximum. With increasing speeds h increases, thus resulting in a falling off in power in the overspeed zone. For this reason there must be some falling off in power in this zone. Mr. Kimball's assumption of a constant cylinder output with a constant normal boiler capacity appears inconsistent with actual cylinder performance with a constant steam supply.

Mr. Withington raises the point that the slope of the power curve at low speeds should be the same in Figs. 6 and 5 since the permissible overload torque should be approximately the same for both Diesel- and straight-electric locomotives. This is true and, as a matter of fact, identical motor characteristics were used, though the former is on variable voltage at the high speeds, since EI = const, and the latter approaches a constant line voltage. Mr. Withington perhaps is confused by the different scales for both power and speed used in these figures. Thus the power-curve slope at low speeds for either Fig. 5 or Fig. 6 is approximately $^{0.80}/_{0.25} = x/\gamma$, where x = per cent of rated horsepower and γ = per cent of rated speed. The tractive force for any speed γV_R (where V_R is the rated speed) corresponds to the horsepower xH_{PR} (where H_{PR} is the rated horsepower). For the low speed range, the tractive force is, $Z = 375xH_{PR}/\gamma V_R$. But the rated tractive force is $Z_R = 375\,H_{PR}/V_R$. Therefore, the tractive-force amplification is $\phi = Z/Z_R = x/\gamma$ = (overload capacity of motors in starting zone). The value of x/γ in the low speed range, is practically the same in Figs. 5 and 6.

Discussion

Experiments and Calculations on the Resurge Phase of Water Hammer[1]

F. KNAPP.[2] Before commenting on the details of computations used by the author, the writer wishes to state that the type of surge discussed in the paper is only the simplest case of certain surge phenomena not yet investigated by the usual water-hammer theory.

Suppose, for example, a penstock with a projecting point as shown in Fig 1 of this discussion. Suppose further that the valve at the lower end of the penstock is opened very quickly, producing a "primary" surge drop of appreciable magnitude. This drop wave travels up the line until it intersects the zero-pressure line at section X. As the pressure in the pipe cannot fall below zero, the question arises regarding the behavior of the wave between section X and the intake. In the following discussion, this type of surge will be called type A.

Another case, type B, is represented by a primary surge rise with a steep or vertical wave front and of such magnitude that the negative secondary wave, reflected totally at the closed valve, cuts the zero-pressure line similarly as in the type-A surge.

Another case, type C, is produced by a primary surge drop such as shown in Fig. 1 of this discussion. At section Y the angle γ of the surge-drop face is smaller than the angle α of the lower portion of the penstock, but greater than angle β of the upper part.

Another case, type D, is analogous to type C with the exception that the primary surge is not a drop, but a pressure rise.

Following up the pressure and velocity conditions in the pipe line, it will be noted that only the surges of types C and D represent conditions capable of graphical analysis. In the case of type C, a vacuum is formed at section Y and the water column is separated into two independent columns. The lower column soon attains a steady state, depending on the gate movement, and all pressure waves traveling in the portion are reflected totally and with negative sign at the cavity and partially at the open gate. Consequently, the pressure and velocity conditions at section Y are known at any time.

A similar process takes place in the upper column. That part of the primary surge drop transmitted to the upper part of the line before the column broke is reflected totally and with negative sign both at the intake and at the cavity, thus accelerating the water column. If C_{1t} denotes the velocity of the lower column at section Y, and C_{2t} denotes the velocity of the upper column at the same place, then the two columns reunite when

$$\int C_{1t}dt = \int C_{2t}dt. \quad \ldots\ldots\ldots\ldots [1]$$

At the instant of the reuniting of the two columns, the velocities C_{1t} and C_{2t} are thus known. As the surge produced is proportional to the instantaneously destroyed velocity, the magnitude of the resulting pressure rise can be computed easily. Computations carried out for this type of surge revealed these pressure rises to be of surprisingly great magnitude, but of short duration in most practical cases due to the proximity of section Y to the forebay of the surge tank.

Type-C surge has great practical importance, and by it can be explained many penstock failures caused by surges of so-called "obscure origin." It is a well-known fact that the pressure distribution in the upper part of the penstock due to repeated but small movements of the governor is far from being linear but is in a curious manner approaching the distribution of surges with steep wave faces of the rapid type. Most penstock ruptures are also caused in the upper part of the line and cannot be explained by surges starting at the gate, since these pressure rises would first have broken the most-stressed lower part of the line. The events of irregular surge-drop distribution together with projecting angles of the penstock, causing surges of type C, are thus the natural explanation of such accidents.

Little is known about surges of types A and B, which at present can be fully investigated only experimentally. Gibson[3] investigated curves of type-A surges and made the following statement: "Where the pipe slopes upward toward its inlet, so that beyond a certain point in its length the absolute statical pressure is less than the drop in pressure caused at the valve by sudden opening, then on the passage of the first wave of negative pressure the wave motion becomes partially discontinuous after this point is reached and the wave travels on to the inlet with a gradually

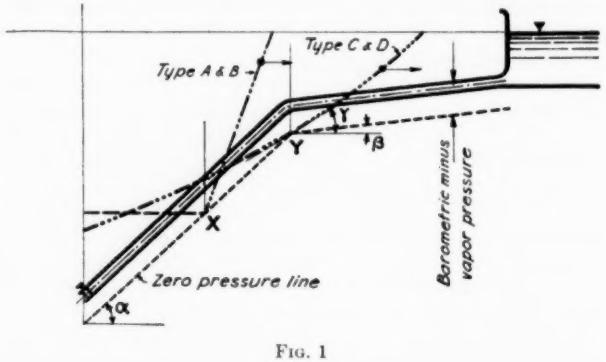

FIG. 1

diminishing amplitude. The amplitude with which it reaches the intake, and which will be probably 2 or 3 lb per sq in. less than the absolute statical pressure at the inlet, decides the state of velocity of the reflected wave. This will evidently be less than the preceding case, and under such circumstances the wave motion dies out very quickly. As the valve opening becomes greater, the efficiency of the valve as a reflecting surface becomes less, so that with a moderate opening the pressure may never even attain the pressure due to the statical head." It is to be hoped that the hydraulic laboratory at the California Institute of Technology will extend the study of water hammer to the surge types outlined in this discussion.

The author performed his calculations assuming incompressible water and rigid pipe walls. Nevertheless, his computed results compare extremely well with the experimental data. Of course, the coefficient C for the initial velocity with which the water starts away from the valve has been taken from test results.

Application of the elastic-column theory to the author's case shows that the starting and recoil velocities do not decrease and

[1] Published as paper HYD-59-12, by Joseph N. LeConte, in the November, 1937, issue of the A.S.M.E. Transactions, vol. 59, p. 691.

increase steadily as assumed by the rigid-column theory, but increase or decrease in steps corresponding to the reflection time of the penstock. While the author's formula for the case treated, namely, instantaneous closure, is relatively simple, it would become quite complicated or laborious for the case of a finite closing time.

Computations made by the writer based on data given in the paper gave the results shown in Table 1 of this discussion for the time t_1 of test No. 5*A* on the 2-in. line.

Although the elastic-column theory, with friction losses considered concentrated at the intake, gives results well within the precision of engineering calculations, the rigid-column theory furnished surprisingly closer results. The writer attributes this fact to the surge velocity taken as 4765 fps from test No. 4*A*. Also, the value of atmospheric pressure minus vapor pressure of water has been assumed to be 33 ft. A type of surge similar to that discussed by the author occurs sometimes in low-head pumping installations and therefore is of practical interest. The test results presented also do away with the opinion held by some engineers that the recoil of the water column takes place completely as soon as the wave reflected at the intake arrives at the gate. Basing his deductions on the elastic-column theory, the writer expected the behavior of the water column to be the same as shown by the author's experiments, and is glad to have the experimental confirmation.

TABLE 1 RESULTS FOR TIME t_1 OF TEST NO. 5*A*

	Difference between observed and computed time, per cent
Rigid-column theory (LeConte)	− 1.13
Elastic-column theory:	
Friction neglected	+16.38
Friction assumed concentrated at intake	− 4.85
Velocity V_0 = 2.707 fps	− 3.64

(The following discussion was submitted jointly with the discussion of the paper by Lorenzo Allievi.[4] For the complete discussion of the latter paper see pp. 445–450 of this issue.)

Louis Bergeron.[5] Several of the papers presented at the Second Symposium on Water Hammer referred to the graphical method of calculation for water hammer. The general equations are essentially the same as those utilized for analytical determinations of water hammer, but the various relations can be expressed graphically rather than by means of involved equations.

Numerous presentations of the graphical methods have been made in French and German, and quite recently the writer published a complete demonstration of the graphical method as applied to water hammer and surge phenomena.[6]

The general expressions for water hammer developed in the demonstration cited have a physical significance which may be expressed as follows: For an observer traveling along the pipe at a speed $\pm V_w$, the pressure H, plotted as a function of the velocity V, is always found on the straight line passing through the point characteristic of the regime existing at the time and place of his departure, and of angular coefficient tan $\gamma = \pm (V_w/g)$. This is a general law, whatever be the plane waves F and f, or their values, even if they have the particular value zero (viz., during the initial permanent regime), for then the regime is represented by the same point of the line. Likewise, the law is universal, being valid for all homogeneous mediums in which the variation of regime is propagated by plane waves.[6] Thus, it may be employed to study the transverse movements of a stretched cord, the longitudinal movements of a metal bar, the variations of regime in canals (within the limit of changes in level that are small as compared to the depth), transients in electric lines, etc.

Whatever the phenomenon to be studied, this simple relation permits one literally to follow it by the eyes of fictitious observers who travel the course of action from one extremity of the medium to the other, and to reconstruct it by means of a graph which corresponds rigorously to the realization, at slow speed, of the physical course studied.

Water Hammer With Cavitation During the Resurge Phase

Let us apply this reasoning to the problem solved graphically by Le Conte.[1] In order to find a graphical solution taking into account the head loss, this loss will be considered as concentrated at a single point close to the reservoir, as shown in Fig. 2 of this discussion. It should be noted that if one desired to know exactly the regimes at various points along the pipe it would be necessary to divide the total loss among several points between *A* and *B*.

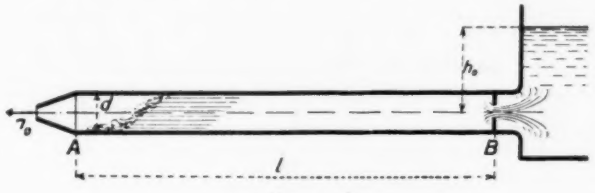

Fig. 2

In Figs. 3*a*, 3*b*, and 3*c* of this discussion, H_0 is the geometric head; H_{atm} is the head corresponding to atmospheric pressure; ψ_0 is the parabola $H = kQ^2$, relating the pressure at *A* to the discharge when the orifice is fully open; *MN* is the parabola giving the pressure at *B*, downstream of the constriction which has been calculated to create a loss of head equal to the friction loss from *A* to *B*. When the discharge is negative the pressure at the same point *B* is given by the parabola *MN'*, whose ordinates are the same as those of *MN* but with their sign changed. If the velocity head $V^2/2g$ is not negligible it should be added to the ordinates of *MN*, *MN'* remaining the same. This follows from the fact that with flow in the sense from *B* to *A* there is a negligible entrance loss in the pipe, but with flow in the opposite direction there is an exit loss (loss of kinetic energy) equal to the velocity head.

Start with the intersection O_A of ψ_0 and *MN*, shown in Fig. 3*a* of this discussion, which is the point characteristic of the initial permanent regime. For an observer leaving *B* during this regime, the characteristic line is O_AP, making with the horizontal the angle $\gamma = \tan^{-1}(V_w/gA)$. If he arrives at *A* at the exact instant of closure (which is assumed to be instantaneous) the function ψ_A is then the axis of the ordinates and the point characteristic of the regime is O_A' at the intersection of this axis with O_AP. The regime has passed instantaneously from O_A to O_A' and the excess pressure is represented by $\overline{MO_A'}$. The observer returning to *B* sees the line $O_A'1_B'$ (as yet unlimited in length) and, upon his arrival at the diaphragm constriction at the time $l/V_w = 1$ the regime point will be $1_B'$, at the intersection of *MN'* and this line.

Retracing his route the observer sees the characteristic line $1_B'=2_A'$ (as yet also unlimited). He arrives, at time 2, at *A* where the orifice is still closed, and since the pressure may only decrease to $-H_{atm}$, i.e., absolute zero, the function ψ at this time and place will be the horizontal line of ordinate $-H_{atm}$, and the characteristic point will be $2_A'$. This also shows that

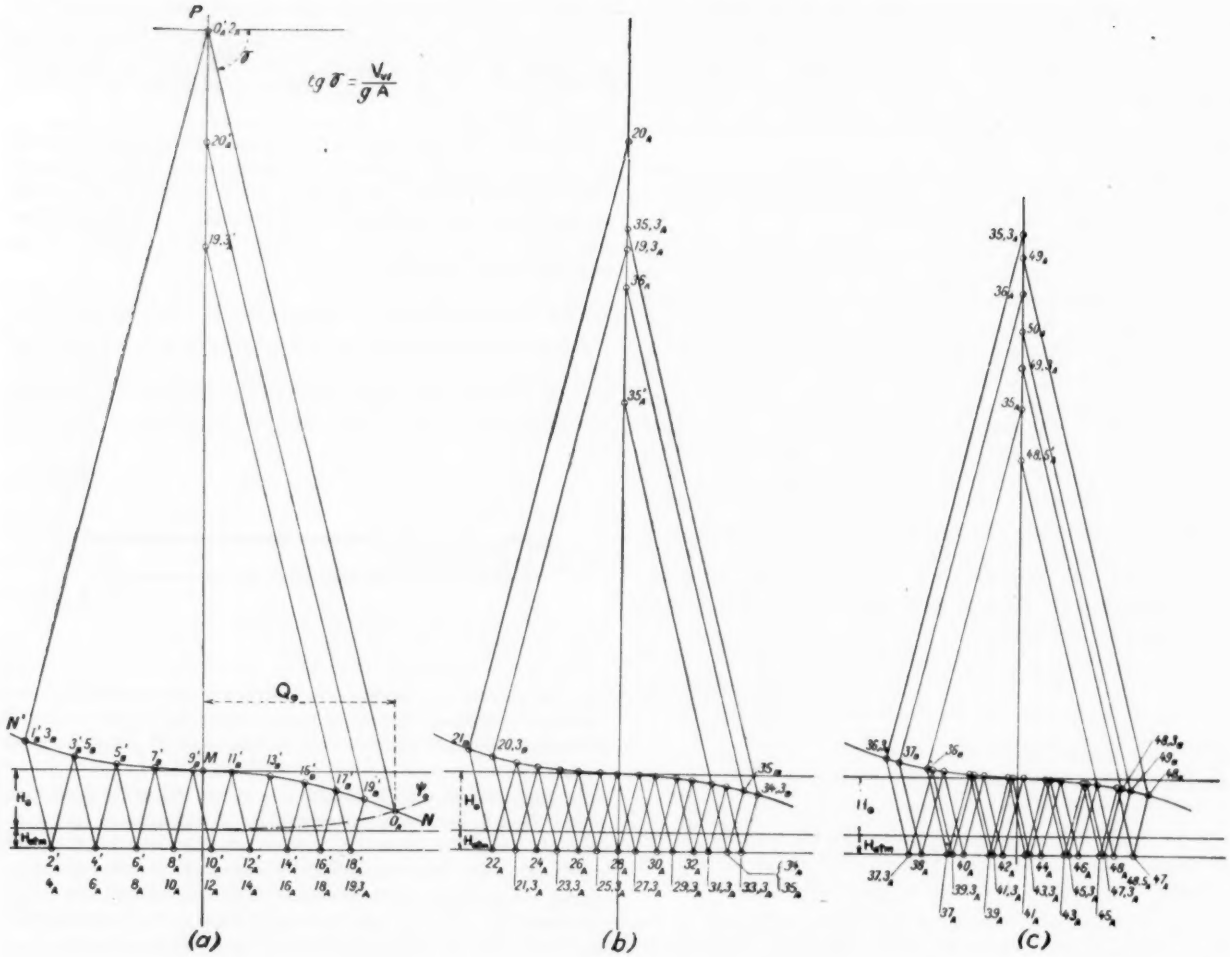

FIG. 3

the reversed flow will be equal to the abscissa of this point and is of such magnitude as to cause a cavity to form at A. Henceforth the traverses of the observer between A and B will trace the broken line $2_A'$, $3_B'$, $4_A'$, ... $17_B'$, $18_A'$, $19_B'$, whose termini are alternately on the horizontal $-H_{atm}$, at A, and $N'MN$, at B. One sees that the discharge decreases in A then recovers its initial sense, closing the cavity. By constructing the discharge curve, shown in Fig. 4 of this discussion, one easily calculates that the closure takes place at time 19.3 on a discharge given by the point $18_A'$. For an observer arriving at B exactly at this instant, the excess pressure of this discharge will give the regime point $19.3_A'$ on the ordinate axis. But first the observer, who leaves B at the time 19, seeing there the regime $19_B'$, arrives at A at the time 20 where he finds no discharge, i.e., the regime point $20_A'$ on the axis. Therefore, one sees that at A from the time 19.3 to the time 20, the pressure is the ordinate $19.3_A'$, and then it is that of $20_A'$ from the time 20 to the time 21.3, at which latter time the cavity starts to form again, as shown in Fig. 3*b* of this discussion.

Thus, from the fact that the period of oscillation of the discharge at A is not an exact multiple of $2l/V_w$, the excess pressure of the successive shocks presents an increasing series of peaks. Here is found the explanation of one of the causes of the harmonics that are seen in Fig. 5 of this discussion, which is taken from a paper by Langevin. This example also shows the precision with which the graphic construction reproduces the actual phenomenon.

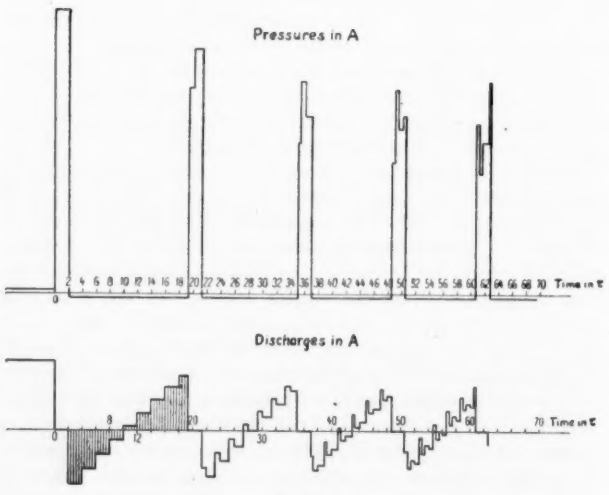

FIG. 4

AIR RESERVOIRS

Figs. 6 and 7 of this discussion relate to Allievi's numerical example *b* given on page 655 of his paper,[4] the results of which example are given in column *B* of Table 4 of the paper.[4] The numerical values given correspond to $v_0 = 1$ m per sec, $V_w = 1000$

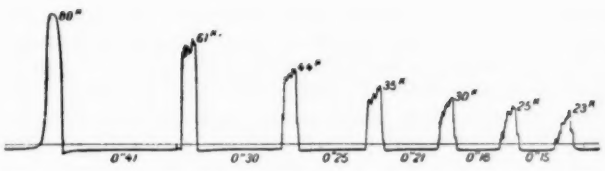

FIG. 5

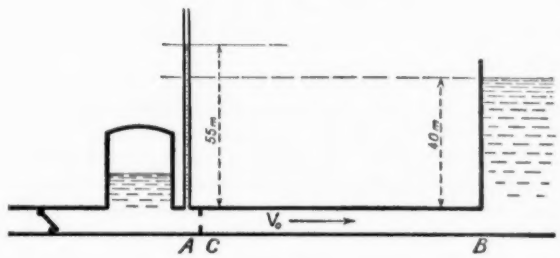

FIG. 6

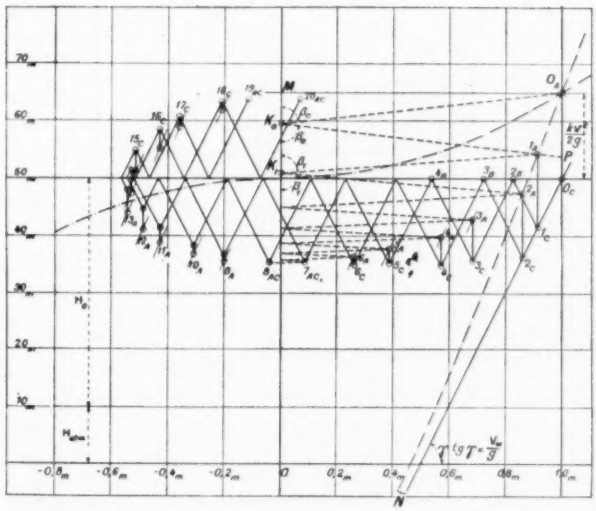

FIG. 7

m per sec, and $2g = 20$ m per sec per sec. Volume C_0 is the same as in Allievi's example *a*, where $H_0 = 50$ m, and $\sigma = 5$. To determine C_0 start with $\sigma = 5 = (1000\ C_0H_0)/W_0$ and $W_0 = 1000\ LA(v_0^2/2g)$, which gives

$$C_0 = \frac{5 \times 1000 \times (1^2/20)LA}{1000 \times 50} = 0.005\ LA$$

or, for example, for $LA = 2500$ cu m, $C_0 = 12.5$ cu m.

In Fig. 7 of this discussion let the abscissas be v to avoid distinguishing L and A in the product LA, and choose, for the time j, a fraction $1/n$ of $2l/V_w$. Then

$$\frac{v_T''' + v_{(T-j)}'''}{h'''} A = \frac{2C_T}{[(H_T''' + H_{atm}) + h'''](2l/nV_w)} \quad \ldots [2]$$

and

$$\tan \beta = \frac{C_T}{(H_T''' + H_{atm}) + h'''} \frac{nV_w}{LA} \quad \ldots\ldots [3]$$

Further, the volume $C_{(T+j)}$ becomes

$$C_{(T+j)} = C_T - \left(\frac{v_T + v_{(T+j)}}{2} Aj\right) = C_T - v_{mean}\left(\frac{2LA}{nV_w}\right) \ldots [4]$$

Fig. 7 is drawn with $V_w = 1000$, $LA = 2500$, and $n = 2$, for which $nV_w/LA = 0.8$ and $2LA/nV_w = 2.5$. The plan of the installation is shown in Fig. 6 of this discussion, B being the reservoir with water level at 40 m. The loss of head of 15 m, distributed between A and B, will be assumed as concentrated at a constriction placed at A. The air reservoir will thus have a piezometric head of $40 + 15 = 55$ m, and will be under an absolute pressure of $H_0 = 55 + 10 = 65$ m. The initial permanent regime in A is shown in Fig. 7 of this discussion by the point O_A, and in C by the point O_C. The time $j = l/V_w$ is taken as unity.

For an observer leaving B at time 0, while the regime there is still that of point O_C in Fig. 7, the characteristic line is O_CN, whose angular coefficient $\tan \gamma = V_w/g = 1000/10 = 100$. If the observer passes the constriction, the pressure increases by $15v^2$, which results in the parabola O_AN of the pressure variation in A.

A fictitious observer who leaves A at time 0, goes to the surface of the reservoir and returns at time 1, sees upon his leaving A a line O_AK_0, and on his return sees a line K_01_A, which makes an angle β_0 with the vertical, where, following Equation [3] of this discussion

$$\beta_0 = \tan^{-1} \frac{C_0}{(H_0 + H_{atm}) + h_0} 0.8$$

or, in estimating $h_0 = 11$ m, $\tan \beta_0 = [12.5/(65 - 10.5)]0.8 = 1/5.4$, which means that for $\overline{O_AM} = 1$ m, one has $\overline{MK_0} = 5.4$. This allows one to draw O_AK_0, then, since $\overline{O_AP} = 2 \times 5.4 = 10.8$ m, K_0P may be drawn, whose intersection with the parabola O_AN gives the point 1_A (of the regime in A at the time 1) sought, and, on the same vertical, the point 1_C of the regime C at the same time.

For an observer leaving B at the time 1, the regime there is still given by the point O_C and the characteristic line is still O_CN in C (changing to the parabola O_AN in A at time 2). But the observer traversing the reservoir sees the lines whose angle is now β_1, determined, in estimating h_1 as 7 m by

$$\tan \beta_1 = \frac{C_0 + (v_{mean} \times 2.5)}{54.5 \times 7} 0.8 = \frac{12.5 + (0.945 \times 2.5)}{47.5} 0.8 = \frac{1}{4}$$

From the point 1_A draw a horizontal equal to 1 m, then a vertical equal to —4 m, join the point obtained with 1_A and thus find the point K_1; repeat the construction starting from point K_1 and draw the line K_12_A, locating 2_A (the point sought) at its intersection with the parabola O_AN, and the point 2_C at its intersection with O_CN.

To find the regime in A and C at the time 3, consider again the first observer who found point 1_C; in going to the reservoir B he sees the line 1_C2_B (as yet unlimited) and on arriving at B finds the characteristic point 2_B at the intersection of this line and the horizontal which represents, in terms of absolute pressure head, the constant level of the reservoir B. Coming back to C he arrives there at time 3, seeing the line 2_B3_C (as yet unlimited) and passing the constriction he notes this line augmented by the head loss $15v^2$. There he meets the observer of the air

TABLE 2

	Z_i	V_i	K_i
1	0.73	0.850	0.16500

reservoir for whom the lines have been drawn with an angle β_2, determined, in estimating $h_2 = 4.5$, as

$$\beta_2 = \tan^{-1} \frac{14.86 + (0.88 \times 2.5)}{47.5 - 4.5} 0.8 = \frac{1}{3.15}$$

These lines give the points 3_A and 3_C. The construction of the graph shown in Fig. 7 of this discussion is continued in this manner.

The points 2_A, 4_A, 6_A, etc., correspond to the times of "whole rhythm," and permit the construction of Table 2 of this discussion, established following Allievi's[4] notation.

One sees that, due to the bead loss in the pipe, there is no excess pressure at the time of the backflow. However, head losses as high as the one in the writer's example are rare; for example, if $LA = 2500$ was obtained with $L = 2000$ m and $A = 1.25$ sq m, the head loss would be only about 2 m instead of 15 m, and the air reservoir of 12.5 cu m would permit the attainment of a very high surge pressure (found in Fig. 8 of this discussion) which was made for the case of zero head loss and which corresponds to Allievi's example *a* (page 655 of the paper[4]), the results of which are given in column *A* of Table 4 of the paper.[4] However, this condition may be avoided by the use of the following artifice, previously advised by Comte de Sparre and analogous to that indicated many years ago by Johnson for surge-tank use.

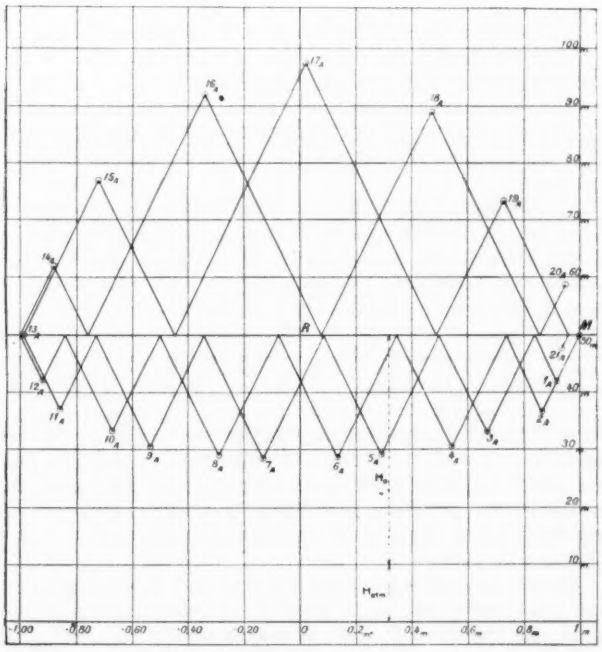

FIG. 8

The air reservoir on the pipe is fitted with a constriction as shown in Fig. 9 of this discussion. As nearly as possible this constriction is constituted of a nozzle whose coefficient of discharge, in an emptying sense, is 1, and in the sense of filling flow is 0.5; in other words, for the discharge at equal rates in the two directions the head loss is four times as much for filling flow as for emptying flow. The writer has used this artifice for ten years in installations at Rouen, Dieppe, Clermont-Ferrand, and other places in France.

Suppose now the instantaneous closure of a valve at time 0. For the observer arriving at *C* from *B* at this time the characteristic line is *MN*, in Fig. 10 of this discussion, passing through the point *M* of the initial regime. If the observer passes the constriction, its head loss is added to the line, resulting in the parabola *PN*. As the pressure in *A* could not change instantaneously, the regime point O_A will be at the intersection of this parabola and the horizontal *MR* of ordinate $(H_0 + H_{atm})$. On the same vertical, at its intersection with the line *MN*, the point O_C will be the regime point in *C* at the time 0. One sees that the velocity as well as the pressure both fall rapidly at *C*.

For the observers arriving at *C* just at the time 2, the characteristic line remains *MN*, and in *A* the parabola remains *PN*. Calculating tan β_1 and tan β_2 as before, one finds the points 1_A, 2_A, and 1_C, 2_C.

But the observer leaving *C* at time 0, i.e., point O_C, arrives again in *C* at time 2 and sees there, as the characteristic line, the line $1_B N_2$; then, passing the nozzle, he sees the parabola $P_2 N_2$. However, the pressure in *A* at time 2 (point 2_A) not being able to change, the regime point for this observer will therefore be $2_A'$ on the horizontal through 2_A and the parabola $P_2 N_2$. Thus, at the time 2 the velocity varies rapidly at *A*, and both the velocity and the pressure vary rapidly in *C*, due to the return of the wave leaving at time 0.

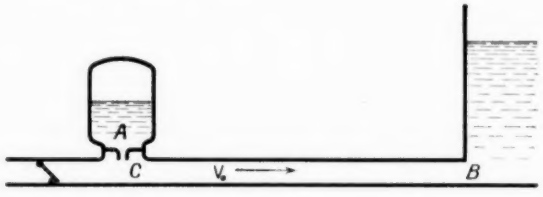

FIG. 9

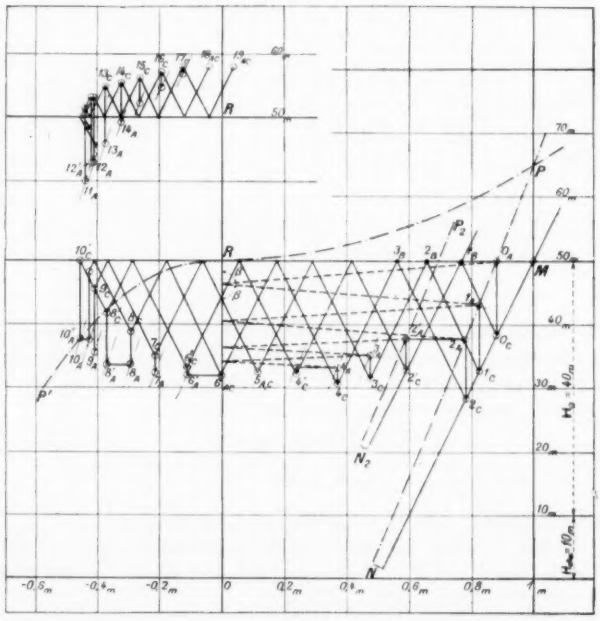

FIG. 10

Fig. 10 continues as before with the exception that at every "whole rhythm" one has anew a rapid jump with all the corresponding regime points doubled, as $4_A4_A'$, $6_A6_A'$, ... and $4_C4_C'$, $6_C6_C'$, $8_C8_C'$, etc. It is seen that the pressure ratio is only 1.15 in place of 1.95, the maximum pressure thus being very much lower; yet, note also that the maximum depression, obtained at 2_C, is only 0.57, which ratio is exactly the same as that for the air chamber without a nozzle. This nozzle arrangement is therefore not only interesting but it is indispensable—

the simple addition of the constriction, without creating a greater vacuum in the pipe, divides the surge pressure by six; in other words, it has the effect of a much larger air reservoir. It is easy to determine, for a given reservoir, the optimum value of constriction for a minimum pressure increase in the pipe by making several graphs similar to Fig. 10 of this discussion and constructing tables and curves of the results.

Table 3 of this discussion, the values in which were taken from the writer's graphs, has the same notation as Allievi's[4] Table 4 to facilitate their comparison.

Very Small Air Pocket in a Pipe

It has often been said that a very small air pocket in a pipe is extremely dangerous. The graphical method described by the writer enables one to investigate easily this question.

Suppose in the preceding case, rapid stoppage of discharge occurred with a very small air reservoir on the pipe, as shown in Fig. 11 of this discussion. For the observer leaving B at

TABLE 3

Column A, Allievi's Table 4[a]			Reservoir with constriction		
i	Z_i	V_i	i	Z_i	V_i
1.0	0.735	0.855	1	0.570	0.775
2.0	0.610	0.535	2	0.610	0.365
3.0	0.570	0.130	3	0.640	0
4.0	0.575	−0.285	4	0.775	−0.290
5.0	0.660	−0.665	5	0.965	−0.425
6.0	0.840	−0.915	6	1.065	−0.410
7.0	1.240	−0.875	7	1.110	−0.325
8.0	1.840	−0.340	8	1.140	−0.195
8.5	1.950	0.020			
9.0	1.780	0.465	9	1.150	−0.040

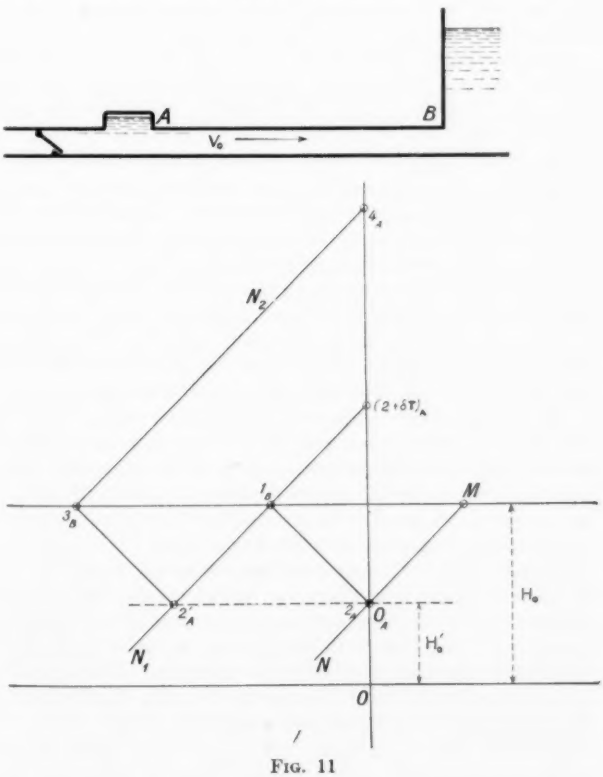

Fig. 11

the time −1 the characteristic line is MN, also shown in Fig. 11. Upon his arrival at A he finds the discharge zero, giving the regime point O_A (the small air pocket having expanded instantaneously in the ratio H_0/H_0' by reason of its very small volume), this regime existing just to the time $2l/V_w$. At this instant, the observer who left A at time 0 arrived in B at time 1 (finding the regime 1_B), returned from B seeing the line 1_BN_1, and arrived again in A. Upon his arrival, the pressure in A being H_0' exactly (because of the air pocket), the regime point will be $2_A'$ with a reverse flow equal to $\overline{O_A2_A'}$. This condition will last only an extremely short time because, of the small volume of the air pocket, which, being compressed will annul the discharge and will result in the regime point $(2 + \delta T)_A$ at the time $(2 + \delta T)$. But for the observer leaving A precisely at the time 2 the characteristic line passes through $2_A'$ and gives the regime point 3_B in B at the time 3; upon his return he sees the line 3_BN_2, but this time upon his arrival at A he will find the flow zero, giving the regime point 4_A which determines the maximum surge pressure. This maximum exists only during a time less than δT, but, as shown in Fig. 11 it is equal to $3v_0V_w/g$ or triple the pressure increase obtained when there is no air pocket.

Such is the maximum surge pressure which is approached as the volume of the air pocket diminishes; but, fortunately the conditions which permit the velocity $\overline{O_A2_A'}$ to exist throughout the pipe are rarely realized, so that the maximum is likewise rarely attained.

Author's Closure

The author is greatly indebted to Mr. Knapp and to Professor Bergeron for their discussion of his paper on "The Resurge Phase of Water Hammer." They have given a broader view of the problem, and have furnished other important methods of attack. The author's idea when the work was first taken up at the University of California was to work out a reasonable analytical solution, and back up this theory with laboratory tests. It is obvious that the recoil coefficients C have been obtained from the experimental record, but it is of interest to note that this coefficient is a constant for a given pipe line for all velocities within the range of the experiments. The problem is a most interesting one and the author hopes that similar work can be carried on at the University laboratories using pipes of different sizes and lengths.

Air Chambers for Discharge Pipes[1]

E. E. Halmos.[2] The writer wishes to call attention to a typographical error in the formula at the top ot page 653 which is confusing and requires correction. The expression referred to should read as follows:

$$\int_0^{i-1} V\partial t - 2\int_0^{i} V\partial t + \int_0^{i+1} V\partial t = \frac{C_0}{S} \cdot \left(\frac{1}{Z_{i-1}} - \frac{2}{Z_i} + \frac{1}{Z_{i+1}}\right)$$

M. A. Mason,[3] P. Danel,[4] and A. Craya.[5] Following a practice which he initiated in his 1913 paper,[6] the author

justly employs and stresses the importance of the use of dimensionless parameters in solving this problem and others connected with water-hammer studies. As in most of the cases arising in the applied sciences, the choice of the parameters to be used requires some care. A general study such as the author has made, involving the influence of certain factors, may require an entirely different choice of dimensionless variables if the effect of other factors is to be considered. It may be stated here that the author's use of the dimensionless parameter $\sigma\rho$ in his equations is exactly paralleled by Bergeron's use of the term

$$\tan \beta = \frac{C_T}{[(H_T''' + H_{atm}) + h'''](j/2)}$$

for if the coordinate axes of Bergeron's graphs are made nondimensional then $\tan \beta = C_0 V_w / A L v_0$, which is seen to be exactly the same as the author's $\sigma\rho$.

Unfortunately the equations given by the author for the analytical study of air-chamber problems may not be employed in all such cases without error. Their use must be restricted to those problems in which the assumptions stated as Equation [10] of the paper[1] may be considered as sufficiently accurate. This will be the case when the pressure-velocity curve is continuous, as in the examples given by the author. But when the curve has cusps, as in the examples treated by Bergeron[7] and Angus,[8] the assumption may no longer be made without introducing large error. Further, the analytical method does not itself offer any criterion as to when Equation [10] of the paper is valid and when it is not. Herein lies an advantage of the graphical method. The graph itself shows clearly whether intermediate points, i.e., other than those of the "total or whole" rhythm $2L/a$, must be considered, and, in addition, indicates just how small the phase must be divided. This indication of the need for intercalary regimes is, of course, a criterion as to the validity of the assumption expressed by Equation [10] of the paper; an indicated need for smaller time intervals shows Equation [10] to be invalid.

It can be shown that the assumption of a continuous pressure-velocity curve may safely be made for any case in which both ρ and θ, following the author's notation, are large. However, in this case, a computation made without considering the elasticity of the water and pipe gives a good approximation to the true value and is much simpler to make than the calculations with the author's equations.

Bergeron has demonstrated[7] a graphical method for the solution of air-chamber problems, in which method account was taken of the elasticity of the water, the pipe, and the air in the reservoir. The solution obtained for a general case showed that if the ratio of the pipe area to reservoir area A/A_R, the pressure head of the air in the reservoir H_{air}, the term (initial pressure head plus the atmospheric head minus the head of water in the reservoir), and the initial velocity in the pipe all have the same values for any two cases, then the relation between the velocities and pressures obtained during perturbed flow are the same in the two cases. Further, if V_0, the initial velocity, is changed, then the pressures and velocities during perturbed flow vary as V_0 in comparison to the first case cited. Finally if the term

$$\frac{A}{A_R}\left[\frac{H_0 + H_{atm} - H_R}{H_{air}}\right]$$

keeps a constant value, the pressure-velocity relation at any instant varies very little with changes in the reservoir air pressure. It follows from these statements that by setting a maximum allowable superpressure, and constructing a network of curves relating various values of this latter term to the pipe length, the proper air reservoir for a given set of conditions can be found easily.

It was also shown that in certain cases if the elasticity of both the water and the pipe are not considered, the maximum surge pressure may reach a much higher value than that computed, taking account of elasticity. For instance, in the example solved by Bergeron,[7] this maximum reached a value five times the maximum computed considering elasticity.

In cases where the difference in the maxima (as computed by methods involving or not involving the elasticity of the media) is great, Equation [10] of the paper is invalid. Nevertheless, the author's equations applied to such a case would result in a computed maximum more nearly the true value than a maximum value obtained in neglecting the elasticity. Intermediate cases, such as those computed by the author where no loss of head is involved, may be solved quite accurately by his method. Note, for example, example *a* on p. 655 of the paper.[1] Bergeron points out that the analytical method results in values very nearly the same as those obtained by a graphical computation.

Correction for Loss of Head

In the present state of our knowledge of water-hammer phenomena it is necessary to admit that it has not been possible to consider in a rigorous manner the effect on the phenomena of losses due to liquid friction. However, both the graphical and analytical methods of computing water-hammer pressures are susceptible of changes which take this effect into consideration. In the analytical method, the head loss may be considered through the introduction of a term kv_0^2 in the equations of flow, as is done by the author. In the graphical method loss of head is introduced by Bergeron, Strowger, Angus, and others through the medium of concentrated losses at local discontinuities, such as, diaphragms, or similar constrictions, with the sections of pipe between them considered in the computations as ideal pipes with no loss of head. It is not necessary to discuss here the subtle question of the necessary number and magnitude of such discontinuities as that is covered by authors dealing with the graphical method. What should be stressed is the fact that once loss of head has been introduced by this means we are no longer dealing with an actual pipe, but with an ideal pipe fitted with constrictive devices, and all computations must be made accordingly.

The artifices described have been considered legitimate by the various authors treating the subject and the author has good precedent for introducing his correction in the form employed. However, an error has been found in the final Equations [20*a*] of the paper, which, while not at all invalidating the method, may lead to large errors and should therefore be corrected.

In order to show the nature of the error let us consider the case of an air chamber located on a pipe, and let the friction losses (represented by the term kv^2) be concentrated at a constriction placed in the pipe close to the air-chamber entrance. Call Y_i the effective pressure head at the air chamber, and Y' the pressure head on the other side of the constriction, with the direction of flow being from Y_i to Y'. Then one has the relation

$$Y_i = Y_i' + kv_i^2$$

and

$$Y_{i-1} = Y_{i-1}' + kv_{i-1}^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where $k>0$ if $Y>0$, and $k<0$ if $Y<0$. Substituting these values in Equation [1*a*] of the paper, one obtains

[7] "Variation of Flow in Water Conduits," by L. Bergeron, Comptes Rendus des Travaux de la Société-Hydrotechnique de France, Paris, France, no. 47, May 14, 1932, p. 615H.

[8] "Air Chambers and Valves in Relation to Water Hammer," by R. W. Angus, Trans. A.S.M.E., vol. 59, November, 1937, paper HYD-59-8, pp. 661–668.

$$(Y_i - kv_i^2) + (Y_{i-1} - kv_{i-1}^2) - 2(y_0 - kv_0^2) = a/g(V_i - V_{i-1}) \quad \ldots\ldots [2]$$

Following Allievi, let $Z_i = Y_i/y_0$ and let $W_i = V_i/v_0$, whence, by substituting into Equation [2] of this discussion, there results

$$W_i - W_{i-1} = \frac{1}{2\rho}\left[Z_i + Z_{i-1} - \frac{kv_i^2}{y_0} - \frac{kv_{i-1}^2}{y_0} - 2\left(1 - \frac{kv_0^2}{y_0}\right)\right] \ldots\ldots [3]$$

Note here that ρ is actually evaluated for an initial pressure head which is corrected for the friction effect.

Again following Allievi, let $K_i = kv_i^2/y_0$ and let $A = 1 - kv_0^2/y_0 = 1 - K_0$.

Then

$$W_i - W_{i-1} = \frac{1}{2\rho}[Z_i + Z_{i-1} - 2A - K_i - K_{i-1}] \ldots [4]$$

and adding this equation to a similar one for time $(i - 1)$, one obtains

$$W_i - W_{i-1} = \frac{1}{2\rho}[Z_i + 2Z_{i-1} + Z_{i-2} - 4A - (K_i + 2K_{i-1} + K_{i-2})] \ldots\ldots [5]$$

Finally the true forms of Allievi's Equations [20a] and [5b] are found to be

$$Z_i + 2Z_{i-1} + Z_{i-2} - (4A + K_i + 2K_{i-1} + K_{i-2}) = 2\rho\left(\frac{2C_0}{gv_0}\right)\left(\frac{1}{Z_i} - \frac{2}{Z_{i-1}} + \frac{1}{Z_{i-2}}\right) \ldots\ldots [6]$$

and

$$W_i - W_{i-1} = \frac{1}{2\rho}[Z_i + Z_{i-1} - (2A + K_i + K_{i-1})] \ldots [7]$$

from which it is readily seen that the omission of the term $A = 1 - (kv_0^2/y_0)$ in Allievi's equations is not correct.

Applying the correct form of equations, as given in this discussion, to example b on page 655 of Allievi's paper,[1] and correcting several numerical errors there involved, it is found that results obtained by the analytical and graphical methods separately, agree very well, and indicate no superpressure in place of 60 per cent as found by the uncorrected equations.

In this connection, note that the computations of surge pressures, for cases involving a correction for liquid friction, may become quite extensive. This is due to the fact, pointed out by the author, that Equations [20] and [20a] of the paper are dependent actually upon two parameters, N and μ, in place of only one, i.e., N, as appears at first glance. Since the use of the equations entails at least two series of approximate values for N, and since each of the two series should be studied for a series of fractional values of μ, then it appears that a correct determination of Z_{max} for the case involving correction for liquid friction requires a minimum of two series of approximations for each of a series of values of μ.

To conclude this discussion of Allievi's contribution to analytical methods for the solution of water-hammer problems there is place to note that an entirely new theory of water hammer in tapered pipes[9] has been developed by Dr. Henry Favre, of the hydraulic research laboratory annexed to the Eidgenossische Technische Hochschule in Zurich.

[9] "Théorie des coups de belier dans les conduites à caractéristiques lineairement variable le long de l'axe," *Révue Générale d'Hydraulique*, nos. 19, 20, and 21, January, March, and May, 1938.

R. W. Angus.[10] This paper[1] follows the procedure adopted by the author in his book[11] published by the A.S.M.E. The method used is not only simple, but elegant, in that it establishes what the author calls a "pendular system" of equations, all similar in form, and which are to be solved successively, using the numerical results from the first equation in solving the second one, and those of the second one in solving the third, and so on throughout the series. A disadvantage of this arrangement is that errors are cumulative and that it is not possible to know what happens in any interval without finding the results in all the intervals preceding it, but these defects exist in many other solutions of water-hammer problems and are not serious if the calculations can be made quickly and are not too sensitive to permit the use of an ordinary slide rule.

The author's notation interferes somewhat with convenient reading, but it is consistent with that used in his earlier papers; the frequent use of the asterisk is an easy cause of errors. The author's general Equation [1] is from the original paper[5] and the transformations down to the series of Equations [6] of the paper[1] are quite easy. The values of ρ^* given in Table 1 of the paper would cover most cases of power plants, but in pump-discharge lines, which are those to which the air chamber is primarily applicable, the table is too limited. For example, in a pumping line recently examined, the writer found a value of ρ^* exceeding 4 and, indeed, in most low-head piping, such as that on filtration work, the pipe characteristic may considerably exceed four.

The writer would agree with Equations [7], [8], and [9] of the paper, but he thinks that considerable error may result from the assumption of Equation [10], except in the first interval. The author[1] refers to a pipe line supplied by a pump without inertia, and which, therefore, stops instantaneously with power interruption; a check valve is supposedly installed between the air chamber and the pump, this valve closing instantly with power failure and preventing any return flow through the pump.

Curiously enough, that is the identical problem inadvertently selected by the writer in one of his papers,[8] and a direct check is thus easily made as to the assumption of Equation [10] of the paper under discussion.[1] In the first interval it does hold, but an examination of Fig. 5 in the writer's paper[8] shows that such an assumption cannot be made in the remaining intervals. Thus, in the second interval $v_1 = 0.29$ and $v_2 = -0.21$, but the maximum value of the velocity is at the center of the interval and is $v_{1.5} = -0.75$ and the average of all values between v_1 and v_2 is very much greater numerically than $(v_1 + v_2)/2 = (0.29 - 0.21)/2 = 0.04$, and is of opposite sign to it. Similar statements apply to other intervals. This example is one that shows an unusual pressure rise and in which the chamber is of little value, for the pressure ratio H/H_0 reaches a maximum value of 2.40 which exceeds $1 + 2\rho = 2$ due to sudden closure, therefore, the air chamber used is much too small for the system, but the solution of the problem was the method of proving this fact.

Fig. 5 of the writer's paper[8] is for a long pipe with $2L/a = 10$ sec, in which case the error is greater than for shorter pipes, and no method will be accurate unless the actual period of time used in the calculation is small; thus, the writer started with periods of 0.2 sec, lengthening later to 0.5 sec, and finally to 1 sec, in such a way as to make the velocity change small in the selected period.

With this qualification, and allowing for typographical errors, the equations of the paper[1] under discussion are correct and most helpful; Equation [18], for instance, is correct and not affected by the foregoing argument, but all of the other equations are.

The author is to be commended for his constant practice of

[10] Head of the Department of Mechanical Engineering, University of Toronto, Toronto, Ontario, Canada. Mem. A.S.M.E.

[11] "Theory of Water Hammer," by L. Allievi, translated by E. E. Halmos.

giving numerical illustrations, and he has given in Table 2 of the paper various values of Z for different pipe conditions indicated by various values of ρ and σ. From Equation [14] the product of these quantities is found in terms of the initial air volume, initial velocity v_0, the pipe area S, and $\mu = 2\,L/a$. In the writer's example $\sigma^*\rho^* = 2C_0/\mu S v_0 = (2/\mu v_0)(C_0/S) = (2 \times 10)/4\mu = 5/\mu$, so that the Table 2 of the paper[1] may be expressed in terms of ρ^* and $\mu = 2L/a$ as given in Table 1 of this discussion.

TABLE 1 VALUES OF $2L/a$ CORRESPONDING TO THE AIR CHAMBER IN ANGUS' PAPER[8] AND TO THE AUTHOR'S DATA

σ^*	$\rho^* = 0.5$	$\rho^* = 1$	$\rho^* = 2$
30	0.333	0.167	0.0833
5	2.000	1.000	0.5000
2	5.000	2.500	1.2500

The writer worked out the first two cases by the method explained in his paper[8] and found the value of Z_1 at the end of the first interval to agree exactly with that given by the author,[1] but at other intervals there was a considerable divergence, particularly in connection with the maximum and minimum values. The writer would be indebted to the author if the author would state whether there is any limit beyond which his formulas cannot be used.

The author's method of including friction is ingenious and gives another of his series of fascinating pendular equations. The writer agrees with the author that "provided the friction is neglected the air chambers are very inadequate instruments for the intended purpose of rendering innocuous the kinetic energy of the liquid column by the simple means of pneumatic accumulation." The air chamber may be used to store potential energy, but is not efficient for kinetic energy.

The author's suggestion of designing the passage between the air chamber and the pipe in such a way that the resistance for flow into the chamber from the pipe is very much less than the flow out of the chamber into the pipe, is most valuable and will result in enormously increasing the values of the air chamber.

A. A. KALINSKE.[12] The author made a notable analysis of the pressure and velocity variations which follow certain instantaneous initial conditions in a pipe equipped with an air chamber. Although the author in his various analyses and typical problems is only concerned with the behavior of air chambers on pump-discharge lines, the theory presented can be utilized, with only slight changes in some of the formulas, for the case when an air chamber is used to control water-hammer pressure caused by a quick-closing valve in a water-supply line. However, to be analogous to the case of sudden stoppage of power and coincident closure of a foot valve in the pump-suction pipe, for which the author developed his theory, it is necessary to apply his equations only to conditions where complete instantaneous closure occurs. No doubt the theory can be extended to include cases of slow closure of valves and gates.

The author's final equations for the pressure and velocity at various intervals of time $2L/a$, following the specified instantaneous initial conditions, are most unique and amazingly simple to use. The basis of the author's simplification is an important assumption which he makes and which may not be true in all cases. The assumption is that the variation of velocity during the phase interval $2L/a$ is linear; therefore, when the velocity at the beginning and end of the interval is known, the average velocity may be easily determined. Except for very long pipe lines, when $2L/a$ is large, this assumption is undoubtedly quite accurate and justifiable.

The writer has applied the author's theory to the case where an air chamber is needed to control the water-hammer pressure due to an ordinary quick-closing valve in a pipe line. In this case the pressure at the end of the first phase can be obtained from Equation [18] of the paper with a change in one sign, thus

$$Z_1^2 + Z_1 (N - 4\rho^* - 1) - N = 0 \quad \ldots\ldots\ldots [8]$$

According to the author's nomenclature Z is the ratio of the absolute pressure at the end of any specified phase interval and the initial absolute pressure. The term ρ^* is the ordinary pipe-line constant and N is a dimensionless parameter equal to the half ratio of the total initial potential energy of the air chamber and the analogous potential energy of the pipe line.

The values of Z at the end of the second, third, etc., phases can be obtained by the use of Equations [20] of the paper without any alteration. The velocity can be obtained by the use of a system of equations similar to the author's Equations [5a], except for a single change in sign. Their general type is

$$v_{i+1} = v_{i-1} - v_0/2\rho^* (Z_{i-1} + Z_{i+1} - 2) \quad \ldots\ldots [9]$$

In most instances when calculating pressure changes due to water hammer in water-distribution pipe lines, the losses due to fluid friction are large enough to necessitate their being taken into account. The author gives a satisfactory and straightforward method for taking friction loss into account by introducing the term kv_i^2. For the case of instantaneous closure of a gate the correction due to friction must, of course, be made opposite to that made for the pump-discharge line by the author. The pressure rise during the first phase is given by

$$Z_1^2 + Z_1 [N - 4\rho^* - (1 - K_1)] - N = 0 \ldots\ldots [10]$$

The term K equals kv_i^2 divided by the initial absolute pressure which for this case is equal to the absolute static pressure minus the initial friction-loss head.

The system of equations to be used for obtaining the pressure at the other phase intervals would be similar to the author's Equations [20a] with the signs on the K_i factors reversed. Unless close attention is paid to the author's nomenclature the reason for nonappearance of the initial velocity friction factor, K_0, in the author's Equations [18a] may not be apparent. Its disappearance is due to the fact that Z_0, which equals $(y_0 + h)/y_0^*$, and K_0 which equals kv_0^2, combine to give unity since $y_0^* = y_0 + h = kv_0^2$, where h is atmospheric pressure.

As the author points out, to have a basis for determining sizes of air chambers for pipe lines, in order that the pressure will not rise above a certain maximum value of Z_m, it is necessary to analyze the behavior of the air chamber and pipe line from the standpoint of energy conservation. Energy considerations reveal a fact that is usually lost sight of, that is, that the kinetic energy of the water is only a small part of the total energy stored in the air chamber at the value of maximum pressure. If no great friction losses exist in the pipe itself, or between the pipe and the air chamber, the air chamber accumulates a great deal of energy that is represented by the potential energy of the water entering the air chamber as the pressure rises, and the air is compressed. The author calculates this potential energy thus

$$\text{P.E.} = H_s w (U_1 - U_2) \ldots\ldots\ldots\ldots [11]$$

Where H_s is the absolute static pressure in feet of water, $(U_1 - U_2)$ is the volume of compression or the volume of water entering the air chamber between the initial and final conditions, and w is the weight per unit volume.

In pipe lines where there is appreciable friction loss, this potential energy would decrease by the amount of energy loss that this volume of water suffers as it flows down the pipe and into the air chamber. At any instant this energy loss is represented by the product of the weight of the water entering the air chamber at

[12] Instructor in Hydraulics and Assistant Research Engineer, Institute of Hydraulic Research, State University of Iowa, Iowa City, Iowa.

that increment of time, and the difference between the static pressure and the flow pressure. The total energy loss will be equal to $mw\,(U_1 - U_2)\,kv_0^2$, where m is some coefficient less than unity and usually greater than 0.75. This coefficient is nearly equal to unity because the rate of water entrance into the air chamber is high when the friction loss is high. The value of this coefficient has been checked experimentally.

Therefore, the energy stored in the air chamber is

$$W_0 + H_s w(U_1 - U_2) - mw(H_s - H_1)(U_1 - U_2) - \Delta W \ldots [12]$$

In this equation W_0 is the initial kinetic energy of the flowing water, H_1 is the absolute initial pressure before the flow in the air chamber starts, and ΔW represents the energy stored in the pipe walls and the water, minus the potential energy of the volume of water flowing into the space produced by the dilated pipe and the compressed water. If the air chamber were fairly large so as to affect a considerable pressure reduction, the term ΔW would not be very significant. For rough calculations the following equation can be used for obtaining the energy stored in the air chamber

$$W_0 + H_1 w\,(U_1 - U_2) \ldots [13]$$

Assuming that the compression of the air in the chamber is isothermal, the volume of the air chamber under initial conditions can be computed approximately from

$$U_1 = \frac{LSV_0^2}{2gH_1[\log_e r + (1/r) - 1]} \ldots [14]$$

where L is the length of the pipe line, S is its area, v_0 the initial water velocity, r the ratio of the maximum absolute pressure and the initial absolute pressure, and U_1 is the volume of air under initial pressure conditions. The actual volumetric capacity of the air chamber U_a would be obtained from the relation $U_1H_1 = U_ah$, where h is the atmospheric pressure. Thus, it is quite apparent that the size of an air chamber is influenced considerably by the initial pressure conditions in the pipe line.

Equation [14] of this discussion is valid only when no restriction exists between the pipe line and the air chamber. The author shows quite clearly how restricting the flow of water into the air chamber makes possible the use of a smaller chamber. However, the statements relating to the amount of restriction of friction loss between the pipe line and the air chamber need experimental verification. The optimum amount of restriction should be determined and experiments made checking the theoretical deductions.

There is no question but that the author's dimensionless parameters, which completely describe any pipe line and air-chamber installation, will be of inestimable value in interpreting and conducting experimental work. They will be of great aid in the presentation of the experimental data and in its extension for practical use.

Author's Closure

The following refers only to the analytical methods employed in the paper.

Some Doubts?

Some doubts have been raised by different writers concerning the approximation of Equation [18] determining Z_1 and of Equations [20] (pendular system), such doubts referring to the arbitrary assumption of Equation [10], viz., the linearity of V during and along a phase. The following observations may throw some light on the question.

Determination of Z_1 by Equation [18].

The law of the variable value Z during the first phase can be exactly obtained by means of the differential equation

$$\frac{\partial Z}{\partial t} = \frac{2Z^2}{N_\mu}(1 - 2\rho^* - Z) \ldots [\alpha]$$

which can be established by means of Equations [1a], [5], and [9], and which admits integration by a rather complicated formula[13] not available for further investigations.

But for the present object it may be considered sufficient to examine some results for a certain middle value of ρ^* corresponding to heads of from ~50 to 60 m, viz., for $\rho^* = 0.5$. With this assumption Equation [α] of this discussion becomes

$$\frac{\partial Z}{Z^2} = \frac{-2\partial t}{N_\mu}$$

whence integrating

$$\frac{1}{2Z^2} = \frac{2t}{N_\mu} + \text{const}$$

which for $t = 0$, $Z = Z_0 = 1$ gives const $= -0.5$, so that finally the foregoing equation of the curve diagram of Z during the first phase (parabolic curve) can be written

$$Z = \sqrt{\left(\frac{N_\mu}{N_\mu + 4t}\right)} \ldots [\beta]$$

and for $t = \mu$

$$Z_1 = \sqrt{\left(\frac{N}{N + 4}\right)} \ldots [\beta\beta]$$

Comparing now the exact values of Z_1 obtained from Equation [$\beta\beta$] with the approximate values obtained from Equation [18] of the paper it is seen that for a large range of values of σ^* (large range of volumes of air chamber) there is a small difference between the two series of values.

COMPARISON OF VALUES OF Z_1 FROM TWO EQUATIONS, $\rho^* = 0.5$

σ^*	N	Equation [18] of paper, Z_1	Equation [$\beta\beta$] Z_1
30	15	0.888	0.888
15	7.5	0.805	0.808
5	2.5	0.608	0.620
2	1.0	0.414	0.448
1	0.5	0.280	0.333

From this it is evident that, for middle values of ρ^* and with the exception of very small air chambers, the assumption of linearity expressed by Equation [10] of the paper can be satisfactorily accepted.

Such is not the case for small values of σ^* corresponding to small air chambers and small values of N as can be verified by the construction of parabolic diagrams represented by Equation [β], the curvatures of which are then strongly accentuated. These curvatures, probably less acute, must obviously be repeated in the diagrams of Z referring to the following phases. Alike analogous curvatures must obviously characterize the diagrams of V.

Determination of Z_1 by the Pendular System, Equations [20].

The effective law of V for small air chambers must show, in three consecutive phases $i - 1$, i, and $i + 1$, one of the two shapes shown in Figs. 1 and 2, which are apparently in contradiction with the hypothesis of linearity stated by the *arbitrary* assumption of Equation [10] of the paper.

Such is, however, not the case, because Equation [10] has not

[13] $$\frac{Z - 1}{Z(1 - 2\rho^*)} + \frac{1}{(1 - 2\rho^*)^2}\log_e\frac{2\rho^* Z}{Z(1 - 2\rho^*)} = \frac{2t}{N_\mu}$$

an expression which loses any sense when ρ^* approaches the value 0.5 and therefore Equation [β] is substituted.

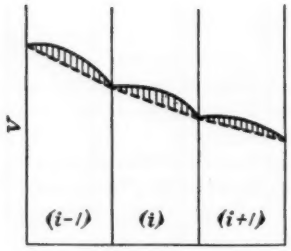

FIG. 1

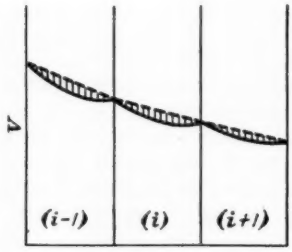

FIG. 2

been applied to single phases, but to the expression connecting three diagrams—areas of consecutive phases

$$\int_0^{i-1} V\partial t - 2\int_0^{i} V\partial t + \int_0^{i+1} V\partial t \ldots\ldots\ldots [\gamma]$$

The difference, for each phase, between the real area and the hypothetical area corresponding to linear variation is represented by the lunulae sketched in Figs. 1 and 2. It is now easy to perceive that if the areas of the successive lunulae vary with a certain uniformity, which can be plausibly assumed, their influence on the value of the foregoing expression $[\gamma]$ is insignificant and can be neglected.

These considerations fully justify Equation [16] of the paper and the plausible approximation of the pendular system, Equations [20], even for very small air chambers.

An Error?

Messrs. Mason, Danel, and Craya state that an error has been made and that the first members of the equations concerning acceleration, taking into account liquid friction, should be written

$$(Y_{i-1} - kV_{i-1}^2) + (Y_i - kV_i^2) - 2(y_0 - kv_0^2)$$

whence it appears that these writers assume that the initial head for the pumping regimen, that is, for ascending flow, has the value $y_0 - kv_0^2$ instead of the well-known $y_0 + kv_0^2$, which is an error undoubtedly, and an inexplicable one indeed.

Methods Employed to Remedy Water-Hammer Shock in Pumping Systems[1]

J. G. MILLER.[2] In the past, most papers on water hammer have treated the subject either from the theoretical point of view or as it applies to penstocks or other large hydraulic lines, delivering several thousand gallons per minute. In designing such lines, where little if any margin is allowed for contingencies, it is particularly important to know what maximum water-hammer pressures will be encountered so that rupturing of the pipe can be prevented. Consequently, this hydraulic phase of water hammer has been investigated by numerous engineers, while other places of occurrence have been more or less neglected. There are many cases of this sort where water hammer is not anticipated but is found to exist, after the pipe line is built. Then the problem is one of eliminating the trouble as cheaply and as effectively as possible. The author's paper in dealing with shock pressure from this point of view offers considerable useful and timely information.

In his paper, the author discusses the effectiveness of the so-called "recoil valve" in reducing water-hammer pressures. This valve, it seems, has been developed especially for use on water lines, where water hammer is encountered. Since the author has used it in all the cases discussed, it seems that a description of this valve is not only desirable but necessary.

H. J. Bartlett[3] suggests using an "ordinary check valve, equipped with an outside lever and weight, installed in such a way that the weight would aid in closing," for the same purpose that the author uses the recoil valve. Mr. Bartlett concludes with the statement: "In actual service such a valve will close when the pump stops, slightly before forward motion of the water ceases and thus there is no reversal of flow at all. In the many, many cases, where such valves have been used, we have yet to hear of one where they have failed to produce the desired results."

Since no description of the recoil valve has been given in the author's paper, the writer is unable to tell the difference between the recoil valve and the ordinary check valve with the weighted disk. However, in his discussion of check valves, the author makes the statement that "more severe conditions can sometimes be met by fitting loaded disks to otherwise standard check valves...." From this the writer concludes that the recoil valve is not an ordinary check valve with a loaded disk. Question is raised also as to when he deems it inadvisable to use the loaded-disk check valve and, in view of Mr. Bartlett's statement, what are the particular advantages of the recoil valve?

It is encouraging to note that both the author and Mr. Bartlett agree that the slow-closing or cushioned check valve not only fails to improve a water-hammer condition but sometimes will make it more severe.

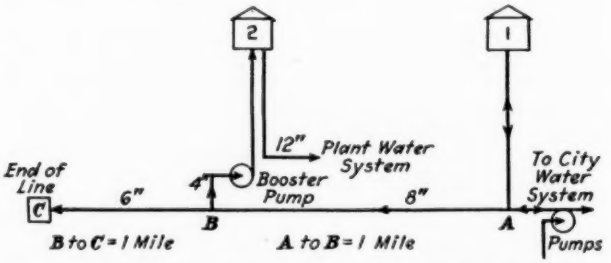

FIG. 1 DIAGRAMMATIC LAYOUT OF BRANCH LINE IN WHICH WATER HAMMER IS FREQUENTLY ENCOUNTERED

In case 4 the author uses an air chamber as a means of decreasing water hammer. This method of solution is considered effective in reducing shock pressures by most piping designers if the air chamber can be made large enough. However, in many cases, it is not practicable to install an air chamber of sufficient capacity to reduce shock pressure more than the 10 to 15 per cent usually needed to eliminate the characteristic clanking sound. If greater reduction is required, some other solution frequently must be found. Where such necessity exists, it would seem that a valve similar to the one used in case 3 offers a more general solution to problems similar to case 4 than an air chamber.

It would be interesting to learn whether the author has had experience in solving water-hammer problems in branch lines. This phase of the subject has not received much attention from the practical point of view. The writer's Fig. 1 shows a case of a branch line where water hammer is known to occur, which may or may not be serious depending on the circumstances. The height of both tanks is approximately the same. The purpose of the pump is to overcome friction in the main, thus speeding up the filling of tank No. 2 from tank No. 1, following intermit-

[3] "Checking Up on Check Valves," by H. J. Bartlett, *The Valve World*, issues of July-August and September-October, 1938, pp. 152–158.

tent heavy use of tank No. 2. While the pump is running, the pressure at B and also at C will be equal to the pressure at A minus the friction loss from A to B (assuming no flow from B to C). When the pump is stopped, the pressure at B and C increases nearly 100 per cent above normal pressure at A, due to shock following stopping of the pump. This case is not necessarily typical of all branch-line problems, but is a type frequently encountered. A discussion by the author of a similar case or any other case of water hammer in branch lines with which he has had experience will add much to the usefulness of the paper.

Author's Closure

Mr. Miller is to be thanked for his informative contribution, and for raising several very interesting questions.

The general features of the "recoil" valve are given under the section *Remedy*, of case 1, and in the final paragraph of the article. Unfortunately a general sectional drawing would not convey the features sufficiently convincingly. The commercial check valve is a competitive product with the design controlled by cost. When water hammer, due to valve-slam, occurs, the cost of the check valve is negligible compared with the threatened expense of repairing damage. Hence a valve embodying all the greatest refinements known, verified and found out by experiment, becomes a relatively inexpensive remedy. The recoil valve is neither more nor less than this.

The question of when a loaded-disk check valve should be used is generally decided by the existence, or otherwise, of a check valve in the system. In order to avoid the removal of this, a loaded disk would be tried as a first attempt. If that failed the check valve would be replaced by a recoil valve. A loaded disk alone is regarded as a makeshift as the body design of ordinary check valves does not conform with the ideal characteristics.

In his reference to case 4, Mr. Miller overlooks the emergency possibility of a sudden shutting down of the pumping plant due to failure of the electric supply. In such circumstances it would usually be impossible to bring into service a valve of the type employed in case 3. It should also be noted that in case 4 the water hammer did not arise from the slamming of the check valve. Admittedly air chambers are not always a practical proposition and it is then necessary to fall back on some form or other of pressure-relief or concussion-relief valve. Under suitable circumstances these are quite successful in reducing, though not altogether eliminating, surge pressure. They must, however, be used with caution and understanding, and are rarely successful in short-pipe systems.

Regarding Mr. Miller's interesting branch-line problem the first essential is to determine, as precisely as possible, the origin of the water hammer, distinguishing carefully, if necessary, between shocks due to check-valve slamming and pressure surges due to changes in the rate of flow and arising from the elasticity of the water columns. As so often happens in problems submitted, sufficient data are not given to permit of a useful discussion, but the behavior suggests that there may be check-valve slamming in conjunction with the usual elastic surging of the water column on the suction side. With boosting arrangements possessing a very large water system on the suction side, the widespread disturbance set up in this system when the pumps are at work cannot settle down so rapidly as the relatively small system on the delivery side. It commonly happens that the surge pressures built up on the suction side pass through the pump by reopening the check valve on the pump delivery and thus obtain relief. If this does not happen in the case quoted excess pressures due to check-valve slamming are suggested on the delivery side. First attention should therefore be given to the check valve and, as the booster connections are small (4 in. diam) compared with the suction main (8 in. diam), further relief to the suction system should be considered, such as connecting a by-pass, with check valve, direct from the suction side of the pump to the 12-in. main leading to the plant water system.

The author desires to acknowledge the cooperation of his staff in preparing the material submitted.

Speed of Water-Hammer Pressure Wave in Transite Pipe[1]

W. S. Pardoe.[2] Professor Kessler in his paper has given a beautiful demonstration of the accuracy of Joukowsky's formula

$$a = 4670 \sqrt{\left(\frac{1}{1 + \frac{K}{E}\frac{d}{t}}\right)} \quad \ldots\ldots\ldots\ldots [1]$$

or he has an expensive method of determining the modulus of elasticity of Transite. The coefficient 4670 or the acoustic ve-

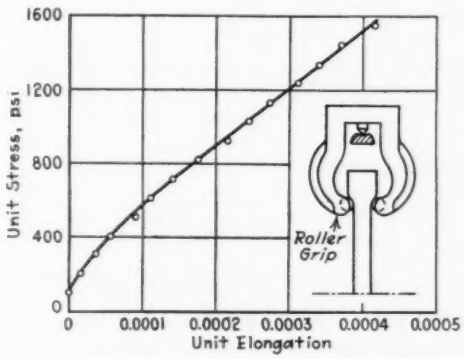

Fig. 1 Stress-Strain Curve of Cement Asbestos
(Ultimate strength = 2310 psi; secant modulus = 3,500,000 psi.)

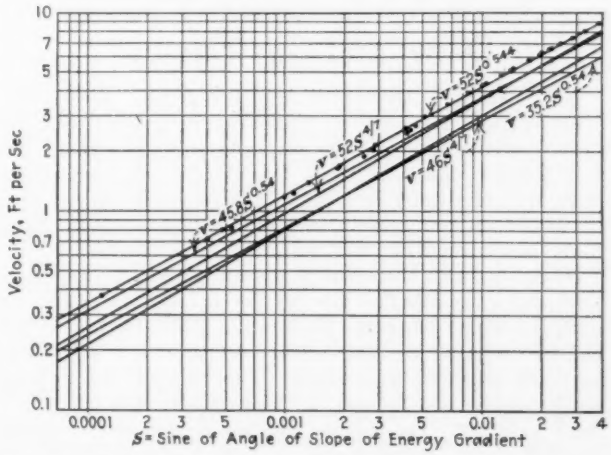

Fig. 2 Test of 150 Mm Cement-Asbestos Pipe and Comparison With Cast-Iron Pipe

Cement-asbestos	$v = 52S^{0.544}$
Hazen-Williams, clean cast iron	$v = 45.8S^{0.54}$
Hazen-Williams, tuberculated cast iron	$v = 35.2S^{0.54}$
Flamant, new cast iron	$v = 52S^{4/7}$
Flamant, slightly incrusted cast iron	$v = 46S^{4/7}$

[1] By Lewis H. Kessler, Transactions of the A.S.M.E., January, 1939, vol. 61, p. 11.

[2] Professor of Hydraulic Engineering, University of Pennsylvania, Philadelphia, Pa.

locity in water in an inelastic pipe line is obtained from the formula

$$h = \frac{aV}{g} = V\sqrt{\left(\frac{K}{wg} \times 144\right)} \quad \ldots\ldots\ldots\ldots [2]$$

If K = 294,000 psi and w = 62.3 lb per cu ft, a = 4670. Professor Kessler must have used K = 300,000 psi.

In March, 1925, the writer made some tests[3] on Italite pipe, made in Genoa, Italy, for the Asbestos Association at the civil engineering laboratories at the University of Pennsylvania. This product was called cement-asbestos pipe and was the forerunner of the Transite pipe. Fig. 1 herewith shows a modulus of elasticity of this material (sample cut from pipe laterally) of 3,500,000 psi which checks Professor Kessler's median value of 3,375,000.

The velocity of the stress wave for 14-in. class-B cast-iron pipe is

$$a = 4670\sqrt{\left(\frac{1}{1 + \frac{294{,}000}{13{,}000{,}000} \times \frac{14}{0.65}}\right)} = 3825 \text{ fps} \ldots [3]$$

and that for the Transite pipe is

$$a = 4670\sqrt{\left(\frac{1}{1 + \frac{294{,}000}{3{,}500{,}000} \times \frac{14}{1.185}}\right)} = 3360 \text{ fps} \ldots [4]$$

or 12 per cent less, which lowers the water hammer by the same percentage.

Fig. 2 shows the velocity-slope curves for cement-asbestos pipe and for various cast-iron-pipe formulas. As

$$V = 52\,S^{0.544} = C \times R^{0.63}S^{0.54} \times 0.001^{-0.04} \ldots\ldots [5]$$

or C = 142.5 in the Williams and Hazen formula. This checks the value of 140 given by Professor Kessler.

Cooling-Tower Fundamentals and Their Application to Cooling Diesel and Gas Engines[1]

E. J. Kates.[2] The writer fully agrees with the author's statement, in referring to Diesel-engine applications, that "partial recirculation is often advisable with thermostatic control, keeping off-engine water temperatures uniform without changing jacket-water circulation." So important are the benefits of such an arrangement, both as to engine and as to cooling tower, that it would be well to set forth some of the reasons.

By-passing with thermostatic control benefits the engine by producing a vigorous flow of water through the jackets and permitting a higher off-engine temperature. Also the rate of flow and the off-engine temperature do not change with engine load as would otherwise be the case. The vigorous flow prevents vapor pockets and reduces the heat-transfer skin effect from metal to water. The uniform temperature and small temperature rise reduce heat strains in the metal walls. The high temperature improves engine thermal efficiency, particularly at partial loads. Thus engine reliability is increased, maintenance is reduced, and fuel consumption is decreased.

At the same time, the recirculating system permits reducing the size of the cooling tower for two reasons: First, since some of the water discharged from the engine is by-passed around the cooling tower, the flow over the tower is reduced, thus permitting the use of a smaller tower; second, the higher temperature of the water, flowing over the tower, produces a greater temperature difference between the water on the tower and the air.

G. C. Boyer.[3] While not a designer of cooling towers, the writer would like to make the following inquiries from the viewpoint of a consulting engineer, who utilizes them as part of a Diesel power plant:

1 Does not the fine breakup in spray-type towers take the place of arrestation by decks in the deck-type tower? Does not a large contact area take the place of the time element in the deck tower?

2 What is the effect of increasing the height of a deck-type tower above 30 ft? In the paper the author limits his towers to 30 ft in height. This question is raised because it appears if the height of a tower is increased, then it is possible to decrease the length of the tower with a corresponding saving in foundation cost.

3 Is it not true that the capacity of any distribution system falls off with a decrease in pressure? Is it not, therefore, as necessary to insure maintenance of pressure on one type of distribution system as on the other? Reference in this connection is made to a comment in the paper, regarding the deck-type versus the spray-type tower.

In discussing mechanical-draft spray-type towers, the author mentions limitations to which they are subject, without specifying them, so far as the writer can discover in the text. Enlightenment on this point would be helpful.

It might be of interest to cite the performance specifications for a cooling tower, prepared by the writer. The system involved was of the closed type, consisting of a spray-type tower with the heat-exchanger coils located at the bottom. A definite requirement was established for the distribution of 300,000 Btu per hr, with a jacket-water temperature off the engine not exceeding 140 F when 76 F wet bulb and a 3-mph wind prevailed.

As a side light on this specification, it was the writer's contention in discussion a year ago on the subject of a closed cooling system, that 140-F off-engine temperature was the upper limit practicable. Exception was taken to this by Edgar Kates, who stated that 160 F was entirely permissible. In preparing the foregoing specification the writer decided to compromise between these two figures and fixed the off-engine water-temperature requirement at 150 F. The result was that the Diesel-engine manufacturers refused to tolerate a cooling-water temperature above 140 F, stating that the higher requirement, if maintained, would definitely rule them out as bidders. The temperature was, therefore, reduced to 140 F.

The answer on that point is the same as it was a year ago. When the Diesel-engine manufacturers will agree to raise the temperature off the engine with a closed cooling-water system, engineers will write their specifications accordingly.

Incidentally the same manufacturer, who objected to 140 F in this engine cooling specification, has an experimental engine running with a temperature differential across the engine of 1 degree F and a temperature off the engine approaching 160 F. The rate of putting water through this engine may well be imagined!

Author's Closure

The fine breakup in spray-type towers does take the place of filling, in so far as it provides water surface in contact with air. In a deck tower, besides the wetted deck surface, there is also

[3] "Tests of Cement-Asbestos Pipe," by W. S. Pardoe, *Engineering News-Record*, vol. 96, January 28, 1926, p. 169.

[1] Paper by Gustave J. Bischof, published in the January, 1939, issue of the A.S.M.E. Transactions, vol. 61, p. 25.

[2] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[3] Burns & McDonnell Engineering Company, Kansas City, Mo.

drop surface due to the splash of falling water on the decks. The time element is especially important where long ranges and close approaches to the wet bulb are required. This time element can only be obtained by the use of decks to interrupt water fall in an atmospheric tower or by filling in a mechanical-draft tower. There are really two distinct phases to be considered in the evaporative cooling of water; namely, water surface and time of contact with air. Neither one can wholly substitute for the absence of the other. Careful study of the particular requirements of each installation is necessary to select the type of tower most suitable.

In regard to the most economical height of the tower, there should be no attempt to limit the height of an atmospheric-deck tower to 30 ft, even though this height has been more or less standardized for towers 12 ft wide inside of the louvers. As Mr. Boyer points out, there are times when it is desirable to go higher than 30 ft. The question is largely one of the least expensive installation in terms both of first cost and operating cost. The first cost of the combined tower and foundation may be decreased by increasing the height of the tower to about 42 ft and shortening it, but the pumping head will also be increased by the same amount. Consequently, pumping costs will go up. Beyond 42 ft, wind stresses become so large that either a wider tower or one with spread footings is desirable for stability, thus adding to the tower cost with little or no foundation savings. It might seem on first thought that a wider tower would take care of more water per foot of length. However, experience indicates that wider towers should be loaded less per square foot of deck area, as they do not cool as efficiently due to the greater obstruction to lateral air movement and progressive saturation of the air as it moves across the tower. It is evident that many factors enter into the most economical design in any particular case and it pays to study carefully all factors before the final decision is made as to dimensions.

It is true that the capacity of any distributing system is roughly a function of the square root of the pressure. If the tower operates at all times, at the definite capacity for which the distributing system was designed, then the type of distributing system is not of great importance. However, there are many installations where the distributing system is designed for a maximum circulation and is run for varying periods at much less than rated capacity. Here it becomes important to consider the part that pressure plays in the cooling of the water by means of water-surface production. In a deck tower only a small portion of the heat dissipation occurs on initial water breakup between distributing system and the top deck. Practically all the heat is dissipated during the descent of the water through the decks. Hence, it is of slight importance whether the distributing system operates at over capacity under high pressure or at under capacity with but a dribble, as the decks distribute the water and form a good portion of the total surface. In fact, the less water circulated over a deck tower, the less density of water per square foot of deck area and the better the cooling.

On the other hand, a spray-type tower without decks depends solely on fine initial breakup of water leaving the nozzles. There is in fact no other place for drop surface to form. If, therefore, a spray-type tower of a given rated capacity should be operated at less capacity or with lower pressure at the nozzles, the water is no longer broken up into drops but dribbles from the nozzles, and cooling effect falls off. The only effective way to decrease capacity in a spray tower and maintain cooling is to substitute smaller-capacity nozzles or shut off a certain portion of the nozzles uniformly throughout the tower. While the above discussion deals with atmospheric-deck towers versus atmospheric-spray type towers, the same reasoning applies to mechanical-draft towers with and without filling.

The Drafting of Steam Locomotives[1]

E. G. Young.[2] The author has discussed several matters which have been argued ever since a front-end problem was first recognized, which goes back as far as 1870.

The clearness with which the author shows the blowover effect, that is, the increase of back pressure on one side due to the exhaust from the other, is of particular importance. The indicator cards which he has used show much more of this effect than others seen by the writer, and it seems proper to ask whether the separation between exhaust passages was carried up actually into the nozzle stand, as is now recognized to be good practice, or whether the passages merged within the cylinder castings.

There are two questions with regard to the use of the four-ported Layden-type nozzle tip which arise; one of these the author has clearly answered in favor of this nozzle. The problem of "filling the stack" is one which will not down. The four-ported nozzle "fires" with first one pair (diagonally opposite) of holes and then the other. It would certainly not appear that either pair would set up a stream of steam and entrained gases which would satisfactorily fill the stack, but it becomes evident from the lower right chart of Fig. 5 of the paper that the alternate action actually does set up such a train as to fill the stack effectively at low speeds and obtain much better results than the plain nozzle. The second question is not answered, that is, the one regarding the back pressure resulting from a given rate of steam discharge. When one end of one cylinder releases, the bulk of the steam flows out through the exhaust ports in the very limited time between release and the end of the stroke, and it must flow through a nozzle-tip opening of half the area but the same perimeter as the plain nozzle for which the special nozzle is substituted. It is true that in the case of the special nozzle, the steam impulse has the opening all to itself, but it is also true, as is obvious from the exhaust-wave diagrams shown in the paper, that the interference from the opposite exhaust is very small. The expectation would be that the exhaust pressure would be considerably higher when equal amounts of steam are discharged by the four-ported nozzle.

In discussing the "characteristics and limitations" of the exhaust-pressure and draft relationship, the writer believes that there is a much more fundamental limitation on this ratio as an indication of the degree of efficiency with which a front-end arrangement operates, than any mentioned by the author. Exhaust pressure is a result of a certain weight of steam being released through a nozzle of given form and dimensions in a certain time. Draft, similarly, is an unsatisfactory unit; it results in part from the method of releasing the steam, and equally from the resistance of the path through which the air and combustion gases must travel. Paradoxically enough, the purposes of the draft-producing devices on a locomotive are not to produce draft, but to move air though the fire, and draft is only a suitable unit for comparison when a constant resistance to the gases is present. The actual problem of front-end design is to produce an arrangement which will pull an optimum weight of air through the fire for each pound of steam generated and discharged, maintaining at the same time three mechanical conditions: (1) Minimum back pressure, (2) clearing the smokebox, and (3) lifting the smoke above the train. The greatest difficulties lie in the mutual incompatibility of these mechanical requirements.

The author's case for the variable nozzle—and automatic

[1] Published as paper RR-60-4, by J. R. Jackson, in the October, 1938, issue of the A.S.M.E. Transactions, vol. 60, p. 573.

[2] Research Professor in Railway Mechanical Engineering, University of Illinois, Urbana, Ill. Mem. A.S.M.E.

operation is highly desirable—is one of the strongest which has come to the attention of the writer. The use of a fixed-area and fixed-form nozzle is a concession to the mechanical difficulties involved in the variable type. It represents a tacit assumption that it is economically more profitable (or more efficient in terms of dollars and cents) to assume that a locomotive works at a constant steam output under all conditions, and to fix upon a nozzle arrangement (including size, shape, and distance from the top of the nozzle to the top of the stack) which is most efficient for that output, and to accept inferior performance when working at any other output rate, than to use a nozzle variable in form or area. Certainly no data have been developed proving this to be the case.

A. I. Lipetz.[3] The author presented a very complete and thought-provoking paper. No conclusions are given but it will serve as a splendid introduction to a research study of drafting steam locomotives.

The historical data on the earlier research made by MacFarland with a multibladed fan driven from a live-steam noncondensing turbine is of great value and interest. The mentioning of the exhaust-steam turbine tried by Goss and the reasons given for the failure of both Goss's and MacFarland's attempts, are very important; we seldom get information on unsuccessful attempts, but they are just as valuable, for future research, as those which succeed. The Lewis exhaust ejector, which actually was a variable nozzle with a wide stack, and the partial success obtained by it is very interesting. The discussion of the tortuous development of the idea of enlarging stack and nozzle diameters is very significant and instructive. The mentioning of the necessity of smoke-lifting properties of a good drafting arrangement is appropriate, as in a great many cases the absence of this property explains the failure of some promising designs.

The discussions of the characteristics and limitations of the relationship between exhaust pressure and draft, obtained by a study of locomotive-test results of a standard single circular nozzle, together with the Lewis exhaust governor and the Layden nozzle with four round openings of constant area, are very enlightening. The idea of operating the two exhausts in order to eliminate the middle hump of indicator cards usually obtained, and to permit the ejecting effect of the exhaust of one side for the work of the cylinder on the other, should be studied more carefully. Partly unsuccessful results of tests made abroad (Germany and Russia) with the Stumpf nozzle have not been mentioned. They should be carefully analyzed.

The future investigator should, first of all, pay attention to the question of a variable versus a constant nozzle, in view of the splendid results which are now obtained on many European locomotives with the Kylchap front-end arrangement with constant nozzle. The Chapelon locomotives in France and England have shown a remarkable increase in power and the possibility of attaining very high speeds, at which the exhaust is not impaired in any way. The latest test made on the London & North Eastern, with the Sir Nigel Gresley locomotive at a speed of 125 mph at a continuous run, should set locomotive designers thinking about this subject. It seems that the only question left open to investigate is whether the Kylchap arrangement is suitable to American conditions, especially in so far as smoke-lifting properties are concerned.

In conclusion, the author enumerated certain recommendations which he would suggest to the future investigator as a result of the aforementioned thoughts. He is quite right in his statement that the energy thrown away by the exhaust steam is greater than what is required for the elevation of smoke and gases above the locomotive cab and for heating feedwater. The present drafting arrangement is probably not yet giving the maximum efficiency in itself and is not conducive to maximum power of the locomotive. Although it is over 100 years old, it is still open to improvements.

A. Giesl-Gieslingen.[4] The front ends of the modern locomotives on the Missouri-Pacific Lines are indeed examples of very sound standard practice and speak for the experience of the author under whose direction these front ends were designed or modified. Railroad mechanical engineers will be thankful for the account which the author has given of his experiences.

In many respects it is unfortunate that the ideas of D. M. Lewis were not developed further. Apart from the considerable cost of his experiments, the main reason therefore becomes apparent from Mr. Lewis' patents which reveal that good ideas were associated with a number of distinct fallacies regarding the requirements of efficient front-end action. For instance, placing the elongated nozzle crosswise to the axis of the locomotive was decidedly a mistake; Henry B. Oatley realized this about 20 years ago as evident from his U. S. patent covering an elongated stack and nozzle placed longitudinally. The Oatley design should not be missing in a discussion of Lewis' experiments and the tests made in 1933 by the Missouri-Kansas-Texas Lines unmistakably show its merits, even if the efficiency was still impaired by lack of experience in proportioning such a novel arrangement. If one considers that the elongated front-end arrangement offers the designer a still greater number of variables, it is clear that, without a correlating theory, the development of a highly efficient arrangement is likely to be very expensive and time-absorbing. From the standpoint of freedom in choosing the proper stack and nozzle areas on large locomotives, further from the standpoint of smoke-lifting power, back pressure and, last but not least, reduction of exhaust noise (this is a surprisingly pronounced feature of the elongated stack and nozzle) the Oatley arrangement is indeed worthy of most active consideration.

The effect of the noise reduction is so pronounced that those who have had experience with these stacks even cited it as a disadvantage. The engineers, accustomed to the sound of the standard exhaust, were unable to determine when the engine was working near capacity and were, therefore, induced to overwork their boilers. During the 15 or 20 years which have since passed, this argument has, of course, lost the weight which it might have had at that time. As a means of gaging locomotive capacity and efficiency of working, the valve pilot has appeared as a scientific aid, and noise reduction, on the other hand, is coming in for increasing attention by the public and by the authorities.

Another subject for the treatment of which we are indebted to the author is the utilization of the energy in the "exhaust puff" which occurs at the moment of release from any one cylinder. This energy, instead of disturbing the fire at lower speeds, can be put to work for reducing the back pressure in the opposite cylinder as the author shows in his diagrams. It is interesting that this basic idea had been patented to James Milholland as early as 1847; like a good many successors, Milholland proposed the use of concentric nozzles for this purpose but in the interest of reducing the height required for the development of exhaust passages, which is a primary necessity on large modern locomotives, the concentric arrangement is out of date and the openings should be placed side by side in some manner for which the author gives us a workable solution.

With reference to the author's Fig. 7, it might be mentioned that the relation of the curves for "steam to engines" and exhaust pressure is distinctly erroneous above a pressure of approximately 8 lb. The author's contention that "there is a

[4] Lokomotivfabriks, A. G. Wien XXI, Germany. Mem. A.S.M.E.

limitation in the economic working range of a steam locomotive, drafted with conventional constant area nozzle" is, in the light of modern designs decidedly no longer correct within the narrow limits illustrated in Fig. 7. Tests made with well-developed standard front ends reveal that the CO_2 content can be kept within the narrow and very favorable range of 14 to 15 per cent from light loads up to a back pressure slightly exceeding 12 lb. When the boiler is forced beyond that range, the air supply per pound of coal burned will fall off considerably, and maintenance of good combustion will require reducing the nozzle area rather than increasing it; this is proved by countless experiences. Lewis' idea to keep the back pressure constant regardless of the rate of working was a decided fallacy and it is surprising that it finds the author's support. While it is true that with certain coals and at high speeds combustion can be improved by closing in the nozzle somewhat at very light loads, this observation does not signify the trend throughout the working range of the locomotive and it must be our aim to get along with a constant-area nozzle which, if the front end is to be well proportioned, will fulfill all requirements of efficient operation.

The problem of smoke lifting at very light loads can certainly not be solved by closing in the exhaust nozzle and thereby increasing the force of the exhaust; unless we are satisfied with an effect amounting to only a small percentage increase in the speed limit at which smoke trailing will begin, this method would lead to an entirely excessive air supply at light loads as can easily be demonstrated. From the theoretical standpoint, this problem could be fully solved by reducing the stack area together with the area of the exhaust nozzle at light loads and high speeds; with an elongated stack and nozzle this could be done quite easily. However, in practice it will probably be preferable to effect smoke lifting by external air streams, the force of which increases with the speed of the air against the locomotive.

H. S. VINCENT.[5] The author has had long experience with the drafting of steam locomotives and has achieved a considerable measure of success in this field. He has made a desirable contribution to our knowledge of what takes place in the cylinders and smokebox of a locomotive by the design and use of specially constructed instruments. It is to be hoped that a method will be devised for accurately registering the pressure in the exhaust cavities of the locomotive cylinder at a point immediately below the nozzle stand and that this record can be synchronized with the temperature reading taken in the same position. Such a record will afford much needed data for determining the relative effectiveness of any piece of drafting apparatus.

Discussing more particularly some of the author's conclusions, the writer believes that the complete separation of exhaust-steam passages for right and left locomotive cylinders is not essential for eliminating or reducing the "hump" in the exhaust line of indicator cards. The Pennsylvania Railroad has for a number of years on all of its locomotives provided a choke in the cylinder-exhaust passages, of smaller area than the nozzle tip, thereby partially converting the pressure energy of the exhaust "puffs" into kinetic energy. This construction eliminates or greatly reduces the "blowback" into the opposite cylinder. Its effect can be seen by reference to the indicator diagrams shown in any of the Pennsylvania test bulletins.[6]

The complete separation of the exhaust passages will, of course, eliminate the "hump" but this necessitates some form of double nozzle. The abandonment by the railways of the use of two separated nozzles was not brought about entirely by the dictum of the American Railways Master Mechanics Association as the author asserts. This form of nozzle never gained any general acceptance by the American railroads. Its incidental disadvantages, such as cross firing into the stack were the real reasons for its discontinuance.

The Layden four-ported nozzle, to which the author refers, permits a practical separation of the locomotive exhaust passages and is so designed that the steam issues from each pair of nozzles concentrically with the bore of the stack. In the construction of the Layden nozzle, two of its four apertures are available for each cylinder. The statement is sometimes made that the four apertures of the Layden nozzle are equivalent to a single nozzle of equal area. This is not correct.

One of the peculiarities of the operation of the Layden nozzle is that at the moment of the release of steam in one of the cylinders, two of its nozzles are filled with steam at the maximum exhaust pressure, whereas the remaining two nozzles are exhausting steam from the opposite cylinder at minimum pressure. Thus, at low running speed the relative weight of steam escaping through each pair of nozzles may be in the ratio of six to one. The effect of this operation on the fire and in draft pulsations is the same as if the locomotive were equipped with a single nozzle having an area about 16 per cent greater than that of the two effective nozzles.

In the tests conducted by E. G. Young[7] on a front-end model, it was demonstrated that with the same front-end setup, the four-hole nozzle, of which the Layden nozzle is assumed to be the prototype, gave an air flow 21 per cent greater than that given by a circular nozzle of equal area and with the same jet pressure. In this case the area of the four-hole nozzle was equal to the one hole of the circular nozzle. It has been assumed in some instances that this test represented the relative effectiveness of the Layden nozzle as compared with a circular nozzle of equal area. It is evident that such is not the case. Had the holes of the model-test nozzle been isolated as in its prototype, the result would undoubtedly have been quite different. We may therefore expect that the back pressure required to draft a locomotive successfully, will be about the same with the Layden nozzle as with the standard circular type.

In his second conclusion the author avers that the energy liberated from the cylinder at release opening of the valves is more than is required for drafting the locomotive. If this refers to the thermal energy remaining in the steam, the statement is correct, but no method has so far been devised for utilizing this energy. It has been nearly 40 years since Goss gave as his conclusion, from a series of tests conducted at Purdue University, that the total weight of steam passing through the cylinders of a locomotive is required to draft the locomotive when using the Master Mechanics standard front-end arrangement. Any of the energy of the exhaust steam which is diverted for other purposes must be compensated for by a corresponding increase in back pressure, with its attendant loss of cylinder power. Subsequent experience has well authenticated this pronouncement of Goss's.

The writer believes that no energy is "thrown away" in the present method of drafting a locomotive. The author's draft records show conclusively that the pressure in the smokebox of a locomotive varies widely and continuously and that these variations are synchronous with similar pulsations of the exhaust pressure. The mean of these constantly varying pressures both in the cylinder-exhaust passage and in the gas passages is the force which operates to pull the gases through the tubes. If it were practicable to smooth out the exhaust pulsations without

[7] "A Study of the Locomotive Front End, Including Tests of a Front-End Model," by Everett G. Young, Bulletin No. 256, Engineering Experiment Station, University of Illinois, Urbana, Ill., May, 1933.

loss of energy or without lowering the average pressure, the draft effect would at least be equal to and would probably be somewhat better than that obtained with pulsating pressures. No attempt should be made to lower the average exhaust pressure in the cylinders unless there is a corresponding reduction made in the resistance offered to the gas flow.

Referring again to Young's model test,[8] it was found when using a $1^5/_8$-in. circular nozzle with the standard Master Mechanics front-end arrangement that with an exhaust-jet pressure of 6 lb, the weight of air moved per hour through the tubes was 4317 lb. When this setup was replaced with a smokebox arrangement similar to that designed by W. F. Kiesel, Jr., and widely used by the Pennsylvania Railroad, while still retaining the $1^5/_8$-in. circular nozzle, a weight of 4840 lb of air was moved per hour with the same jet pressure. Thus, an increased air flow of 12 per cent was obtained solely by reducing the resistance offered by the Master Mechanics front-end arrangement.

The writer has shown elsewhere[9] that a locomotive equipped with the Kiesel front-end arrangement, including a radial ported nozzle, will move a weight of gas in unit time about 29 per cent greater than can be moved in the same locomotive when equipped with the Master Mechanics front-end arrangement and circular nozzle of equal area. Thus, a means is provided for a significant increase in the steaming capacity of the locomotive.

The author's projected design of variable nozzle and ejector are still in the experimental stage. It will be interesting to follow his experiment along this line. The exhaust card taken from his experimental equipment as exhibited in his Fig. 8, shows approximately zero back pressure at an operating speed of 5 mph. This is not an unusual record as published[10] indicator cards from a locomotive equipped with a Layden nozzle also show zero back pressure at a speed of 4.5 mph.

The writer is inclined to believe that a variable exhaust is not destined to replace the constant-area type. There have been numerous experiments made with different forms of variable nozzles but so far none have been adopted or used to any extent, probably because no decided advantage from their use has been shown. The constant-area nozzle has been the standard for over one hundred years. This successful use would seem to demonstrate that it is correct in principle.

The author states "the only justification for the variable nozzle over the constant-area nozzle is that the former will increase the economic range of the locomotive by increasing the range through which draft proportional to the rate of steam demand on the boiler is realized." He then presents his Fig. 7, to prove that the locomotive there shown, because it is equipped with a constant-area nozzle becomes less efficient in steaming capacity when operating beyond a cutoff of about 49 per cent of the stroke, at a speed of 14.7 mph. The locomotive cited by the author is one of a class designed originally for transfer service involving low speed and not requiring high boiler capacity. The test as shown by the author's Fig. 7, was made on the original design. Subsequently, this class of locomotive was equipped with a feedwater heater and other changes made to increase its boiler capacity; it was then placed in road service.

It is evident that every locomotive has an economic limit of operation beyond which it will show reduced efficiency. The locomotive as shown by the author's Fig. 7, was not designed to operate at 14.7 mph when working at a cutoff over 50 per cent of the stroke. In Fig. 1 of this discussion is shown the normal speed-effort curve for this locomotive, which is consistent with its original boiler rating. This curve indicates that at a speed of 14.7 mph the locomotive will normally develop a tractive effort of 68,000 lb. This is equivalent to 2670 ihp. The small crosses show the cylinder tractive effort that was developed in the test and the cutoff at which this tractive effort was developed. These indicate that at a speed of 14.7 mph the locomotive should operate at about 45 per cent cutoff.

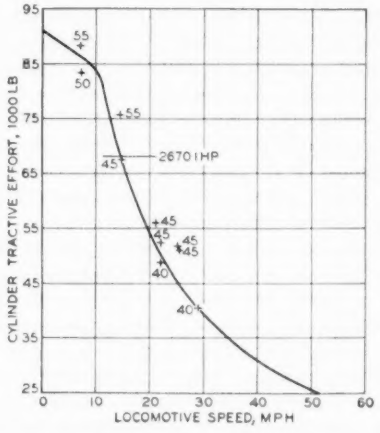

FIG. 1 SPEED-EFFORT DIAGRAM FOR PENNSYLVANIA $30^1/_2 \times 32$-IN. DECAPOD LOCOMOTIVE NO. 790

Referring again to the author's Fig. 7, it will be observed that up to a maximum cutoff of about 49 per cent, at the given speed, the locomotive functions consistently. It is only when the locomotive is pushed to a cutoff beyond the limitation of its boiler that its operation becomes relatively inefficient. In fact, below 49 per cent cutoff it will be seen that the draft curve exactly parallels the curve of coal fired, indicating that the draft arrangement is fully responsive to the demand upon it.

In the test cited, locomotive No. 790, was equipped with the Master Mechanics front-end arrangement and a Goodfellow nozzle. We now have available a drafting mechanism which in combination with a constant-area nozzle will move approximately 30 per cent more gas in unit time with the same jet pressure than was possible with the arrangement used on locomotive No. 790. It would seem therefore that we can claim to have an apparatus which in the words of the author "provides draft proportional to the rate of steam demand on the boiler."

W. F. KIESEL, JR.[11] This subject, the drafting of locomotives, is quite old; the ejector principle on which it is based was developed more than 75 years ago, and as early as 1870 the value of its fundamental principles was appreciated even if not fully understood. That is evidenced by patents Nos. 106,515 and 107,603, issued respectively to James Smith on August 16, 1870, and A. J. Dufour on September 20, 1870, on a radial-ported nozzle. Carefully organized experiments to determine the most efficient shape of stacks date back to 1860. In these tests, small round nozzles, mostly less than 1 in. diameter, were used.

The author of the paper under discussion records the "high lights of his experiments as viewed in retrospect." That seems to be an invitation for others to do likewise. Based on 50 years of experience, the writer submits the following comments on the subject.

Nozzles. The circular shape was excellent for small nozzle

areas. When these areas had to be increased for larger locomotives, the Goodfellow nozzle with four projections into the circle showed a definite superiority. For still larger areas, the ported nozzle showed similar superiority over the Goodfellow nozzle. That experience, amply proved by tests, indicated that there should be a definite relation between periphery and area.

Early experimenters determined that the nozzle area should be approximately 4 per cent of the net flue (flue and tube) area, and later writers quote the same figure; however, an examination of modern locomotives will show that their nozzle areas are almost invariably less by a large percentage. It has been definitely established by tests that the nozzle area can be increased to 4 per cent of the net flue area by a judicious redesign of the drafting appliances, thereby increasing the evaporation capacity and reducing cylinder back pressure. Experimental installations on four railroads resulted in an increase of nozzle area of approximately 35 per cent, a 35 per cent increase in evaporation capacity, and an 8-lb reduction in cylinder back pressure at an evaporation equal to the maximum performance when using the smaller nozzle. At high speed, that represents a material increase in drawbar horsepower for no greater expenditure of water and coal.

Stacks. Best steaming results have been realized when the area of the top of the stack is half of the net flue area; however, under light working conditions, the velocity of gases leaving the stack is low and the products of combustion are not propelled as high into the air as with smaller stack diameters. If the area at the top of the stack is reduced to one third of the flue area, the exit-gas velocity will be increased by 50 per cent, engendering a loss in nozzle area and correspondingly a loss of approximately 12 per cent in evaporating capacity.

The smokebox arrangement can be adjusted to even smaller stack diameters, and with the use of the ported nozzle it will show a decided advantage over the Master Mechanics front-end arrangement. In every case, the distance from the top of the nozzle to the top of the stack should be as great as the design permits—clearance restrictions prevent making that distance too great.

The foregoing indicates that in connection with locomotives used for light work there is a choice between a smoke-lifting mechanism and a reduction in stack diameter, with a corresponding small reduction in nozzle area and capacity.

In an existing locomotive it is extremely difficult to make changes that will reduce resistance to flow of gases into the ash-pan through the firebox, around the arch, and through the flues. The resistance through the smokebox and stack can be reduced by judicious design. For heavy-duty freight locomotives, the area of the top of the stack should be half the flue area. For locomotives intended for light service, the owner should state his preference of the alternatives just presented by the writer.

Cross fire of the exhaust should no longer exist on any locomotive less than 15 years old. That occurrence was cured as far back as 1900 by introducing an exhaust-passage choke vertically below the nozzle and located either in the exhaust pot or preferably in the cylinder saddle. This choke also causes the steam flow from one cylinder to induce a reduction in back pressure in the other cylinder. In this respect, Figs. 2, 3, and 6 of the author's paper show a deplorable condition of locomotives in question.

A great help in maintaining a balanced steaming condition for all variations of power utilization with proper fixed nozzle is to cut down the net opening of air passages through the grate to approximately 125 per cent of the net flue area. That also prevents stripping a light fire off the grate when the driving wheels slip or when starting with full throttle.

Since the desired steam generation, and hence the draft on which it depends, is closely proportional to the amount of steam passing through the nozzle, it is difficult to visualize how a variable nozzle can be of any benefit except to counteract some error in smokebox design that creates unbalanced results. It is much simpler to improve or correct the design than to add mechanisms which obstruct draft due to bulk; such mechanisms have thus far proved detrimental instead of beneficial and are expensive in first cost and maintenance.

Proceeding now to a review of the paper, it is noted that the author took part in, or supervised, tests of fan applications by McFarland and Goss, as well as tests of the Lewis exhaust governor. He does not record that these are of value to the locomotive, and apparently favors the Layden double-ported nozzle, which by inference from the author's statement covering tests of five different appliances on the same locomotive is the least efficient of the five.

In Fig. 8 of the paper, the author presents tentative exhaust-pot designs which he believes may correct undesired behavior found in previous tests, but which may be corrected in a much simpler way, as previously presented by the writer in this discussion.

When comparing the author's first test, using the Layden nozzle, with the fifth test, using the Kiesel nozzle, it should be pointed out that the Kiesel nozzle has approximately 30 per cent more nozzle area, hence 30 per cent more steaming capacity, and at an evaporation rate of 60,000 lb per hr (not including the feed-water heater) it will cause a reduction in cylinder back pressure of more than $7^1/_2$ lb. The author's criticism of the latter scheme is twofold: (1) It is a poor spark arrester at high capacity, and (2) it results in much trailing smoke under light working conditions.

Regarding the first criticism, the spark arrester is made of a material called "Draftac," which is approved by the Interstate Commerce Commission and used by practically all railroads. Since the author gives no reason for his opinion, it may be assumed that on a dark night more red shows at the top of the stack at 130 per cent capacity than at 100 per cent capacity, which is true because the locomotive must get rid of an additional volume of cinders at the higher capacity. However, sparks that will pass through the $^3/_{16}$-in. slits in the Draftac netting are not considered dangerous; the Draftac netting can be replaced by a louver arrangement which on test has reduced considerably the red color at the top of the stack.

Regarding the author's second criticism, if the bad trailing-smoke condition could not be corrected by a smoke lifter, the stack diameter can be reduced to provide whatever reasonable gas-exit velocity the locomotive owner may specify, with the smokebox arrangement modified to suit.

For brevity, the writer has summarized results of his experience, much of which has been obtained from actual tests. While reviewing the paper, the writer transferred the results of his tests onto the author's comparative tests to show vital economic relations which the author neglected to mention.

Opinions differ as to variable nozzles. Experimenters have tried many different types without the least success, and will continue to try more indefinitely, presumably with the same results.

Author's Closure

As discussion of the paper has brought out, the subject of drafting steam locomotives is indeed an old one. In attempting to cover the subject in a single paper, the author may be charged with having made some statements without presenting complete data in support of them.

It is difficult to see where there is basis in the paper for Dr. Giesl-Gieslingen's feeling that support is given to the idea, attributed to Lewis, of keeping the back pressure constant regardless of the rate of working. The necessity for an increase in noz-

zle pressure is fully appreciated, other things remaining equal, for an increase in steam demand on the boiler. The author's contention is the desirability for a more proportionate draft to steam demand throughout the possible range of power development for the steam locomotive than can be realized with the single nozzle of fixed area.

The author is familiar with the Oatley design of slot nozzle placed longitudinally, also mentioned by Dr. Giesl-Gieslingen in his discussion of the Lewis exhaust governor. In this connection, it may be of interest to record that an adaptation of the Lewis governor, placed longitudinally instead of transversely, was applied to a locomotive in England about 1922 or 1923 and was reported to have performed satisfactorily. It might be added that, in the author's experience, the relatively high draft efficiencies obtained with the Lewis slot nozzle and rectangular stack, either in the longitudinal or the transverse positions, were due to the increase in the exhaust-jet surface with the slot as compared with the conventional circular-nozzle design.

The point is made that the indicator cards presented in the paper are examples of poor design and bad practice as regards cross-fire effect and that, through proper design of passages and nozzle, the extreme pressure build-up against the piston in the working cylinder from the release puff in the opposite exhausting cylinder could be greatly reduced or eliminated. This is agreed to and yet the contention stands that the cards shown more nearly represent actual conditions of steam locomotives in service today than is generally suspected.

Messrs. Vincent and Kiesel cite the Pennsylvania Railroad locomotives, built during the last 15 years, as examples of proper design of exhaust passages and nozzle in the conventional single-nozzle drafting arrangement. The value of this design is fully appreciated. Acknowledgment is also made of the outstanding work in locomotive-design research carried out by the Pennsylvania Railroad in the locomotive-testing plant at Altoona. It is true that the conventional indicator diagrams, presented in the Pennsylvania Railroad Bulletins, show more satisfactory exhaust-pressure lines than are shown on the conventional diagrams presented in the paper. However, it would be of interest to have available exhaust cards, taken with a 10- or 20-lb indicator spring, for the Pennsylvania Railroad locomotive cited.

The designs and experiments of Stumpf, mentioned by Dr. Lipetz, are familiar to the author. Full credit is accorded to Stumpf for the idea and demonstration, through the design of exhaust passages and nozzle, of utilizing the energy in the exhaust from one side to reduce the pressure on the opposite side. The Stumpf design, however, had to be carefully worked out; that is, the shape and area of the exhaust nozzle in relation to the exhaust passages had to be carefully maintained to realize the desired back-pressure control. This, in the author's opinion, is also true of the Pennsylvania Railroad or other single-nozzle constructions. In other words, very good results are to be realized from the proper relationship of exhaust passages and nozzle so long as this relationship is maintained. A change in nozzle to reduce the area, as is common practice, would be expected to cause a less satisfactory back-pressure relationship than was obtained with the ideal nozzle-exhaust-passage relationship.

After consideration of the factors involved, it appears obvious that the simplest, most efficient, and most flexible method of eliminating the blowback or cross-fire effect in the conventional two-cylinder steam locomotive is the complete separation of the exhaust passages and nozzles, yet, this is not in more general use today because:

a The double nozzle is generally considered as less efficient for drafting the locomotive, other things being equal, than a single nozzle.

b It has been and is accepted that cylinder back pressure is satisfactorily controlled through the design of the exhaust passages, either within the nozzle stand or in the passages in the cylinder casting connecting into the base of the stand, in relation to the nozzle.

That modern steam locomotives are satisfactorily and economically drafted with the double nozzle, properly designed in relation to stack, is amply evidenced by the many free-steaming locomotives in service today equipped with the Layden double-ported nozzle.

This answers the question raised by Professor E. G. Young relating to the "filling of the stack" with the Layden-type nozzle. The question regarding back pressure, resulting from a given rate of steam discharge from the conventional as compared with the Layden-type nozzle, also raised by Professor Young, involves a fundamental point apparently not generally recognized, as between drafting the same locomotive with a double as compared with a single nozzle; viz., that each of the double-nozzle areas has to be reduced over that of the single nozzle, other things remaining equal, for satisfactory steaming. The following examples are given:

	Areas, sq in.			
		Double nozzle		
Example	Single nozzle	Each side	Total	Type
28 × 30 × 63-in. Berkshire (1930)	40.7	19.24	38.48	Layden
27 × 32 × 63-in. Mikado (1924)	30.7	16.59	33.18	Layden
19 × 24-in. American (1896)	14.19	8.30	16.60	Double

In the double-nozzle arrangement, for satisfactory steaming, each nozzle opening serving one side has to be reduced in area or choked to from 45 to 60 per cent of the area of the single nozzle. This does not mean, however, that there is a proportionate increase in cylinder back pressure for a given rate of total steam discharge. The reduction in area in each of the double-nozzle openings acts as a choke to lengthen the periods of discharge of a given volume of steam from the cylinder and thus extends the time of both the puff and blow phases of the exhaust to keep the smaller nozzle filled between the lesser number and hence increased time intervals between cylinder releases to be discharged through the separate nozzles. The retardation of flow through the double nozzle from the reduced area is only essential for the relatively lower locomotive speeds, because as speed increases and cutoff is shortened, the flow from the nozzle, whether single or multiple openings, becomes relatively continuous. By reason of timing of the cylinder releases with respect to the position and speed of the piston, the pressure build-up due to choke occurs at points which have the minimum effect on torque and, hence, power. The separating wall obviously prevents any influence of blowover on the opposite side. On the indicator diagram this is evidenced by the more rounded toe of the diagram and higher back pressures at the ends of the stroke, typical of the double nozzle. This same influence of choke in the exhaust passages is evident on the indicator diagrams of the Pennsylvania Railroad designs referred to by Messrs. Vincent and Kiesel. In the case of the completely separated exhaust passages, resulting from the double-nozzle construction, there is no possibility of the back-pressure humps at midstroke positions due to blowover, whereas, with the Pennsylvania Railroad design, if the proper ratio between nozzle and exhaust-passage choke is disturbed, there may be distinct back-pressure humps in the indicator-diagram exhaust lines.

Comments by Messrs. Giesl-Gieslingen and Vincent with reference to Fig. 7, presented to illustrate the limitations in the economic working range of a locomotive drafted with a conventional constant-area nozzle, are to the effect that the locomotive in question could not be expected to show economical performance when operated with full throttle and 55 per cent cutoff at 14.7 mph. It appears evident that the abrupt increase in fuel consumption and decrease in boiler efficiency with the lengthen-

ing of cutoff from 48.6 to 55.4 per cent, other things being equal, was not due to exceeding the capacity of the boiler, but to the difficulty in maintaining proper fire-bed conditions by reason of the severity of the draft impulses from the peaks of exhaust pressure at cylinder-exhaust releases, due to nozzle choke. It is the author's contention that an increase in the area of the nozzle could have been expected to result in a distinct improvement in both boiler efficiency and over-all locomotive performance at the 55.4 per cent cutoff load. Change to the Kiesel front-end arrangement developed later, with the increased area of nozzle tip and exhaust-jet surface, could also be expected to give a more favorable drafting condition with consequent improvement in performance. The larger conventional nozzle, of course, would not be suitable for other than the full-stroke operation at the relatively low speed at which the locomotive was being operated during the tests shown in Fig. 7. A reduction in nozzle area would be necessary for satisfactory steaming at higher speeds and shorter cutoffs. This is borne out by the fact that the tests of the locomotive in question included runs with $6^1/_4$-, $6^3/_4$-, and 7-in-diameter nozzle tips in connection with modified front-end arrangements. Furthermore, the maximum evaporation of 58,300 lb per hr was obtained at a speed of 25 mph, 45 per cent cutoff, through adjustment of the front end and nozzle.

The author appreciates the comments and constructive criticisms of the paper. It is hoped that this work will serve to show the desirability for further research to improve the over-all efficiency of the reciprocating steam locomotive by conservation in power and increased steaming range through exhaust-pressure and nozzle-area control.

Some Problems Related to the Preparation of Illinois Coal[1]

WILLIAM G. CHRISTY.[2] Due to section 18 of the new St. Louis Smoke Ordinance, there is considerable interest in the preparation and washing of Illinois coal for use in the St. Louis territory. The section referred to, limits ash and sulphur content of coal sold in the city. It is probable, however, that this provision in the Smoke Ordinance will not eliminate very much smoke. It was intended to cut down the discharge of solids in the form of fly ash and cinders; also, the discharge of sulphur gases from the stacks.

The term "smoke abatement" has really become a misnomer. Those engaged in this work are interested in the elimination of all kinds of atmospheric pollution. The aim is not only to abate smoke but also materially to reduce the discharge of solids and deleterious gases from chimneys. The new regulation in St. Louis is a forward step. This paper shows what can be accomplished by coal producers in an attempt to meet the requirements of the ordinance.

Those located in the East and accustomed to low-ash and low-sulphur coals may wonder why it is necessary to place such a seemingly high limit on ash and sulphur content. It is the writer's understanding that samples of coal sold in St. Louis are analyzed by the City Laboratory. Some samples have been found to contain as high as 28 per cent ash. A few years ago, a well-known consulting engineer in St. Louis analyzed samples of coal and found they contained 7 per cent sulphur. Certainly something should be done to cut down the discharge of solids and sulphur gases from such fuel. A few years ago an aggravated case came to the writer's attention. Called in as a consulting engineer on the case, it was discovered that strenuous complaints were being made concerning the discharge of fly ash from a pulverized-coal plant. The coal used part of the time ran about 30 per cent ash. About $^1/_2$ mile from the plant, on the edge of some timberland, was ground which had never been cultivated. At this point, the deposit of ash was $2^1/_2$ in. thick, which was the accumulation of about seven years' operation of the plant. The truck farmer had had several crops ruined by this deposit. The author has explained some of the difficulties encountered in the preparation of coal. The time is not far distant when other cities using coal of high-ash and high-sulphur content, will probably require that such coal be processed before being used.

H. F. HEBLEY.[3] Modern coal preparation has made rapid strides in the Midwestern States, especially in Illinois. Hand picking of the larger sizes and screening have always been prominent features of the preparation of coal in Illinois, but the labor costs involved in cleaning of the coal by picking have in recent years increased.

The larger sizes of coal, say plus 3 in., are to a great extent sold on appearance. Notwithstanding the fact that coal-cleaning equipment, dependent on the separation of refuse from the cleaned coal by density processes would yield an acceptable product from the point of view of density separation and ash content, the poor appearance might be sufficient to condemn it. However, in many cases such hand picking does not yield the cleaning results which the popular conception attributes to it.

One of the influences, that is forcing a greater consideration of cleaning in Illinois, is the growing realization that smoke, fumes, cinders, and fly ash, which are continuously being discharged to the atmosphere in centers of large population, should be curtailed. Coal cleaning has its place in facilitating attainment of this goal.

A word of warning is required, however, to retard the idea that the cleaning of coal is the panacea for all ills. At best, coal cleaning removes the free impurities and the higher ash-intergrown coal of high specific gravity, yielding a product lower in ash. Probably its next great advantage is the increase in uniformity of the coal prepared.

It should always be remembered that Illinois coal is higher in ash than fuel produced in West Virginia, Eastern Kentucky, and some of the Pittsburgh seams. It is also a known fact that the higher the ash content of a coal, the greater is its heterogeneity. When using coal for steam-generation purposes, it is in part this nonuniformity that causes trouble in the boiler room. Generally, provided a coal is uniform, the designer of a furnace for boiler use can cope with high ash and low fusion; but if the coal changes in characteristics from car to car, the boiler-room personnel is liable to experience trouble.

As an instance, $1^1/_4$-in. screenings, with an average ash content of 14.3 per cent, may vary from 10 per cent to 23 per cent in ash, and have a heterogeneity measured by the probable error of 1.4 per cent. Such a steam coal, unless cleaned, would, under the present St. Louis Smoke Ordinance, be restricted to shipping only 4 cars out of every 100 loaded at the mine into that market.

A cleaning plant, which would reduce the ash to 10 per cent, with a probable error of only 0.6 per cent, would enable the shipping of 98 cars out of every 100 into the market. Such uniformity is naturally of great advantage to the consuming company.

The author mentioned that, where water supply is limited, elaborate settling clarifying systems must be utilized. Such clarification depends on sedimentation and also on the modern method of coagulation. Experiments have been carried on both

zle pressure is fully appreciated, other things remaining equal, for an increase in steam demand on the boiler. The author's contention is the desirability for a more proportionate draft to steam demand throughout the possible range of power development for the steam locomotive than can be realized with the single nozzle of fixed area.

The author is familiar with the Oatley design of slot nozzle placed longitudinally, also mentioned by Dr. Giesl-Gieslingen in his discussion of the Lewis exhaust governor. In this connection, it may be of interest to record that an adaptation of the Lewis governor, placed longitudinally instead of transversely, was applied to a locomotive in England about 1922 or 1923 and was reported to have performed satisfactorily. It might be added that, in the author's experience, the relatively high draft efficiencies obtained with the Lewis slot nozzle and rectangular stack, either in the longitudinal or the transverse positions, were due to the increase in the exhaust-jet surface with the slot as compared with the conventional circular-nozzle design.

The point is made that the indicator cards presented in the paper are examples of poor design and bad practice as regards cross-fire effect and that, through proper design of passages and nozzle, the extreme pressure build-up against the piston in the working cylinder from the release puff in the opposite exhausting cylinder could be greatly reduced or eliminated. This is agreed to and yet the contention stands that the cards shown more nearly represent actual conditions of steam locomotives in service today than is generally suspected.

Messrs. Vincent and Kiesel cite the Pennsylvania Railroad locomotives, built during the last 15 years, as examples of proper design of exhaust passages and nozzle in the conventional single-nozzle drafting arrangement. The value of this design is fully appreciated. Acknowledgment is also made of the outstanding work in locomotive-design research carried out by the Pennsylvania Railroad in the locomotive-testing plant at Altoona. It is true that the conventional indicator diagrams, presented in the Pennsylvania Railroad Bulletins, show more satisfactory exhaust-pressure lines than are shown on the conventional diagrams presented in the paper. However, it would be of interest to have available exhaust cards, taken with a 10- or 20-lb indicator spring, for the Pennsylvania Railroad locomotive cited.

The designs and experiments of Stumpf, mentioned by Dr. Lipetz, are familiar to the author. Full credit is accorded to Stumpf for the idea and demonstration, through the design of exhaust passages and nozzle, of utilizing the energy in the exhaust from one side to reduce the pressure on the opposite side. The Stumpf design, however, had to be carefully worked out; that is, the shape and area of the exhaust nozzle in relation to the exhaust passages had to be carefully maintained to realize the desired back-pressure control. This, in the author's opinion, is also true of the Pennsylvania Railroad or other single-nozzle constructions. In other words, very good results are to be realized from the proper relationship of exhaust passages and nozzle so long as this relationship is maintained. A change in nozzle to reduce the area, as is common practice, would be expected to cause a less satisfactory back-pressure relationship than was obtained with the ideal nozzle-exhaust-passage relationship.

After consideration of the factors involved, it appears obvious that the simplest, most efficient, and most flexible method of eliminating the blowback or cross-fire effect in the conventional two-cylinder steam locomotive is the complete separation of the exhaust passages and nozzles, yet, this is not in more general use today because:

a The double nozzle is generally considered as less efficient for drafting the locomotive, other things being equal, than a single nozzle.

b It has been and is accepted that cylinder back pressure is satisfactorily controlled through the design of the exhaust passages, either within the nozzle stand or in the passages in the cylinder casting connecting into the base of the stand, in relation to the nozzle.

That modern steam locomotives are satisfactorily and economically drafted with the double nozzle, properly designed in relation to stack, is amply evidenced by the many free-steaming locomotives in service today equipped with the Layden double-ported nozzle.

This answers the question raised by Professor E. G. Young relating to the "filling of the stack" with the Layden-type nozzle. The question regarding back pressure, resulting from a given rate of steam discharge from the conventional as compared with the Layden-type nozzle, also raised by Professor Young, involves a fundamental point apparently not generally recognized, as between drafting the same locomotive with a double as compared with a single nozzle; viz., that each of the double-nozzle areas has to be reduced over that of the single nozzle, other things remaining equal, for satisfactory steaming. The following examples are given:

	Areas, sq in.			
		Double nozzle		
Example	Single nozzle	Each side	Total	Type
28 × 30 × 63-in. Berkshire (1930)	40.7	19.24	38.48	Layden
27 × 32 × 63-in. Mikado (1924)	30.7	16.59	33.18	Layden
19 × 24-in. American (1896)	14.19	8.30	16.60	Double

In the double-nozzle arrangement, for satisfactory steaming, each nozzle opening serving one side has to be reduced in area or choked to from 45 to 60 per cent of the area of the single nozzle. This does not mean, however, that there is a proportionate increase in cylinder back pressure for a given rate of total steam discharge. The reduction in area in each of the double-nozzle openings acts as a choke to lengthen the periods of discharge of a given volume of steam from the cylinder and thus extends the time of both the puff and blow phases of the exhaust to keep the smaller nozzle filled between the lesser number and hence increased time intervals between cylinder releases to be discharged through the separate nozzles. The retardation of flow through the double nozzle from the reduced area is only essential for the relatively lower locomotive speeds, because as speed increases and cutoff is shortened, the flow from the nozzle, whether single or multiple openings, becomes relatively continuous. By reason of timing of the cylinder releases with respect to the position and speed of the piston, the pressure build-up due to choke occurs at points which have the minimum effect on torque and, hence, power. The separating wall obviously prevents any influence of blowover on the opposite side. On the indicator diagram this is evidenced by the more rounded toe of the diagram and higher back pressures at the ends of the stroke, typical of the double nozzle. This same influence of choke in the exhaust passages is evident on the indicator diagrams of the Pennsylvania Railroad designs referred to by Messrs. Vincent and Kiesel. In the case of the completely separated exhaust passages, resulting from the double-nozzle construction, there is no possibility of the back-pressure humps at midstroke positions due to blowover, whereas, with the Pennsylvania Railroad design, if the proper ratio between nozzle and exhaust-passage choke is disturbed, there may be distinct back-pressure humps in the indicator-diagram exhaust lines.

Comments by Messrs. Giesl-Gieslingen and Vincent with reference to Fig. 7, presented to illustrate the limitations in the economic working range of a locomotive drafted with a conventional constant-area nozzle, are to the effect that the locomotive in question could not be expected to show economical performance when operated with full throttle and 55 per cent cutoff at 14.7 mph. It appears evident that the abrupt increase in fuel consumption and decrease in boiler efficiency with the lengthen-

ing of cutoff from 48.6 to 55.4 per cent, other things being equal, was not due to exceeding the capacity of the boiler, but to the difficulty in maintaining proper fire-bed conditions by reason of the severity of the draft impulses from the peaks of exhaust pressure at cylinder-exhaust releases, due to nozzle choke. It is the author's contention that an increase in the area of the nozzle could have been expected to result in a distinct improvement in both boiler efficiency and over-all locomotive performance at the 55.4 per cent cutoff load. Change to the Kiesel front-end arrangement developed later, with the increased area of nozzle tip and exhaust-jet surface, could also be expected to give a more favorable drafting condition with consequent improvement in performance. The larger conventional nozzle, of course, would not be suitable for other than the full-stroke operation at the relatively low speed at which the locomotive was being operated during the tests shown in Fig. 7. A reduction in nozzle area would be necessary for satisfactory steaming at higher speeds and shorter cutoffs. This is borne out by the fact that the tests of the locomotive in question included runs with $6^1/_4$-, $6^3/_4$-, and 7-in-diameter nozzle tips in connection with modified front-end arrangements. Furthermore, the maximum evaporation of 58,300 lb per hr was obtained at a speed of 25 mph, 45 per cent cutoff, through adjustment of the front end and nozzle.

The author appreciates the comments and constructive criticisms of the paper. It is hoped that this work will serve to show the desirability for further research to improve the over-all efficiency of the reciprocating steam locomotive by conservation in power and increased steaming range through exhaust-pressure and nozzle-area control.

Some Problems Related to the Preparation of Illinois Coal[1]

WILLIAM G. CHRISTY.[2] Due to section 18 of the new St. Louis Smoke Ordinance, there is considerable interest in the preparation and washing of Illinois coal for use in the St. Louis territory. The section referred to, limits ash and sulphur content of coal sold in the city. It is probable, however, that this provision in the Smoke Ordinance will not eliminate very much smoke. It was intended to cut down the discharge of solids in the form of fly ash and cinders; also, the discharge of sulphur gases from the stacks.

The term "smoke abatement" has really become a misnomer. Those engaged in this work are interested in the elimination of all kinds of atmospheric pollution. The aim is not only to abate smoke but also materially to reduce the discharge of solids and deleterious gases from chimneys. The new regulation in St. Louis is a forward step. This paper shows what can be accomplished by coal producers in an attempt to meet the requirements of the ordinance.

Those located in the East and accustomed to low-ash and low-sulphur coals may wonder why it is necessary to place such a seemingly high limit on ash and sulphur content. It is the writer's understanding that samples of coal sold in St. Louis are analyzed by the City Laboratory. Some samples have been found to contain as high as 28 per cent ash. A few years ago, a well-known consulting engineer in St. Louis analyzed samples of coal and found they contained 7 per cent sulphur. Certainly something should be done to cut down the discharge of solids and sulphur gases from such fuel. A few years ago an aggravated case came to the writer's attention. Called in as a consulting engineer on the case, it was discovered that strenuous complaints were being made concerning the discharge of fly ash from a pulverized-coal plant. The coal used part of the time ran about 30 per cent ash. About $^1/_2$ mile from the plant, on the edge of some timberland, was ground which had never been cultivated. At this point, the deposit of ash was $2^1/_2$ in. thick, which was the accumulation of about seven years' operation of the plant. The truck farmer had had several crops ruined by this deposit. The author has explained some of the difficulties encountered in the preparation of coal. The time is not far distant when other cities using coal of high-ash and high-sulphur content, will probably require that such coal be processed before being used.

H. F. HEBLEY.[3] Modern coal preparation has made rapid strides in the Midwestern States, especially in Illinois. Hand picking of the larger sizes and screening have always been prominent features of the preparation of coal in Illinois, but the labor costs involved in cleaning of the coal by picking have in recent years increased.

The larger sizes of coal, say plus 3 in., are to a great extent sold on appearance. Notwithstanding the fact that coal-cleaning equipment, dependent on the separation of refuse from the cleaned coal by density processes would yield an acceptable product from the point of view of density separation and ash content, the poor appearance might be sufficient to condemn it. However, in many cases such hand picking does not yield the cleaning results which the popular conception attributes to it.

One of the influences, that is forcing a greater consideration of cleaning in Illinois, is the growing realization that smoke, fumes, cinders, and fly ash, which are continuously being discharged to the atmosphere in centers of large population, should be curtailed. Coal cleaning has its place in facilitating attainment of this goal.

A word of warning is required, however, to retard the idea that the cleaning of coal is the panacea for all ills. At best, coal cleaning removes the free impurities and the higher ash-intergrown coal of high specific gravity, yielding a product lower in ash. Probably its next great advantage is the increase in uniformity of the coal prepared.

It should always be remembered that Illinois coal is higher in ash than fuel produced in West Virginia, Eastern Kentucky, and some of the Pittsburgh seams. It is also a known fact that the higher the ash content of a coal, the greater is its heterogeneity. When using coal for steam-generation purposes, it is in part this nonuniformity that causes trouble in the boiler room. Generally, provided a coal is uniform, the designer of a furnace for boiler use can cope with high ash and low fusion; but if the coal changes in characteristics from car to car, the boiler-room personnel is liable to experience trouble.

As an instance, $1^1/_4$-in. screenings, with an average ash content of 14.3 per cent, may vary from 10 per cent to 23 per cent in ash, and have a heterogeneity measured by the probable error of 1.4 per cent. Such a steam coal, unless cleaned, would, under the present St. Louis Smoke Ordinance, be restricted to shipping only 4 cars out of every 100 loaded at the mine into that market.

A cleaning plant, which would reduce the ash to 10 per cent, with a probable error of only 0.6 per cent, would enable the shipping of 98 cars out of every 100 into the market. Such uniformity is naturally of great advantage to the consuming company.

The author mentioned that, where water supply is limited, elaborate settling clarifying systems must be utilized. Such clarification depends on sedimentation and also on the modern method of coagulation. Experiments have been carried on both

in this country and abroad using starch, glue, lime, and caustic soda, in attempting to coagulate the finely divided clay, which stays in suspension in the washery water, causing trouble in the washery process.

In the author's discussion of the presence of sulphur in coals produced in Illinois, he has pointed out that it exists in three recognized types. For engineers, contemplating the installation of a washery process, the pyritic sulphur is about the only type that can be readily removed by any washing process. Therefore, operators may be somewhat disappointed in the small percentage of sulphur reduction in the cleaned coal after it has been subjected to preparation.

Although cleaning has its place in the reduction of smoke and sulphurous-gas nuisance in cities, too much must not be expected of it. It is, nevertheless, a step in the right direction and, probably after uniform coals have been assured, further development along low-temperature-carbonization lines may be justified to yield a truly smokeless coal for use in the cities, where the smoke-abatement problem is acute.

Theory of Elastic Engine Supports[1]

GLENN C. BOYER.[2] It appears from a study of this paper that Fig. 3 contains the "meat" of this exposition on vibration isolation. Some authors call values of the abscissa r (which is equal to f, the forced frequency of the system, divided by f_0) the natural frequency of the system. The interesting thing about this curve is that when $f/f_0 = 0$, the entire forced impulse is transmitted. When $f/f_0 = 1$, the transmissibility becomes infinity, and when this ratio increases to 1.42 the transmissibility factor again becomes unity. As the ratio f/f_0 increases beyond 1.42 the amount of transmitted force becomes less and less approaching zero as a limit.

On the basis of this curve, it appears that what one must do in designing a foundation, where springs are utilized for isolation purposes in connection with Diesel engines operating at rotative speeds of 400 rpm and less, is to be certain that the natural frequency of the spring-supported system is low. In other words, the springs used must take considerable deflection. It is also necessary that the natural frequency of the spring-supported system not be any harmonic of the forced frequency imposed upon it by the engine, in order that an excessive amount of bouncing will not result.

There is the further question of movement of the spring in other than a vertical direction. The frequency of a spring is different when movement is at right angles to the main axis of the spring helix from that when the movement is in line with that axis. In other words, there are two different frequencies to watch.

It is interesting to note that in discussing spring suspensions which have six degrees of freedom, Kimball[3] gives four independent frequencies to which such a system responds. They are torsion, sideways tilt, up-and-down bounce, and sideways shearing oscillation. Of these four independent frequencies, that of sideways shearing oscillation has the highest frequency of the four, and in some cases might be the most objectionable.

The writer is rather impressed by the fact that for engines of any size the foundation requires a massive concrete block practically equal to the weight of the engine. In so far as he can tell from the paper, it appears that the concrete foundation slab between the springs and the engine in each case is practically equal to, if not greater than, the weight of the engine placed on top of it. From this it appears that what is actually happening on some of these larger foundations is that a mass is added to the weight of the engine as a damper before the vibration gets to the springs.

The writer was rather interested in running across this statement by Slocum,[4] printed in 1931: "Steel springs have become the standard means for cushioning shock or impact as in the case of car or automobile springs, but the problem of damping nonperiodic inertia forces of this type is quite different from that of damping vibrations of high frequency and small amplitude. For this reason springs are of limited application in damping vibration where they have been tried for this purpose, as in mounting motors in automobile chassis or for supporting floors in buildings. It has been found that if the springs are stiff enough to furnish the stability required of such construction, their natural frequency is much too high to make them effective as vibration dampers."

The writer may be wrong in his interpretation, but he is wondering what would happen to some of the four-cylinder four-cycle engines, that he has seen dancing around on concrete blocks that weighed several tons, if they were mounted on springs.

It appears that it is possible by the use of springs to amplify impressed-frequency forces under certain conditions. The writer is, frankly, rather hesitant to consider the use of springs by his own organization, and he is speaking as a consulting engineer who must go out and sell this material to clients. In other words, he must design the foundation, put it in, and guarantee results.

Professor Sayre[5] states that springs can fail due to traveling waves within the spring and resonance may occur up to as high as the twenty-fifth harmonic of the traveling wave within the spring. He states that the harmonics which are the most serious usually occur below the twelfth. That appears to mean this: If a helical spring, definitely limited at the top and bottom by plates, is subjected to a certain periodic axial force on the outside of the plates, which has a period of any time from one to nearly 25 times the frequency of the traveling wave within the spring, then, over a period of time, that spring will break.

EDGAR J. KATES.[6] The author deserves our gratitude for this paper on the theory of spring supports for Diesel engines. Despite some questions in the writer's mind as to whether spring supports are needed for properly built six- or eight-cylinder engines, the effects of the bouncing action that springs frequently introduce, and the higher cost of certain types of spring isolation compared to the use of cork or other materials, there is one thing that spring isolation has definitely achieved, i.e., the satisfactory use of four-cylinder four-cycle engines in places where heretofore such engines have transmitted objectionable vibrations to the neighborhood.

The writer fears that the many impressive-looking formulas and curves may mislead some without actual experience into believing that the art of isolating Diesel engines has now been firmly established upon a scientific basis. No doubt the author himself would be the first to agree that spring application is still in the empirical stage and that spring supports designed by experts often act quite differently from what the calculations have indicated. One of the features of spring installations is the easy accessiblity for spring removal. Such removals are required not so much on account of breakages, which are rare,

[6] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

but for the purpose of testing the action of springs of different designs. In fact, this accessibility for change is, in the writer's opinion, one of the most desirable characteristics of a spring support as compared to cork. If the cork job doesn't work it can be changed only at huge expense, whereas the spring job can readily be experimented with until it is right.

If spring supports had no drawbacks they would, of course, always be used in preference to cork. The fact is, however, that many cork isolating installations are still being put in because cork is generally much cheaper.

In Figs. 3, 4, and 5 the term transmitting effect is used. Would not transmitted force be a better designation?

The author states that "damping is decidedly harmful as it increases the transmitting effect of vibrations," and the curves in Fig. 4 seem to bear him out. However, the writer believes this is another case where the theoretical study has been incomplete. Despite the author's conclusion that the low damping coefficient of steel springs contributes greatly to their effectiveness, the writer's opinion is that, in many cases, the action of spring supports would be improved by applying a certain amount of restraint and controlled damping.

The author has devoted some much needed attention to the bouncing effect caused by spring isolators. However, the writer still remains unconvinced that the bouncing action is as trivial as the author implies. It should be noted that in Fig. 6 he is comparing the bouncing effect or operating amplitude of the spring-mounted engine to that of an "ideal system" which is "an imaginary system suspended in space and provided with an infinitely elastic suspension." But what is really of interest is the bounce of the spring-mounted engine compared to one bolted down to a heavy foundation, which is just the opposite of the "ideal system." Consequently the author's statement on page 33 that, in an elastic support with a frequency ratio of 5 to 1 and with zero damping, "the amplitude of motion will be within 4 per cent of the ideal engine," means nothing as a practical matter, and the conclusion he thereupon draws that the "motion of the mass would be virtually imperceptible" is not justified. That these operating amplitudes, or bouncing actions, are not in fact negligible is shown by the figures of from 0.004 to 0.006 in. which the author himself mentions on page 35 and by amplitudes up to 0.018 in. which the writer has measured.

Spring supports are a valuable contribution to the art of vibration isolation, but much fundamental study on them still remains to be done.

K. J. DeJuhasz.[7] By concentrating on a troublesome problem of engine installation, and palliating the nuisance effect of engine vibration on adjacent structures the author performs a valuable service for the Diesel industry. This paper clarifies in many respects the theory and application of elastic supports; some aspects of this subject have, however, not been sufficiently explained.

The helical spring has a certain longitudinal stiffness, also a certain lateral stiffness which in general differs from the former. Hence the system, consisting of the mass of engine plus foundation and the spring, will have a certain natural frequency in the longitudinal direction, and another in the lateral direction. When the six degrees of freedom of the engine are considered, both the longitudinal and the lateral frequencies come into play. The author restricted his treatment to the vertical motion only (i.e., motion with one degree of freedom). In isolators with lateral motion is there a definite optimum relationship between longitudinal and lateral stiffness?

The author uses somewhat interchangeably the terms "isolator," which correctly indicates the function, and "damper," which is a misnomer as damping is undesirable as pointed out by the author.

In Fig. 3 the exact meaning of the term "transmission effect" is not given. Does it refer to amplitude, or energy?

F. L. Yerzley.[8] The writer has enjoyed Mr. Rosenzweig's paper, but does not agree with the general statement that the stiffness of rubber is from two to three times greater under a dynamic than under a static load. The statement may be true, however, under certain conditions with certain compositions.

In the literature on the mechanical characteristics of rubber one frequently encounters the statement that the modulus of rubber is a function of the speed of the test. Therefore, when rubber is to be used as an elastic support for vibration isolation, these mysterious changes would be expected to come into play. Hysteresis, one factor, logically can be expected to produce changes in the elastic moduli as a function of frequency. It is further well established that temperature changes alter the moduli to an extent dependent upon the composition of the vulcanizate. Beyond these two factors, it is not evident why dynamic and static moduli over the same load range should differ.

Rubber is used effectively and widely in both shear and compression to isolate vibration. It has also been used commercially in tension. Since its peculiar elastic properties in many instances make shape a relatively unimportant factor, simplicity and economy may be appreciable. This is especially true where the conformity of rubber to rough surfaces eliminates the necessity of expensive machined fits. The present importance of rubber is based to an appreciable degree upon its dependability after the desired initial characteristics are attained. The writer believes that the data on a range of commercial rubber compounds, given in Table 1, are characteristic of usual performance. Test cylinders $^1/_2$ in. high and $^3/_4$ in. in diameter were subjected to static and dynamic compressive loads. Unfortunately the details of the method must be discussed at some other time,[9] but the broad method of approach has been described elsewhere.[10]

Since the load-compression curve for rubber is not usually a straight line except near the origin no single value of the modulus is adequate for all calculations. This is well illustrated by the fact that the tangent to the load-compression curve at the origin is less than that at the various average loads used in the dynamic tests. The static and dynamic moduli at the same load are for all practical purposes the same. As a matter of general interest, resilience per cycle of loading and unloading in the dynamic-test ranges is also tabulated, showing values from 91.9 to 65.8 per cent depending upon the composition.

Author's Closure

Mr. Boyer's statements may be summarized under the following headings:

1 Necessary deflection of spring
2 Isolation for all degrees of freedom
3 Necessary weight of foundation to insure minimum movement
4 Application of vibration isolators to all types of engines.

It is believed that the answer to all these points can be found in the paper. Obviously points 1 and 2 have to be considered simultaneously. On page 36 reference is made to the pendulum action of the spring isolator in providing isolation for movement of the foundation in different directions. Merely to use any spring is rarely sufficient to produce these results. As in all mechanical devices, the application of one single member, no matter how excellent it is, does not provide a satisfactory solution. It is rather the assembly of the complete unit in all its details which is of importance. In this respect the vibration isolator is no exception. It has to be designed to fit each particular case.

The necessary mass for the foundation can be easily calculated from Fig. 9 and the example given. It is the dynamic-balance coefficient (which depends upon the perfection of balance of the engine) and the permissible amplitude of the movement which control the size of the stabilizing mass, and not, as often erroneously assumed, the speed or frequency of the engine.

High-speed engines usually provide a relatively large stabilizing mass in the engine weight and therefore may require no additional concrete. This is particularly true in such engines where primary and secondary forces and moments are balanced. The omission of the concrete foundation on large engines, even of this class, is not always possible, because without it engine and generator cannot be aligned properly. In such cases, the mass is often immaterial; what is required is a stiff subbase which can be either of cast iron, steel, or concrete. Sometimes, by providing a stiff common subbase, it is possible to mount engine and generator directly on vibration isolators.

However there are many cases of large and slow-speed engines where concrete foundations are required not only for alignment but also for the purpose of providing room for the springs. To place springs from 10 to 15 in. long under the subbase is not desirable, especially when they can be easily assembled within the subbase or foundation. With these foundation assemblies, spring units and satisfactory isolation can be provided and yet raise the foundation but $^1/_2$ in. above the substructure.

Many small three- and four-cylinder engines are mounted directly on vibration isolators without any concrete foundation. Larger engines are provided with the necessary foundation weight and all of them operate satisfactorily for years. But even though the amplitude of motion is greater than with unisolated foundations it is, in the author's opinion, better to let an engine move with an elastically supported foundation instead of letting it strain and damage itself because of a rigid and unyielding support.

The author's experience with a six-cylinder engine is interesting in this connection. Two identical engines were mounted on one foundation. Operation of the first engine was practically perfect, with just a slight quiver to the foundation. When the second engine was started the movement of the foundation became excessive, perhaps as much as 0.05 in. After a careful investigation, an unbalance in the flywheel was detected. When this was corrected by means of a lead weight, the excessive movement of the foundation was completely eliminated. In this case an unbalanced flywheel, probably furnished with many an engine, upset the stability of the entire foundation assembly. If that engine had been mounted on a rigid foundation serious vibration transmission would have resulted as well as damage to the engine, the cause of which might have baffled the operating engineer. The yielding assembly and the springs, however, immediately indicated the presence of unbalance.

To summarize, vibration isolators can be applied to all types of engines using one of the different methods described in the paper. The necessity of providing a stabilizing mass in the shape of a concrete foundation is controlled by the arrangement, design, and type of engine. Practical experience has indicated that the following relative stabilizing masses give satisfactory results to be checked, of course, by the mathematical calculations:

Single-cylinder engine	20
Two-cylinder engine	10
Three-cylinder engine	5
Four-cylinder engine	3
Six- and eight-cylinder engines	0

The author is familiar with the statements relating to the value of springs in Mr. Slocum's book referred to by Mr. Boyer, and is certain that Mr. Slocum, in the light of the new developments, has changed his opinion since 1931.

Correctly designed springs will last indefinitely and break only when there is a defect in material. The reason for this is twofold, as far as vibration isolators are involved: The stress at which the springs operate is low—55,000 psi on an average—and furthermore the change in stress under operating conditions is extremely small. From his own experience in thousands of installations, the author can most assuredly state that spring failures are practically nonexistent.

The experience of Mr. Kates in one plant is illustrative of the statements made in the paper. Three Diesel generator sets are installed in this plant in accordance with his specifications. The foundations of the six- and five-cylinder engines are isolated by means of Korfund cork and that of the four-cylinder engine by means of vibrodampers of the U type. As the engines are running side by side and the operating conditions are identical, an excellent comparison is afforded. Vibration transmission from the six- and four-cylinder engines is imperceptible, and slightly noticeable on the five-cylinder engine which, on account of its primary unbalanced moment, was to be expected. It was considered inconsequential, however, as the plant is not located in a high-class residential district. The bouncing action, as Mr. Boyer and Mr. Kates call it, was not perceptible on the six-cylinder unit. It was barely perceptible on the five and the four. The engines have been giving satisfactory service for almost a year.

It would be possible to work out on paper a correct solution of spring isolation for every case if the engine manufacturers could furnish absolutely correct data on balance, and if a perfect vibration isolator were available. Such perfection is impossible to attain and therefore, as Mr. Kates so correctly stated, the possibility of adjustment after installation is of much importance, so easily accomplished with springs, and so insufficiently attainable with organic materials.

The expected movement of an isolated foundation can be easily calculated and one is referred to the explanations given in the paper in connection with Figs. 6, 7, and 9. If one assumes that an unisolated foundation operates along the 0.6 abscissa of Fig. 6, the correctly isolated foundation will have an oscillation 50 to 100 per cent in excess of the former, which means that oscillation can be restricted to a permissible maximum.

The statements of Professor DeJuhasz in regard to the stiffness of a coil spring in a longitudinal and a lateral direction are quite correct. The stiffness of this type of spring in a lateral direction is such as to make efficient vibration isolation impossible for all six degrees of freedom. Therefore, other means have to be provided in the isolator beside the spring. The pendulum action obtainable in some of the designs referred to in the paper has proved highly satisfactory and efficient for this purpose.

The term "isolator" to designate the isolating medium is as Professor DeJuhasz correctly states preferable to the term "damper." The latter was used in the paper in connection with an isolator known to the trade as "Vibro Damper."

Figs. 3, 4, and 5 indicate the relative transmitted energy of the exciting forces and Fig. 6 the operating amplitudes of isolators for different frequency ratios.

The author is not aware of any fatigue of concrete foundations due to the continuous movement when mounted on springs. There have been a number of cases though, where mill foundations cracked every few months due to excessive vibrations, in which the trouble was overcome by isolating the foundation properly.

The experience with these mill foundations fully substantiates the statement made previously that it is far better to allow a machine to move with an elastically supported base, instead of letting it strain and damage itself on a rigid foundation. The flexible joints of the human body are constantly used for a similar purpose. The slight movement of a foundation may still be called objectionable but it is certain that within a few years it will be looked upon as a matter of course. Opinions have changed about many things which at one time were considered undesirable and even dangerous, but are now accepted as satisfactory and correct.

The Mechanical Characteristics of Rubber[1]

J. F. Downie Smith.[2] For many years it was difficult to get from the rubber companies any data which would help the mechanical engineer in the design of rubber products. In most cases it was necessary to state the problem completely to a representative of a rubber company who would, after consulting his engineering staff, submit a recommended design. This led to a great amount of wasted effort, for frequently the application would not permit the use of rubber, ordinarily because of space limitations, but the designer could not tell about this beforehand.

Within the last few years, however, the attitude of some of the rubber companies has changed, and now one or two of the manufacturers will readily supply upon the request of a responsible designer the information he needs, if it is available. As a sample of this present spirit of helpfulness there is the paper by F. L. Haushalter, who has supplied information greatly needed by the engineer interested in applying rubber products to industry.

It ought to be perfectly clear to the rubber companies that the less mysterious the properties and limitations of each product the more readily will it be accepted by mechanical engineers. At present much opposition to its use is based upon ignorance of its properties.

In a previous paper,[3] the writer quoted data[4] to show that Poisson's ratio varied only a few per cent from 0.5, even for elongations of 700 per cent, and thus claimed that the modulus of elasticity in compression should be three times that of the modulus of elasticity in shear. It is gratifying to find that the data quoted by the author on the compression of rubber between lubricated surfaces bear out this belief.

It is obvious that more data must be taken on rubber loaded in compression if a general theory is to be proposed for this case. The adoption by the author of a modulus of elasticity in compression of 6.5 times the modulus of elasticity in shear is helpful to the designer, but the limitations of thickness to effective width prohibit its use in many applications.

The author states that a simple shear sandwich can be calculated from the equation

$$d = WT/AG \quad [1]$$

where d = deflection, in.
W = load, lb
T = initial thickness of rubber in one sandwich, in.
A = area absorbing load W, sq in.
G = modulus of elasticity in shear, psi

A slightly more accurate formula is

$$\text{strain (deg)} = 57.3W/AG \quad [2]$$

Of course, d/T is approximately equal to the strain in radians, so that Equation [1] gives a first degree of approximation.

Again, the author states that rubber torsion bushings can be designed by use of the formula

$$\theta = \frac{WL}{4\pi bG}\left(\frac{1}{r_1^2} - \frac{1}{r_2^2}\right) \quad [3]$$

where θ = angular deflection, radians
WL = torque, in-lb
b = effective length of rubber section, in.
G = modulus of elasticity in shear, psi
r_1 = inner radius of rubber section, in.
r_2 = outer radius of rubber section, in.

Equation [3] is again only a first degree of approximation; it is the first term of an infinite series. A more accurate equation is

$$\theta = \frac{WL}{4\pi bG}\left[\left(\frac{1}{r_1^2} - \frac{1}{r_2^2}\right) + \frac{1}{9}\left(\frac{WL}{2\pi bG}\right)^2\left(\frac{1}{r_1^6} - \frac{1}{r_2^6}\right) + \frac{2}{75}\left(\frac{WL}{2\pi bG}\right)^4\left(\frac{1}{r_1^{10}} - \frac{1}{r_2^{10}}\right) + \cdots\cdots\right] \quad [4]$$

F. L. Yerzley.[5] Mr. Haushalter is to be commended for the many contributions he has made to the improvement of mechanical structures by the application of rubber. His present paper based upon successful practice adds still another important chapter to the growing volume of literature on its mechanical characteristics. In connection with the paper, it seems worthy of

emphasis that a correlation between durometer hardness and modulus is presented for the range of values useful in mechanical applications. It is no less important that the author has defined limits for maximum permissible loads.

In this paper, one is reminded, however, of gaps in present knowledge which still remain to be filled. The relationship between durometer readings and moduli affords a useful basis for preliminary calculations. Yet it is not possible at the present time to generalize the properties of rubber to the point where it may be expected that a compound of a certain durometer hardness will be suitable for any use requiring a compound with the modulus indicated by the relationship. Compounded and vulcanized rubber is a heterogeneous mixture of multifarious pigment particles, immense organic molecules, and other substances in various degrees of chemical and physical combination. The relative states of the various phases are subject to disturbance by different factors including temperature, degree of strain, chemical instability, and penetration of surrounding media. Underlying principles are still evasive. The end result of any design, therefore, for rubber as for most other engineering materials, must still be confirmed by stringent service tests.

Author's Closure

Dr. Smith is perfectly right in his analysis of the formulas for both the simple shear sandwich and for the rubber torsion spring. For angles up to 30 deg the correction is almost negligible, and it is in this range that most of the applications of rubber springs will be found. For greater deflections there is another factor which must be considered.

It was pointed out by the author in referring to Fig. 17 that the value of the shear modulus G was constant only up to about 20 per cent deflection for 60-durometer rubber and up to about 40 per cent deflection for the very soft rubbers. The real reason for this is that the stress-strain curves of these rubbers in tension are straight only up to those values, then bend toward the deflection axis, indicating a softening of the rubber. It is chiefly for this reason that it is best to limit the deflection in shear-type springs to the limits of the straight portion of the stress-strain curves, for in most applications of springs it is not desirable to have a decrease in the rate of the spring coming in at such a place.

Obsolescence in Woodworking Machinery[1]

E. Dillon Smith.[2] This paper suggested many instances in the woodworking industry where management found equipment obsolete before the physical property had been fully depreciated on the books. Of course such examples are not unique to this industry alone. In fact air lines have had to deal with the obsolescence problem to a greater degree than perhaps any other industry. A brief comment on the methods used by some air lines to handle this problem may, therefore, be of general interest, such being, by inference, applicable to the woodworking industry.

Until recently, when the Civil Aeronautics Authority was created, the air lines had to deal with at least the following governmental bodies when considering obsolescence and depreciation: Bureau of Air Commerce of the Department of Commerce, Post Office Department, Interstate Commerce Commission, and the Treasury Department. If the woodworkers have had difficulties in handling obsolescence before one Federal body, they should consider themselves lucky in comparison to the air lines.

Fortunately for the air lines, however, they have kept complete records on each and every piece of physical equipment. Different depreciation rates are charged on each item, rather than one rate on all equipment. Irrespective of this practice, the air lines have found that some equipment was either still in operation after it had been completely depreciated on the books or that it was obsolete before it had been fully depreciated. In some of the air lines, the management has rather successfully avoided this difficulty by having current analytical studies made of policies and practices, and by always being informed on the tendencies being exhibited in the art of management and equipment design. Thus, some air line managers have learned to be sufficiently alert in their field as to guard almost wholly against being caught with bad equipment. Sometimes this is done by making advantageous sales of old equipment at a net book profit rather than at a distress-sale price, and then buying new and more modern equipment. It would seem, therefore, that one way in which some of the air lines have avoided being caught with obsolete physical equipment has been to employ an alert and informed management.

Author's Closure

In the last sentence of his excellent discussion, Professor Smith strikes directly at the heart of this important and perplexing problem. What is needed is "an alert and informed management." In that connection, however, it should be noted that a management may seem to be both alert and informed and still not realize the increasing importance of the obsolescence problem. This is more apt to be the case in the older industries, where obsolescence was formerly not so important, than in such industries as the air-transportation industry, where obsolescence has been of great importance from the very beginning of the industry.

Professor Smith refers to methods used in the air-transportation industry to minimize the bad effects which often result from the general inability of any industry to predetermine the useful life of its depreciating assets. While the details may differ, every industry could well afford to follow the plan mentioned by Professor Smith, namely, "by having current analytical studies made of policies and practices, and by always being informed on the tendencies being exhibited in the art of management and equipment design."

Pitot Tubes in Large Pipes

By EDWARD S. COLE[1] and E. SHAW COLE,[2] NEW YORK, N. Y.

Comparative calibrations with two different types of pitometer, which reacted differently to angular flows, indicated the absence of angularity effects in large pipes. To check this the authors made actual measurements in two large pipes and found the angularity to be less than 3 deg.

Comparisons with other methods of flow measurement in two large pipes are presented together with velocity traverses in these and other conduits. The velocity traverses show the smooth flow pattern found in large pipes at good gaging points. The authors also discuss the value of pipe factor, i.e., the ratio of mean to center velocity, for determining the suitability of a gaging point as well as for making short tests quickly and accurately, or for making continuous-flow measurements.

IN A previous article[3] one of the authors discussed the history and development of the pitot tube as means for measuring the flow of water in a closed conduit. Comparative tests were conducted in a 12-in. pipe line, and calibrations were made under a number of different conditions to determine the possible source of errors, and to establish the degree of accuracy with which flow could be measured in pipe lines.

For many years the principal source of error has been thought to be angular flows past a pitot tube and, while the comparative tests in the 12-in. pipes proved that the effect of these flows was negligible, it was thought that this work should be extended to pipe lines of larger diameter.

Two types of combined pitot tubes were used for the tests described in this paper, namely, the reversible pitometer widely used in waterworks analysis, and the heavy-duty pitometer frequently used for measuring the speed of ships. Figs. 1 and 2 show these instruments.

[1] President, The Pitometer Company, Engineers, and Pitometer Log Corp. Mem. A.S.M.E. Mr. Cole received the degree of M.E. from Cornell University in 1894 and from that date until 1902 served on the staff of John A. Cole, consulting engineer, Chicago, working on the design, construction, and management of city waterworks plants in the Middle West. In 1896 he developed the pitometer. As a member of the Department of Water Supply, Gas, and Electricity of New York, N. Y., he was in charge of water-supply studies with the pitometer during 1902 and 1903. Since that time he has conducted pitometer investigations throughout the country.

[2] Field Engineer, The Pitometer Company. Mr. Cole was graduated with an A.B. degree from Dartmouth University in 1930, and received his C.E. degree from the Thayer School of Civil Engineering at Dartmouth in 1931. From that date until 1934 he was connected with the Pitometer Log Corp. and worked on various development problems. In 1934 he joined the field staff of the Pitometer Company, Engineers, and has been engaged in pitometer surveys of waterworks throughout the country.

[3] "Pitot-Tube Practice," by Edward S. Cole, Trans. A.S.M.E., vol. 57, August, 1935, paper HYD-57-8, pp. 281–294.

Contributed by the Hydraulic Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Scope of Tests

The program of test and investigation described in the paper is divided into four sections as follows:

1 Determination of pitometer coefficients for still-water conditions or equivalent, and the effect of angularity upon registration of the instrument.

2 Tests in a 40-in. pipe in which both types of pitot tubes were used, and in which the discharge was measured by weighing tanks as a means of checking the discharge measurement established by the pitometer. Additional tests on the angularity of flow and its effect upon pitot-tube coefficients were also included in the studies of the 40-in. conduit.

3 Angularity tests were made in a 40-in. and in a 78-in. diameter steel penstock to determine whether the flow pattern in these larger conduits differed from that found in smaller pipes.

4 Velocity traverses were made in a number of large pipe lines in connection with flow measurements. These curves with their pipe factors (ratio of mean velocity to center velocity) are an indication of smoothness of velocity distribution in such conduits.

Calibrations

The previous paper[3] described three methods of calibration for the reversible pitometer and showed that still-water ratings on the revolving boom at the Alden Hydraulic Laboratory were practically identical with pitometer coefficients obtained in the 36 × 16-in. venturi meter. It was found that no correction for the small projected area of the rod was required for the calibration in the venturi throat; such differences as were found amounted to a small fraction of 1 per cent and were within the experimental error.

When check calibrations were made in a straight 12-in. pipe, which was free from venturi effects, the rod correction was found necessary and investigation showed that its magnitude was a direct function of the projected area of the rod. Several different methods of evaluating this correction were employed and an average correction curve established.

Angularity Characteristics

With still-water ratings or their equivalent, the pitometer orifices are set in the direction of flow. When the instrument is rotated through various angles, changes in registration occur. To establish these relations on both the reversible and the heavy-duty pitometers, tests were made in the 16-in. throat of the venturi meter, observing the change in coefficient caused by various departures of the axis of the instrument from the normal direction of flow.

Basing the values on velocity readings, the change in registration with angularity would indicate slightly higher velocities than true values or would require a decrease in coefficient.

Fig. 3*A* presents the characteristics of the reversible pitometer. The two parts making up the total error of +0.75 per cent at 5 deg will be noted. One of these parts is the change in the pitometer readings, while the other is the cosine curve which is the theoretically correct reading, the sum of the two being the full error in reading the axial component ($V \cos a$) of an angular flow a.

The characteristics of the heavy-duty tube, with a $^5/_{16}$-in. tip, were obtained by the same method and are represented in Fig. 3*B*. Here the error is shown as the difference between the

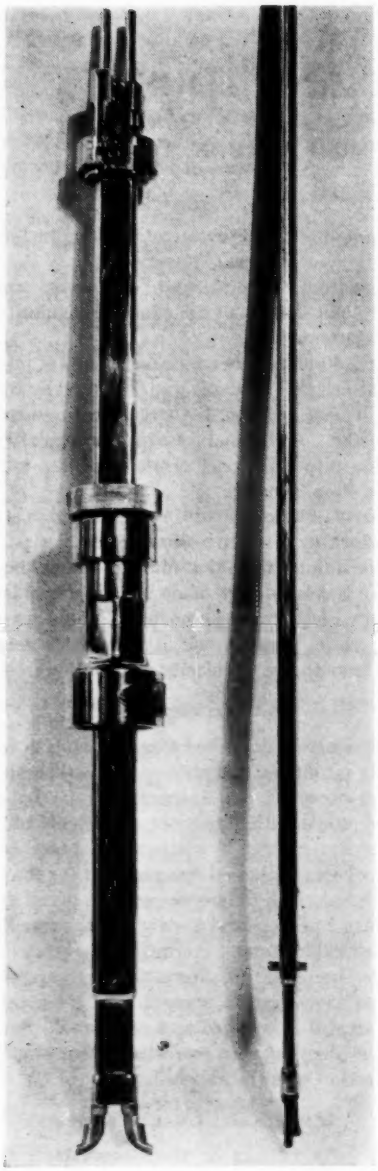

FIG. 1 REVERSIBLE PITOMETER

pitometer readings and the cosine values. As will be seen, this type of tube follows the cosine value closely to 6-deg angularity.

It will be noted from Fig. 3 that the two types of pitometers have substantially different angularity characteristics and should the average angularity of flow in a normal conduit reach as much as 6 deg the discharge measured by the two types under the same conditions should show measurable differences.

To investigate this possibility, tests were made in a 40-in. pipe with both meters and the flow was checked by a calibrated weir. A description of the tests and their results is included herein.

STUDIES MADE IN 40-IN. PIPES

At the Alden Hydraulic Laboratory, Worcester, Mass., a number of tests were made on a 40-in. pipe line to check the coefficients of two of the reversible-type pitometers for comparison with the coefficient of the instrument determined in the 16-in. throat of a venturi meter. Similar calibrations were made with a heavy-duty pitometer, using the same procedure.

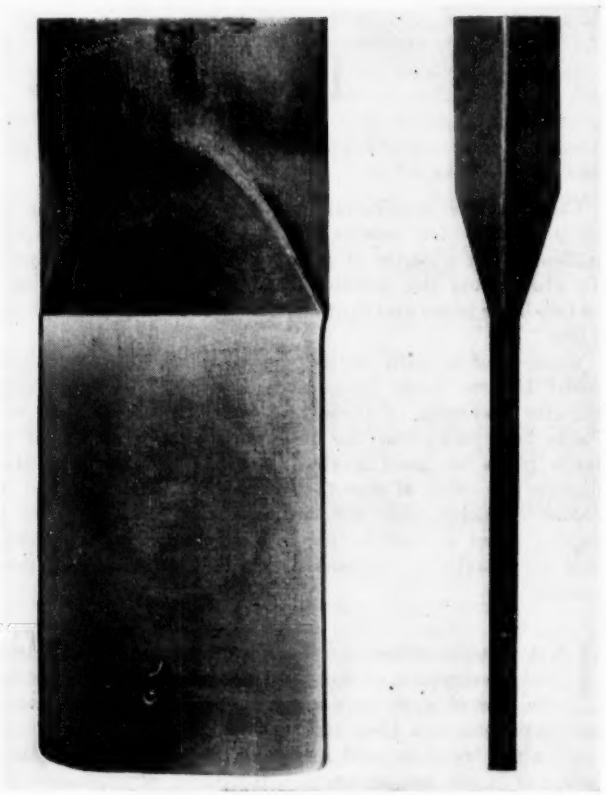

FIG. 2 HEAVY-DUTY PITOMETER

The Reversible Pitometer. The gaging station for this reversible pitometer was located 100 ft below and 40 ft above any departure from a straight section. For traversing, the tube was inserted through 1-in. cocks 90 deg apart, and for calibration the orifices were located at the center of the pipe. The flow was measured over a 10-ft contracted weir which had been calibrated by incremental measurements using a weighing tank.

The first step was to determine the pipe factor from double traverses of the pipe. Sample curves for the reversible pitometer are shown in Figs. 4*A* and 4*B*. Readings were taken at each desired point on the diameter and converted to velocities using the corresponding instrument coefficient established in the 16-in. venturi throat. The plotting of this velocity determination

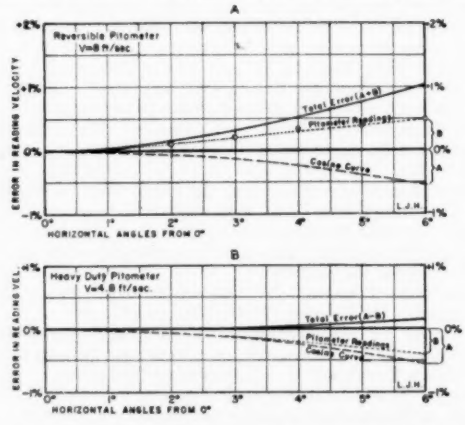

FIG. 3 ANGULARITY CHARACTERISTICS OF REVERSIBLE AND OF HEAVY-DUTY PITOMETERS IN A 16-IN. VENTURI THROAT
(Alden Hydraulic Laboratory, Worcester, Mass., 1934.)

instead of the square root of the deflection takes into account changes in the instrument coefficient at different rates of flow.

This discharge measurement was then checked by another set of runs using the 40-in. pipe with the pitometer at the center of the pipe and the flow measured by the previously calibrated weir. By applying the pipe factor to the center velocity readings a new coefficient of the instrument was secured.

The procedure was as follows: After the discharge had been set to a desired value, about 10 or 15 min were allowed to elapse to secure steady-flow conditions in the penstock and over the weir. The U-tube deflections with the orifices at the center of the pipe were then read in feet of water. Ten readings per minute were made by an experienced observer, and the figures averaged on a calculating machine. Ten readings of head were taken for each position of the orifices shown in Fig. 1, that is, first with one tip upstream and then with the other tip upstream. The head on the weir was read and then the discharge was adjusted to a new value for the next test.

The Heavy-Duty Pitometer. Tests with the heavy-duty pitometer having the $^5/_{16}$-in. tip were carried out in the same 40-in. steel penstock using the same procedure as with the reversible pitometer. The gaging station was at a slightly different location due to the necessity of using much larger entrance connections for the heavy-duty tube.

The pipe factor shifted about 1.5 per cent, averaging 0.808 for the reversible tube and 0.796 for the heavy-duty pitometer. The double traverses are shown in Figs. 5*A* and 5*B*. These discharge measurements were also checked in the 40-in. pipe against the calibrated weir in the same way as the reversible tube.

Correction for Projected Area of Rod. In utilizing the test readings of velocity, it is necessary to apply a correction for the area of the pitometer rod projecting into the pipe. Several methods may be used as determined from tests[3] made at Worcester Polytechnic Institute and at the University of Pennsylvania in 1934 and more recently from additional tests[4] at Worcester.

In general, tests were run in various sizes of pipe, holding the diameter of the rod constant, or in the same pipe with different diameters of pitometer rods. The change in coefficient was related to the reduction in area caused by the rod when the orifice was at the center of the pipe.

The comparison of the corrections for the reversible rod as obtained by the two different procedures in relatively small test sections (4- to 16-in. diameters) shows a spread of about 1 per cent at the 12-in. size, at which point the average change in the coefficient is 2 per cent from the still-water rating. The area occupied by the rod in this case is about 1.6 per cent of the pipe

[4] "Investigation of Errors in Pitot Tubes," by C. W. Hubbard, presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., December 5–9, 1938. See pages 477–506 of this issue.

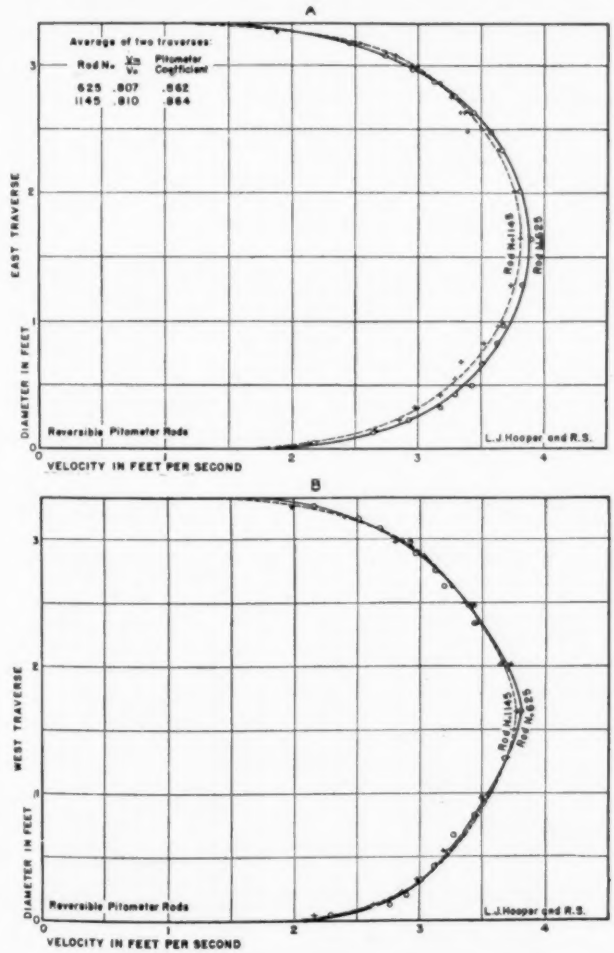

FIG. 4 VELOCITY TRAVERSES IN THE 40-IN. RIVETED STEEL PENSTOCK OF THE ALDEN HYDRAULIC LABORATORY, FOR REVERSIBLE PITOMETER, 1935

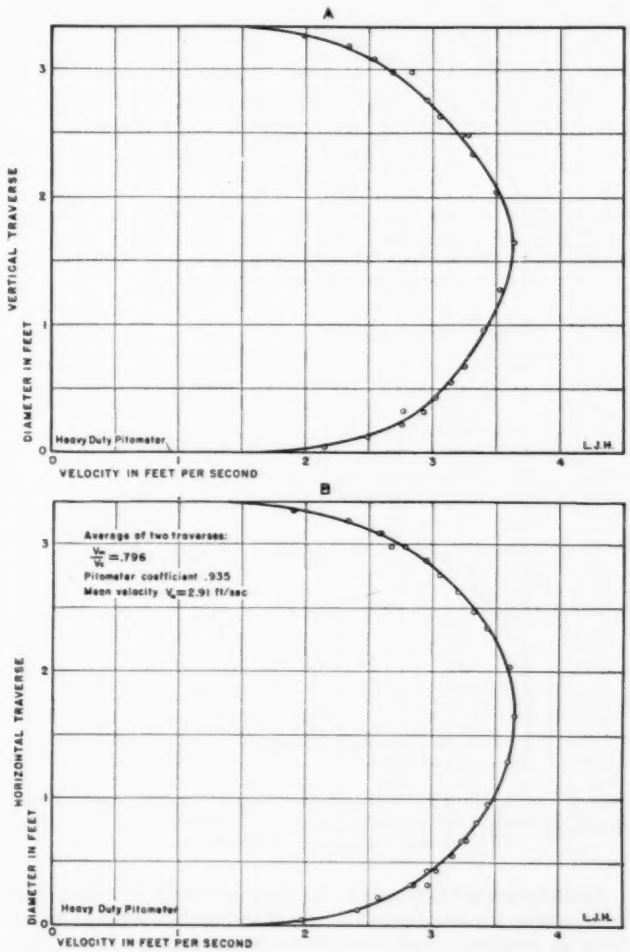

FIG. 5 VELOCITY TRAVERSES IN THE 40-IN. RIVETED STEEL PENSTOCK OF THE ALDEN HYDRAULIC LABORATORY, FOR HEAVY-DUTY PITOMETER, 1935

area; however, as the diameter of the pipe increases, the area decreases to 0.5 per cent in the case of the 40-in. pipe, adding about 0.6 per cent to the coefficient.

With this smaller correction the spread between the two methods of determination is about one fifth that with a 12-in. pipe, or expressed another way the two methods differ from the average curve by only 0.1 per cent, which is within the limits of accuracy of these tests.

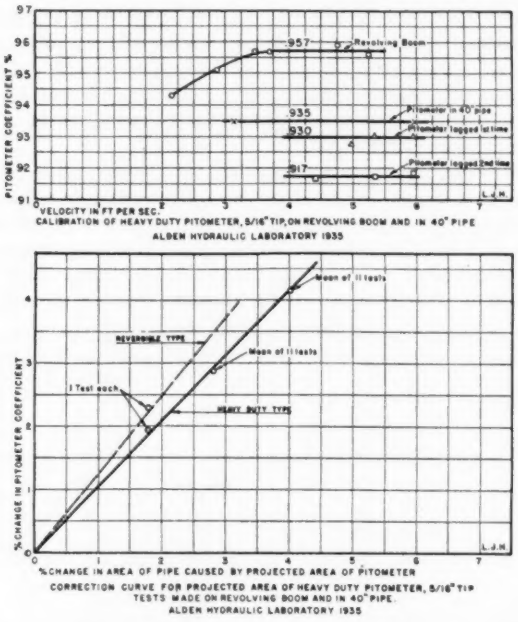

FIG. 6 TOP: CALIBRATION CURVE OF HEAVY-DUTY PITOMETER TIP. BOTTOM: CORRECTION CURVE FOR PROJECTED AREA OF HEAVY-DUTY PITOMETER—MEAN CORRECTION CURVE FOR REVERSIBLE PITOMETER ADDED FOR COMPARISON

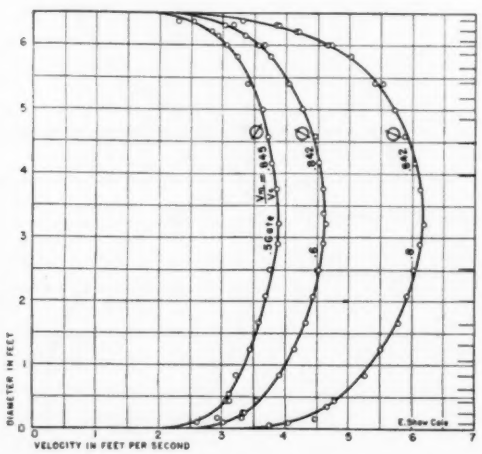

FIG. 7 VELOCITY TRAVERSES IN THE 78-IN. WELDED STEEL PENSTOCK AT THE PLANT OF THE CENTRAL VERMONT PUBLIC SERVICE CORP., RUTLAND, VT., 1937

Similar studies were made in the 40-in. pipe with the heavy rod by changing the rod diameter. Fig. 6 shows the results of these tests as compared with still-water ratings and also gives the calibration correction curve for use with the heavy-duty pitometer. The previously determined correction curve for the reversible pitometer is shown for reference. The two relations do not differ greatly and serve to confirm still further the accuracy of this method.

Due to the large diameter of the heavy-duty rod the area occupied is greater than with the reversible rod, being 1.7 per cent of the total area of the 40-in. pipe. From the correction curve, this will add 1.8 per cent to the coefficients.

Results. Applying the rod correction to the coefficients of the two types of pitometers and comparing them with the still-water rating or its equivalent, the results shown in Table 1 are secured.

From studies made by Allen,[5] Hubbard,[4] and one of the authors[3] of this present paper angularities, ranging from 6 deg down to 2 deg, have been measured in the 40-in. pipe by various means. The coefficient corrections from Figs. 3*A* and 3*B* corresponding to these degrees of angularity are shown in Table 2 compared with the results of the calibration runs. It will be seen from this comparison that either the angularity has little or no effect on the coefficient of the pitometer, or else the amount of angularity

TABLE 1 COEFFICIENTS OF REVERSIBLE AND HEAVY-DUTY PITOMETERS IN 40-IN. PIPES COMPARED WITH STILL-WATER RATINGS OR EQUIVALENT

Reversible pitometer (coefficients obtained at about 3 fps):	
Uncorrected coefficient of instrument in 40-in. pipe	0.863
Addition for projected area of the rod	0.006
Corrected coefficient of instrument in 40-in. pipe	0.869
Coefficient of instrument in 16-in. throat of a 36-in. × 16-in. venturi meter (equivalent to still-water rating at the revolving-boom station)	0.870
Difference from still-water rating, per cent	0.100
Heavy-duty pitometer:	
Uncorrected coefficient of instrument in 40-in. pipe at velocities of about 3 fps	0.935
Addition for projected area of the rod	0.018
Corrected coefficient of instrument in 40-in. pipe	0.953
Coefficient of instrument in still water from boom calibration at velocities varying from 2.1 to 5.3 fps	0.957
Difference from still-water rating, per cent	0.400

NOTE: Both of these check calibrations in the 40-in. pipe agree very closely with the still-water rating or its equivalent.

TABLE 2 COEFFICIENT CORRECTIONS FROM FIG. 3 CORRESPONDING TO DEGREES OF ANGULARITY MEASURED BY ALLEN,[5] COLE,[3] AND HUBBARD[4] IN THE SAME 40-IN. PIPE

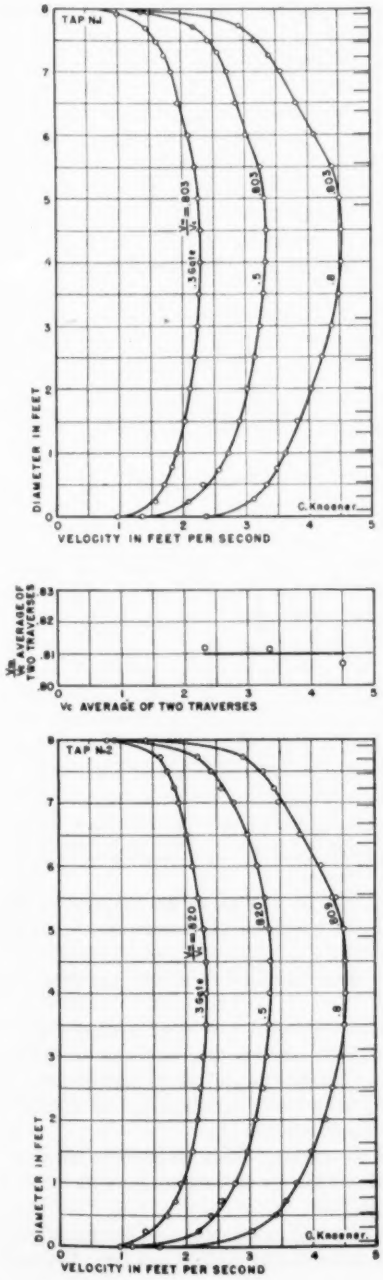
present is much less than the 5 to 6 deg measured previously by Cole[3] and Allen,[5] respectively.

To check these conclusions, another series of tests were made to measure the angularity existing in the 40-in. pipe and in a 78-in. conduit.

Angularity Measurements in Large Pipes

A variety of means have been suggested for measuring the angularity of flow in a pipe line. For the most part these are composed of small vanes which give either a mechanical or electrical indication outside of the pipe. In spite of refinements, most vane measurements have been subject to error due to friction as well as disturbances caused by the shape and size of the vane.



Previous to this time, a study of the dispersion of salt as it passed down a pipe was the only method which did not include mechanical errors. This method however, gave maximum angles and it was impossible to determine the average.

Hubbard[4] recently designed and constructed an angularity indicator composed of a small plow-shaped vane that was electrically connected to a chronograph. The electrical impulses were analyzed by means of the Law of Probability and the mean angle was thus determined.

Hubbard's first instrument was not adapted for field use and in order to carry out more extensive tests one of the authors of this present paper contributed a second instrument of improved design. Subsequently, Hubbard and one of the authors made angularity measurements in two large pipes where the flow characteristics had been determined by pitometer traverses.

The 40-in. pipe at the Alden Hydraulic Laboratory, mentioned previously, was used for one of these tests. Measurements at various distances from the center gave average angles that were less than 2 deg.

A 78-in. steel penstock was also tested. This pipe, located at the Glen Station of the Central Vermont Public Service Corporation, Rutland, Vt., is constructed of welded steel, with telescopic sections, and has plates $^5/_{16}$ in. thick. The gaging station where

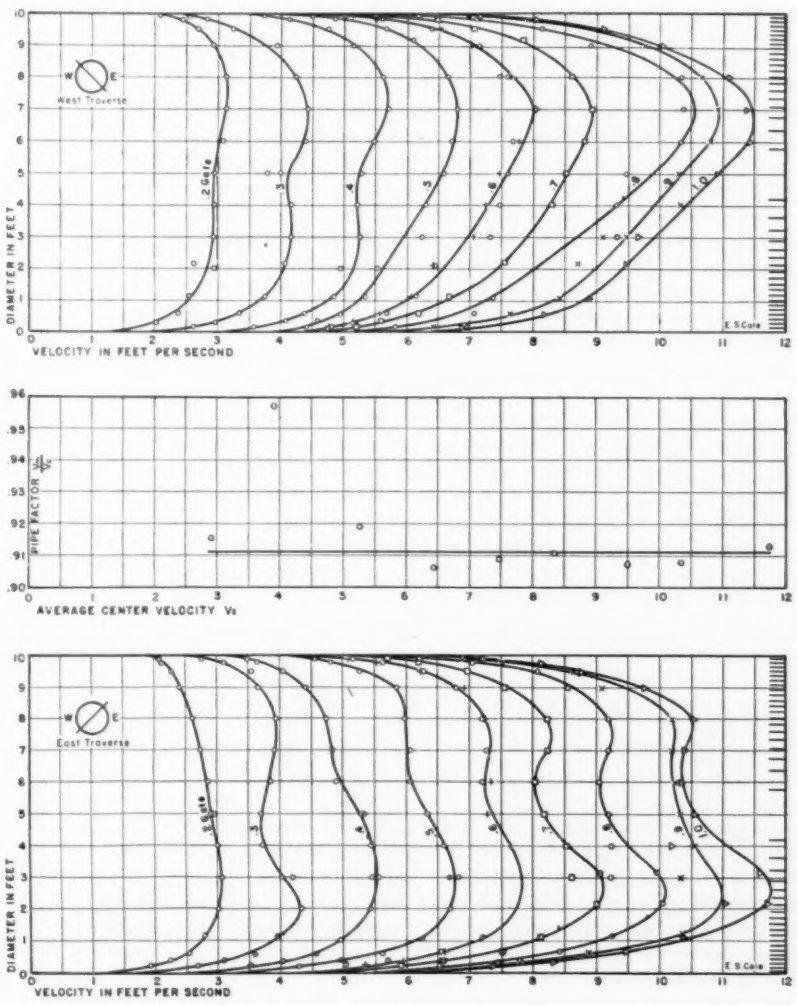


FIG. 13 VELOCITY TRAVERSES IN THE 10-FT WOOD-STAVE PENSTOCK OF THE CENTRAL MAINE POWER CO., RICE RIPS, ME., 1919

FIG. 12 (LEFT) VELOCITY TRAVERSES IN THE 8-FT WOOD-STAVE PENSTOCK OF THE MONGAUP PLANT OF THE ROCKLAND LIGHT & POWER CO., MIDDLETOWN, N. Y., 1938

the angularity tests were made was located approximately 400 ft below and 200 ft above any departure from a straight section; the velocity distribution at this point is shown in Fig. 7. The mean angularity obtained was 1.5 deg.

A 12-in. pipe was also tested in connection with Hubbard's paper[4] and it is interesting to note that the angularity in the 78-in. pipe was about the same as in the 12-in. pipe and slightly less than in the 40-in. pipe. In every pipe that was tested the angularity was found to be less than 3 deg.

Referring again to Table 2 and the angularity curves shown in Figs. 3*A* and 3*B*, it is evident that the close agreement between the tests in the 40-in. pipe and the still-water rating or its equivalent is due to the small amount of angularity; hence, corrections (on the order of 0.1 per cent for the reversible type) for angularity can be neglected as long as the gaging point is properly located and the pipe traverses show stable conditions.

With the heavy-duty pitometer, the difference of 0.4 per cent in the coefficient as determined in the 40-in. pipe line is greater than would be indicated from any angularity correction shown in Fig. 3*B*. However, it is still within the experimental accuracy of test work (probably 0.5 per cent) and since this type of pitometer is relatively unaffected by angularity, as compared to the reversible type, the difference probably can be attributed to other causes.

With the experimental confirmations just described, it can be seen that stable flow is present in large pipes where suitable gaging stations are used, and that the flow conditions do not differ measurably from those found in small pipes. This at once removes any previously expressed doubt as to the accuracy of pitometer flow determinations in large conduits.

Comparisons With Other Methods

Comparative flow measurements by the pitometer method and other methods have been made in three large conduits, i.e., the 40-in. line at Worcester, the Walchensee tests in Germany, and the tests which were made recently at the Galloway plant in Scotland.

In the 40-in. line at Worcester, the agreement was within 0.1 per cent in one case and 0.4 per cent in the other. At Walchensee, Germany's test conditions were far from ideal and the first reports were found to be in error. After the original data were checked and the results recalculated, it was found that the agreement between the salt-velocity method and the pitometer runs was remarkably close, the difference being about 0.5 per cent at half and three-quarter loads. Velocity traverse curves plotted from pitometer readings are shown in Fig. 8.

TABLE 4 ADDITIONAL PLANTS WITH LARGE-DIAMETER PENSTOCKS WHERE VELOCITY TRAVERSES WERE MADE

Plant	Diameter, ft	Pipe factor	Fig. no.
Big Creek No. 8, California	6	0.870	10
Millinocket, Me.	12	0.840	11
Mongaup plant, Middletown, N. Y.	8	0.810	12
Rice Rips, Me.	10	0.910	13
Glens Falls, N. Y.	12	0.915	14

The results obtained at the Galloway plant are given in Table 3 and the traverses are shown in Fig. 9. These tests were made by E. Robert Howland in August, 1936. The differences between the salt-velocity method and the pitometer runs ranged from +0.7 per cent to —0.40 per cent, and averaged 0.1 per cent on one unit and 0.24 per cent on the other.

In addition to the examples just cited and the 78-in. conduit at Rutland, Vt., where angularity readings were taken and for which velocity traverses are shown in Fig. 7, five other groups of traverses are included in this paper to show the uniformly smooth consistent results obtainable in pitometer gagings in large conduits when suitable test sections are employed. The plants where the traverses were taken are listed in Table 4, together with the pipe diameter and pipe factor at each plant, as well as the figure number in which the velocity traverse for each plant is shown. In each case the traverses could be repeated and gave consistent results. Their pipe factors (ratio of mean to center velocity) remained constant over a wide range of velocities. The readings and traverses were easily reproducible even in the case of Figs. 13 and 14, where upstream bends distorted the flow distribution.

The unusually good agreement obtained in the Galloway plant between the salt-velocity tests and the pitometer runs, results of which are shown in Table 3, shows that unsymmetrical flow distribution has no measurable effect on accuracy.

Simplified Gagings

As a result of this research program and its coordination with field test work, a major simplification can be made in pitometer flow measurements in large conduits without impairing the accuracy of the results.

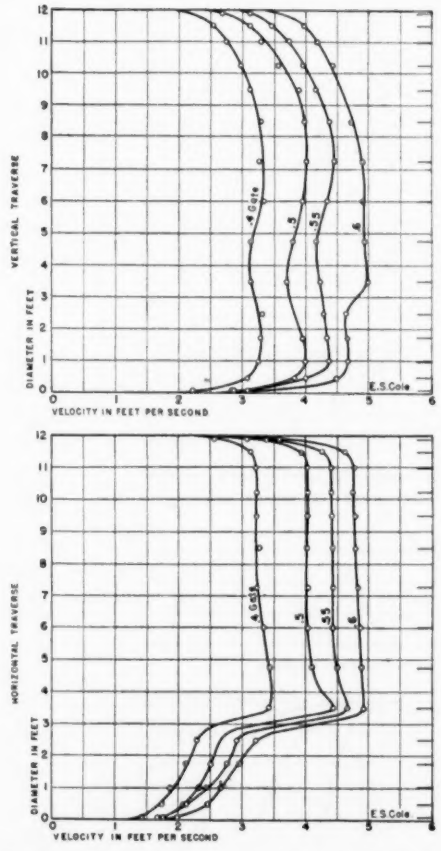

Fig. 14 Velocity Traverses in the 12-Ft Riveted Steel Penstock of the International Paper Co., Glens Falls, N. Y., 1918

It has been shown that with stable flow, the traverses are consistent and that for a given conduit the pipe factor remains constant for a wide range of discharge. It is then possible to determine the pipe factor on a given installation, and thereafter take readings only at the center of the pipe.

This provides means for making short tests with speed and accuracy and also will permit the use of the pitometer for securing a continuous record of the flow.

The Galloway tests were made in this way and the remarkably close agreement with the salt-velocity method has been discussed.

Conclusions

The value of velocity traverses and pipe factor, that is, the ratio of mean to center velocity, as a means of determining the flow pattern in a conduit has not been fully appreciated, and any theory regarding turbulent flow must take into account the behavior of this pattern. For good gaging points, traverse curves are smooth and their pipe factors constant over a wide range of velocities.

Smooth traverses do not have "humps" or irregularities, and in a rough pipe they take the general form of a parabola. Irregular curves have been found in pipes of all diameters and have been an indication of disturbances a short distance upstream. Upstream contractions give flat velocity curves which are smooth if the contraction is gradual as in a venturi throat. They are irregular if abrupt changes in section are present above the gaging section.

Accurate tests can be made when the velocity distribution is carefully determined, for at a good gaging point the pattern will have a form which remains constant even though unsymmetrical.

Although the pipe factor under such conditions remains constant and can be reproduced on different days, as was done for most of the traverses in the large pipes, it is of course closely related to pipe roughness and for this reason should be checked if too long a time elapses between tests. The change in roughness is usually a slow process but in one unusual case where a pipe had recently been cleaned an appreciable change in pipe factor was observed in less than two months.

Where stable flow exists at the gaging section, pitometer measurements of discharge can be made with a high degree of accuracy in large pipes. It is possible to use either the conventional velocity-traverse method at each discharge or to determine the pipe factor and make subsequent measurements of the center velocity only.

Discussion

H. S. Bean.[6] Since the two papers deal with the same general subject, the following is a combined discussion of the present paper and the paper, "Investigation of Errors in Pitot Tubes," by C. W. Hubbard, (see page 477 of this issue).

From their manner of presentation, the authors give the impression that the relative reliability of pitot-tube indications when used in large pipes or conduits as compared to their use in smaller pipes had been questioned. It had never occurred to the writer to question the application of pitot tubes to large pipes, at least from the standpoint of fluid dynamics. Indeed, it has always been his understanding that the pitot tube is particularly well suited to the making of flow measurements in large pipes, conduits of rectangular or irregular cross section, and open channels.

Of course, the use in large conduits presents the problem of making the tube sufficiently stiff to prevent it from vibrating. The meeting of this requirement for stiffness and, at the same time, limiting the size of the supporting leg make the design and construction of the pitot tube rather difficult. One solution is to avoid inserting the tube into the pipe beyond about 0.4 radius (in the case of circular conduits). This has the effect of decreasing the cantilevered end of the tube with a proportionate increase in its relative stiffness. By making partial traverses from each end of two normal diameters, the velocity distribution probably can be determined as reliably as if a full diameter is traversed from one end. This assumes that at the traverse section the pipe is accessible from all sides, which is not always the case.

[6] Chief, Gas Measuring Instruments Section, National Bureau of Standards, Washington, D. C. Mem. A.S.M.E.

Another method of providing sufficient stiffness is to have a support rod extend across the conduit. This is not as simple a solution as at first it may appear. Not only does it appreciably decrease the area of the channel cross section but it complicates the problem of bringing out the pressure leads.

Referring to the question of pitot-tip vibration, it is noticed that this possible source of error has not been treated by Mr. Hubbard. In one case observed by the writer this was believed to have been the major source of an 8 per cent difference between the indications of a pitot-static tube and an orifice. It is suggested, therefore, that it might be well to study the effects of vibration of the tip of the pitot tube and of a pitot-static tube. It seems possible that such vibrations, even if they are not noticeable from the outside, may be the source of some errors, particularly when a tube is cantilevered a few feet into a stream with a relatively short stuffing gland as a support.

The latter paper not only indicates several possible sources of error and the approximate magnitude of their effects, but also some of the precautions which should be taken in the use of pitot tubes. The conclusion reached, that the impact tip correctly registers the true dynamic head, but that the pressure piezometers may easily be in error, agrees with that reported by Dr. A. F. Zahm,[7] thirty-five years ago.

The remarks (oral discussion) by L. J. Hooper on the difficulties of making and using side-wall piezometer holes are not altogether surprising. In connection with the flow-nozzle research, variations have been observed in the pressures measured from several piezometer holes in a common cross section. Such differences are more likely to occur in sections across which the fluid velocity is quite high, as in a flow nozzle or venturi throat.

E. A. Hitchcock.[8] This paper and its discussion were of special interest to the writer because of a former experience in determining the velocity curves for an 8-ft penstock connected to a 10,000-hp water turbogenerator. This work took place during the summer of 1914 and was carried on in detail by H. C. Lord, professor of astronomy at The Ohio State University under the writer's general supervision.

The pitot tip selected for this purpose had been designed by Horace Judd, professor of hydraulics at The Ohio State University, to give with water a unity coefficient. It was made of 1-in-square brass, about 4 in. long with the upstream end having the form of a four-sided pyramid; the opposite faces including an angle of 20 deg. The dynamic opening was at the vertex of the pyramid and the static openings were in the two opposite vertical faces of the pyramid.

It was decided that this tip should be tested under a variety of velocities. This was done by mounting the complete traversing instrument so that it was 2 ft in front of the bow of a motorboat with the tip held 12 in. below the water surface. The boat was operated under constant speed at many different velocities over an accurately measured course of 1786.2 ft. This calibration test was carried out on an arm of Lake Ocoee at Parksville, Tenn. Fourteen runs were made (180 readings taken) with velocities ranging from 6.54 fps to 10.7 fps. The average tip coefficient was determined to be 1.015 and showed no certain variation with the different velocities.

The unit to be tested was located in the No. 2 Ocoee River powerhouse of the Tennessee Electric Power Company.

The traversing instrument had a net 4-ft travel, but readings with generator loads in excess of 4000 kw could not be obtained at the center of the penstock due to tube vibration. The pen-

[7] "Measurement of Air Velocity and Pressure," by A. F. Zahm, *Physical Review*, vol. 17, 1903, p. 410.

[8] Dean Emeritus, College of Engineering, The Ohio State University, Columbus, Ohio. Mem. A.S.M.E.

stock had a straight run of approximately 330 ft to the point where the pitot instrument was attached.

Six trials were made with generator carrying loads from 2000 kw to 7500 kw. During each test the turbine was under hand control. The total net head was 255 ft.

From the traverses it was noticed that velocities were practically constant for a 2-ft radius. Therefore, since the penstock internal diameter was found to be 7.896 ft, its area was divided into two zones, an outer one between the radii 3.948 ft and 1.948 ft, over which the velocity was variable, and the inner one, from the center to a radius of 1.948 ft, over which the velocity was considered constant.

From the runs made, velocity curves were plotted and these gave the velocity values for the ten equal areas of the outer zone. Table 5 was therefore established and the velocity factors computed.

TABLE 5 VELOCITY VALUES FOR 8-FT PENSTOCK, CONNECTED TO A 10,000-HP WATER TURBOGENERATOR

Load on generator, kw	2000	4000	4000	6000	6000	7500
Station	Velocities, fps					
1	2.12	3.85	3.90	5.23	5.22	6.56

Mean	2.889	4.869	4.808	6.763	6.754	8.288
Constant velocities, center zone	3.27	5.47	5.53	7.77	7.73	9.45
Volume per sec, center zone	38.982	65.208	65.923	92.626	92.149	112.653
Volume per sec, outer zone	107.035	180.392	178.132	250.562	250.229	307.062
Total volume of flow per sec	146.017	245.600	244.055	343.188	342.378	419.715
Mean velocity, fps	2.98	5.02	4.98	7.01	6.99	8.57
Ratio of velocities or V_m/V_c (pipe factor)	0.911	0.917	0.900	0.902	0.904	0.907

It is most interesting to note how closely the values given in Table 5, computed now for the first time, agree with those obtained on a 7.5-ft penstock at Walchensee, Germany, in 1935, twenty-one years later.

W. M. Lansford.[9] The problem of measuring large volumes of moving water with satisfactory accuracy is difficult. The authors have done much to develop one method of measurement, describing the use of pitot tubes in large pipes. A problem confronting every user of a pitot tube is that of calibrating the instrument to insure reliable results under the given service conditions. The effect of calibrating a pitometer, in a condition of flow unlike that in which the flow is to be measured, was brought out in a careful study of the velocity distribution at four locations in a 24-in. spiral riveted pipe line in the hydraulics laboratory of the University of Illinois, a portion of which is pertinent to this discussion.

The water was supplied to the pipe line by a 20 × 20-in. centrifugal pump, driven by a 200-hp synchronous motor. From the pump the water was conducted through a valve, an elbow, about 6 ft of pipe, and a second elbow to a straight reach of pipe 62.83 ft long in which was located pitot-tube traverse station No. 1; 60.46 ft downstream from the nearest upstream elbow and 2.37 ft upstream from a third 90-deg bend or elbow. Pitot-tube traverse stations Nos. 2, 3, and 4 were located in another straight run of pipe 111.10 ft long, extending from this third elbow. The location of station Nos. 2, 3, and 4 were at distances 20.12 ft, 56.13 ft, and 101.88 ft, respectively, downstream from the third elbow. The rate of flow was regulated by means of a gate valve near the discharge end of the pipe line approximately 40 ft downstream from station No. 4. The range of velocities was approximately from 2 fps to more than 11 fps. The discharge was measured volumetrically in a calibrated pit which had a capacity of 2500 cu ft. The time was taken by means of a stop watch. Horizontal and vertical traverses were taken at each of the four stations by a reversible pitometer. The coefficient of the instrument (ratio of actual average velocity determined by volumetric measurements to the theoretical velocity $\sqrt{2gh}$ indicated by the pitometer) was computed from the data taken at each station by the equal-area method, described by most textbooks on hydraulics, in which twenty equal areas were used. No correction was made for the projected area of the rod. The results of these tests are summarized in Table 6.

It will be noted that the highest coefficient was obtained at the station located farthest from any upstream disturbance. By using the deviation from smoothness of the velocity-distribution curves plotted from the data as a criterion of disturbance, it was found that the stations arranged in the order of decreasing degree of disturbed flow were Nos. 2, 1, 3, and 4. At the higher velocities there seemed to be as much disturbance, indicated by the irregularity of the velocity distribution curves, at station No. 1 as at station No. 2. All curves obtained from the pitometer reading at stations Nos. 3 and 4 were smooth and regular. The data herein reported were taken very carefully, with many check readings being made.

The results of these tests indicate that the accuracy of the pitometer measurements depends on the use of a calibration factor (coefficient), found by calibrating the instrument at a location in which the velocity distribution or disturbance is similar to that at the location in which the velocity distribution is to be determined.

TABLE 6 SUMMARY OF RESULTS OF PITOMETER TRAVERSES IN A 24-IN. SPIRAL RIVETED PIPE

Station no.	1	2	3	4
Distance from upstream elbow, ft	60.46	20.21	56.13	101.88
Distance from downstream elbow, ft	2.37	90.89	54.97	9.22
No. of horizontal and vertical traverses used in calibration	16	16	12	36
Coefficient $\frac{V_{avg}}{\sqrt{2gh}}$	0.845	0.835	0.859	0.864

Authors' Closure

H. S. Bean raises a question as to the effect of rod vibration which received little attention in the paper. This seeming omission was not due so much to oversight as to the belief that vibration was practically eliminated by the selection of a rod of proper stiffness to meet the field conditions of pipe diameter and velocity.

The authors have used rods of four different strengths, one of which is shown in Fig. 1; another is of 1-in. circular cross section; a third type is of steel with a 2 × 1-in. elliptical section; and the fourth is the 3 × 1¼-in. elliptical heavy-duty rod shown in Fig. 2. Experience usually indicated the type of rod required for a given set of conditions.

Where opposite taps were available in a penstock it was of course easy to make a simple check of vibration effect by inserting two rods so that their tips stood close to each other. One rod projected more, and the other less than the pipe radius. For example in the 12-ft Millinocket pipe there was little difference in the readings of the two rods even when one projected 11 ft and the other but 1 ft, thus indicating that the vibration effect was negligible at that gaging point.

As Mr. Bean points out no precise studies of vibration effects have been published but the authors much prefer to avoid excessive vibration by the use of a suitable rod than to attempt

[9] Assistant Professor of Theoretical and Applied Mechanics, University of Illinois, Urbana, Ill.

to correct for it. The use within a pipe of a support for the rod has not proved necessary or satisfactory in field practice.

W. M. Lansford's contribution of calibrations made at the University of Illinois is greatly appreciated. This investigation of the effect of upstream elbows, a subject on which there are few data, involved a large amount of work as evidenced by the many traverses which were made, but it is believed that the test data are too limited to warrant the conclusion that the pitometer coefficient changes with the type of velocity distribution.

The authors wish that Mr. Lansford had submitted traverse curves of the velocity distribution at his various gaging points, and also pipe-factor curves, for it is their belief that these definitely indicate the suitability of a gaging point. The coefficients obtained at stations Nos. 3 and 4, which were located 34 and 61 diameters, respectively, below one upstream 90-deg bend, agree within less than 0.6 per cent. This reasonably good agreement is to be expected at a normal gaging point where the velocity distribution is fairly symmetrical. Stations Nos. 1 and 2, however, which were located 38 diameters below two 90-deg bends and 12 diameters below one 90-deg bend, respectively, would be considered poor gaging points where a high degree of accuracy would hardly be expected with the usual test methods. No mention was made of straightening vanes and without them the velocity distribution must have been greatly distorted.

In view of other tests which have been made, it is doubtful if traverses on only two diameters were sufficient to give an accurate integration of the distorted flow at stations Nos. 1 and 2. In a previous article[3] calibrations made in a 12-in. pipe at the Alden Hydraulic Laboratory were described. The gaging point was located 38 diameters below two 90-deg bends but the velocity distribution was partially controlled by means of straightening vanes. In spite of these, some distortion of the traverse curves persisted. For this case traverses on two diameters were sufficient as was proved by check calibrations at the University of Pennsylvania.

Calibrations made recently at the Alden Hydraulic Laboratory in another 12-in. pipe and presented in the discussion of C. W. Hubbard's paper "Investigation of Errors of Pitot Tubes," showed that traverses on two diameters did not give an accurate determination of the mean velocity when the velocity distribution was distorted by 12 ft of wire screen which terminated 2 ft 3 in. upstream from the gaging point. When four diameters were traversed the mean velocity was determined with sufficient accuracy to show that the pitometer coefficient had the same value for the distorted flow as for the smooth flow which occurred when the screen was not present. In view of this it would seem that Mr. Lansford's calibrations at stations Nos. 1 and 2 were in need of further confirmation.

The authors are convinced from the results of many calibrations that the type of velocity distribution usually encountered in pipe lines does not materially change the pitometer coefficient. The accuracy of flow measurements made with a pitometer, however, depends on a number of factors other than the coefficient of the instrument. These factors which have previously been discussed in detail include the accurate determination of the mean velocity from traverses. At a good gaging point traverses on two diameters will give the mean velocity with sufficient accuracy for practical purposes, while at a poor gaging point more extensive traversing is required to obtain the same accuracy. The proof of this statement is clearly indicated by the results of Mr. Lansford's calibrations.

The work of E. A. Hitchcock is most interesting and this addition to flow measurements in large pipes was gladly received.

The authors gratefully acknowledge the assistance of Professors C. M. Allen, C. W. Hubbard, and L. J. Hooper of the Alden Hydraulic Laboratory, in the preparation of this paper. They are also deeply indebted to S. Investigation of Errors of Pitot Tubes

By C. W. HUBBARD,[1] WORCESTER, MASS.

In late years some hydraulic engineers have come to distrust the pitot tube as an accurate instrument for measuring the flow of water in pipes. It has been found that some pitot tubes do not have the same coefficient for all conditions of flow. There is, therefore, general disagreement as to the coefficient which must be applied for a particular set of conditions to obtain the velocity within 1 per cent or less of the true value. The following experiments were made in an effort to find the reasons for this variation of the coefficient.

Tests made on an 84-ft rotating boom in still water showed the coefficient of the impact tip to be unity. The pitot deflection was balanced against a centrifugal head.

A method of measuring the angularity of turbulent flow in pipes by use of the law of probability was devised. The measurements made in pipes 12, 40, and 78 in. in diameter check the Prandtl and von Kármán theories of turbulent flow closely and show the mean angularity to be about 2 deg. The effect of the pitot support rod on the reading of the pressure-head piezometers and impact tip was determined. Tests were also made to determine the effect of pulsations.

Tests made to determine the effect of the pitot support rod showed that the support rod did not cause an error in the impact-tip reading, but did affect the pressure measured by the wall piezometer. The rod was also found to affect the reading of the pressure orifice of the pitot-static tube. It follows that any form of combined type of pitot tube in which the error could be determined by calibration of the instrument alone would give accurate results.

The average magnitude of pulsations was found to be too small to cause an error in reading of the pitot tube.

The conclusions drawn from these tests were that the impact tip correctly registered the true dynamic head whether the flow was smooth or turbulent, but that the pressure piezometers were likely to be in error. Since the pressure piezometer of the pitot-static tube was a part of the instrument and calibrated with it, this instrument was considered more reliable than the simple pitot tube using wall piezometers.

THE EXPERIMENTS of W. M. White, Lewis F. Moody (1),[2] and others have demonstrated that the coefficient of the impact orifice of a pitot tube is unity in nonturbulent water. However, examination of past test results shows that the individual values of the coefficient varied from 1 to 3 or 4 per cent from the mean of all the tests.

The rotating current-meter rating station at the Alden Hydraulic Laboratory of the Worcester Polytechnic Institute is particularly fitted for tests to obtain the impact coefficient to a greater degree of refinement than by ordinary methods. This apparatus consists of an 84-ft rotating boom constructed of structural steel. It is set on a foundation consisting of a large rock located in a 2-acre pond.

Calibration of Impact Orifices on Rotating Boom

When these tests were made the boom was driven through a rope drive and gearing by a cylinder-gate water wheel operating under a head of about 5 ft. The maximum speed of the boom was about 5 rpm, which gave a maximum peripheral speed at the outer end of about 20 fps. The speed of the boom was varied by changing the gate opening of the water wheel and by two shifts of gears. The velocity of the instrument under calibration could also be varied by the selection of the radius at which it was mounted on the boom.

This boom was constructed under the direction of Prof. C. M. Allen in 1910 for the purpose of calibrating current meters and has been described by him (2). The station has been in use since then for both student and commercial testing. A sketch of the apparatus is shown in Fig. 1.

The usual method of calibration of an instrument has been to measure the time during which the boom rotates through an exact number of revolutions and compute the actual average velocity of the instrument from this time and the distance traveled. The actual average velocity was then compared with the indicated velocity. Obviously, the accuracy of the tests was directly affected by the precision of the time measurement and the steadiness of the velocity of movement. Linear measurements such as that of the radius of rotation of the instrument were easily made to a much greater precision than the time measurements.

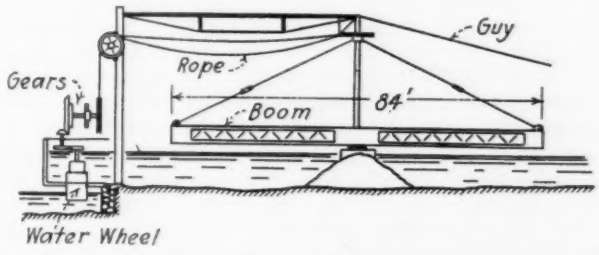

Fig. 1 Arrangement of Boom for Calibrating Flowmeters

However, if the velocity of rotation of the boom could be measured by some application of centrifugal force, an instantaneous indication of velocity would be obtained without any time measurement. Such a method would be particularly applicable to the calibration of pitot tubes since both the instrument deflection and centrifugal force vary as the square of the velocity.

The first method which was attempted was simple in theory but had some practical disadvantages. This method was based on the principle that the centrifugal acceleration acting on the leveling bubble of an engineer's level located near the end of the boom, would require the line of sight to be brought normal to the resultant of the accelerations of gravity and centrifugal force to bring the bubble to the center of the vial. By using a hand level with a prism, it was possible for the operator to observe both the cross wires and the bubble simultaneously. The level was mounted on a frame near the end of the boom at a measured

radius. An initial reading was taken on the leveling rod fastened to the mast at the center of the boom, with the boom stationary. When the boom was revolving at a constant speed the observer depressed the level until the bubble was central and observed the rod reading. Using the law of similar triangles, the change in rod reading was to the radius of the leveling instrument as the centrifugal acceleration (V^2/R) was to the acceleration of gravity. The principle of this method is shown in Fig. 2.

The method gave good results on one test of a Cole pitometer, but required three or four men to observe and record the data. It was also necessary that the boom rotate in an exactly level plane, a difficult condition to maintain with long guys.

A more effective method was to balance the pitot deflection directly against the centrifugal pressure generated in a horizontal radial pipe and measure the error in the pitot deflection. This was accomplished as indicated in Fig. 3. A pitot tube was clamped to the boom at a distance R out from the axis of rotation, about 40 ft. The pitot tip was carefully set so that it was tangent to its path at the forward end. A second pitot tube was mounted as close to the center of the boom as possible which was at a radius of about 8 ft. A line consisting of two lengths of $^1/_2$-in. brass pipe was then run radially outward from the inside pitot tube to the outer one which was to be calibrated. A differential U-tube containing a liquid having a specific gravity of 1.1 was

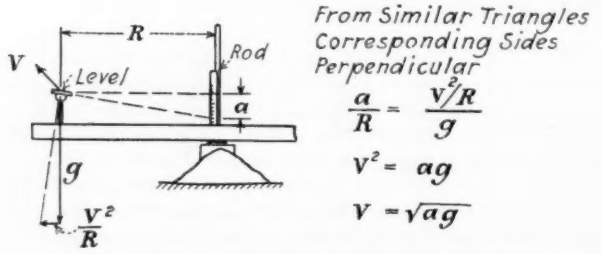

FIG. 2 LEVEL METHOD OF CALIBRATION WITH BOOM

connected between the outer end of the radial pipe and the impact tip of the outside pitot tube. When the system was filled with water the combination of the inside pitot tube and the radial pipe generated a head just equal to the true velocity head at the outside pitot station. In this way the pitot deflection was compared directly with a pressure equivalent to the true velocity head.

It can be shown that the difference in pressure caused by centrifugal force between the two ends of the radial pipe is equal to the difference in the velocity heads. This difference in pressure is not only theoretically correct but changes instantly with any momentary change in speed of rotation. Since there is no continuous motion of the water in the radial pipe, there is no friction to modify the calculated centrifugal pressure.

Since the velocity at any point along the boom is proportional to the radius, the centrifugal-pressure difference is then equal to

$$\frac{V^2 - v_1^2}{2g} = \frac{V^2}{2g}\left(1 - \frac{r_1^2}{R^2}\right) \quad \ldots\ldots [1]$$

With an inner radius of 8 ft and an outer radius of 40 ft, the pressure difference becomes

$$\frac{V^2}{2g}\left(1 - \frac{8^2}{40^2}\right) = 0.96\,\frac{V^2}{2g} \quad \ldots\ldots [2]$$

The total pressure existing at the outer end of the radial pipe equals the centrifugal head plus the velocity head of the inner pitot tube minus the elevation of the pipe. Since the inner velocity head represents only 4 per cent of the total reference pressure, the effect of an error in registration of the inner pitot tube is multiplied by 0.04, producing a negligible error in the reference pressure.

The Moody type-A pitot tip was used at the inside station as Professor Moody's tests, as shown in Fig. 5A of his article (1), showed a coefficient well within one per cent of unity in still water.

A sensitive differential manometer was connected between the outer end of the radial pipe and the impact tip of the pitot tube under test and the error in deflection of the outer pitot tube was read directly by the manometer, no accurate measurements of the actual velocity then being required. It can be shown mathematically that the location of the manometer along the radius makes no difference in the reading. In the early tests the position of the manometer was shifted over a radial distance of 3 ft while the boom was turning and no change in reading was noted. The manometer consisted of a standard Cole U-tube of $^5/_{16}$-in. glass containing monochlorbenzine having a specific gravity of 1.1, magnifying the pressure difference by about ten times. It was necessary to set the U-tube in a plane normal to the radius so that the centrifugal force on each leg was the same.

If the coefficient of the pitot tube under test were unity, the pitot-tube pressure would just balance the reference pressure and the deflection of the U-tube liquid would be zero. If the coefficient were not unity, then the U-tube would not balance by a small amount equivalent to e feet of water.

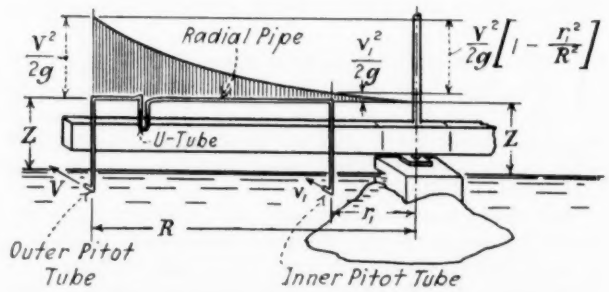

FIG. 3 METHOD OF CALIBRATION USED IN PRESENT TESTS

Expressing the error in reading in the more familiar form of a coefficient

$$V = C\sqrt{(2gH)}, \text{ or } V^2/2g = C^2H \quad \ldots\ldots [3]$$

where

V = true velocity, fps; C = coefficient; and H = velocity head indicated by pitot tube. If the error in dynamic head is e ft of water at a true velocity of V fps, then

$$H = (V^2/2g) + e \quad \ldots\ldots [4]$$

Substituting this value of H in Equation [3] for true velocity head

$$\frac{V^2}{2g} = C^2\left(\frac{V^2}{2g} + e\right), \qquad 1 = C^2\left(1 + \frac{e}{V^2/2g}\right)$$

or

$$C = \frac{1}{\sqrt{\left(1 + \dfrac{e}{V^2/2g}\right)}} \quad \ldots\ldots [5]$$

Method of Test.

Two types of pitot tubes were tested on the rotating boom. These were the round-nose tube and the impact tip of a Cole pitometer. The details of the form of both of these tubes are shown in Figs. 4 and 5 and a photograph in Fig. 5A. The pitot tips were submerged 6 in. or more below the surface of the pond during the tests.

Before starting a series of tests the specific gravity of the U-tube liquid was determined. The U-tube was then connected between the pitot tube and radial pipe and all air pumped out of the piping system. If the U-tube balanced when the boom was stationary, the boom was started rotating at some constant outer pitot velocity between 5 and 20 fps. One observer on the boom read the U-tube deflection at approximately every eighth of a revolution, the other observer on shore timed the run with a stop watch and recorded the U-tube readings on an adding machine. A single run consisted of from 2 to 3 revolutions of the boom. During a test the U-tube reading was constantly changing from small plus to small negative readings (about 0.01 ft of water).

The average of the U-tube readings during the run was taken as the mean error in pitot deflection. The average velocity of the pitot tube was obtained within 1 or 2 per cent from the stop-watch readings. Since the term $V^2/2g$ has little weight in the formula for coefficient, an error of 2 per cent in velocity measurement did not appreciably affect the results.

Experiments showed that the pond was of sufficient size so that there was no stirring action of the pitot tube which would cause the whole body of water to rotate. The effect of unequal temperature of the water in the pond and in the radial pipe was

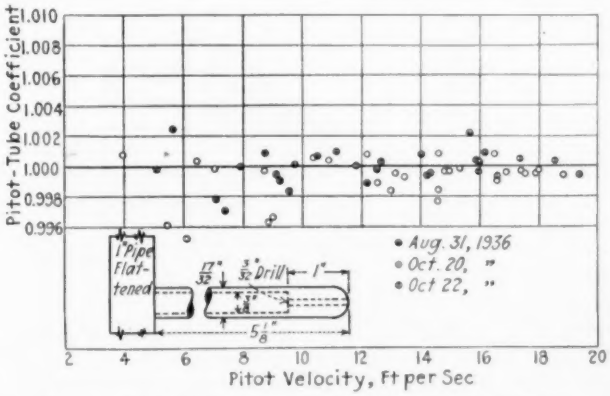

FIG. 4 TEST OF PITOT IMPACT ORIFICE ON ROTATING BOOM
(Average coefficient = 0.9995.)

negligible. The difference required to cause an error of 0.1 per cent was computed to be 16 F.

Test Results.

The test results in Figs. 4 and 5 show that the coefficient of the impact tip of a pitot tube is unity in quiet water.

The coefficient obtained by averaging all the tests for the round-nosed tube was 0.9995.

ANGULARITY OF FLOW IN PIPES

There has been much discussion among hydraulic engineers about the effect of angularity of flow in turbulent water upon the accuracy of tests made with current meters or pitot tubes. By angularity of flow is meant the constant wandering of particles of water back and forth across the average path of the stream in a straight conduit. Estimates of average angles of flow vary greatly and few reliable data are available.

Various experiments have shown that the impact orifice of a pitot tube correctly registers the cosine component of velocity at angles as large as 5 deg, but if the water approaches the pitot tip at angles of from 5 to 10 deg or more, an appreciable error will be obtained.

When water or any other fluid is flowing through a long straight pipe the velocity is known to be greater at the center than at the walls. At low velocities of flow the layers of fluid telescope or shear smoothly by each other with apparently no disturbance of the various particles. If the rate of flow is increased to normal values above the critical velocity, the rate of shearing apparently becomes so rapid and the shearing force so great that the water in one layer "seizes" on some of the water in the adjacent layer and tears it out of position, causing a whirl or eddy to start.

These eddies, as they move along with the bulk of the water around them would cause a sudden "side slap" against a small stationary vane. The front of the eddy would move the vane in one direction and the rear of the eddy would move it in the opposite direction. The combined rotation and forward motion of the particles within the eddy would make them appear to approach a vane at a constantly changing angle. When the

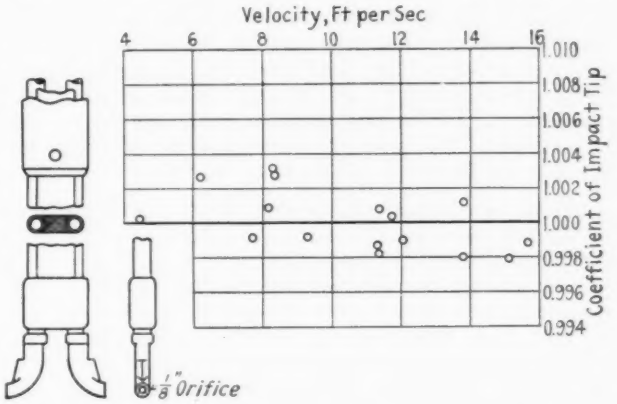

FIG. 5 TEST OF IMPACT TIP OF COLE PITOMETER ON ROTATING BOOM

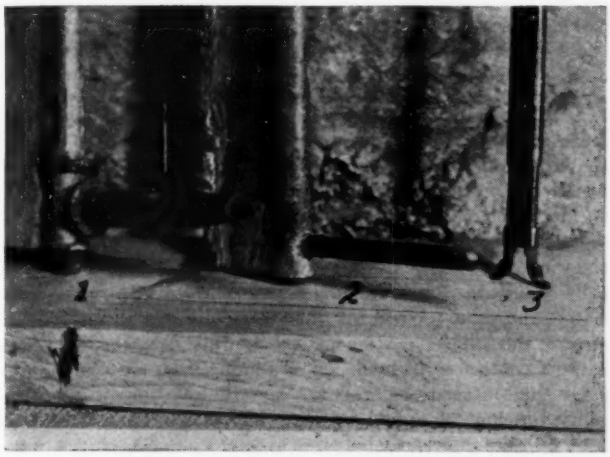

FIG. 5A PITOT TUBES USED ON BOOM
(1, Inner pitot tube, Moody type-A; 2, outer pitot tube; 3, Cole pitometer.)

outer or slower whirling particles of water struck the vane, they would appear to approach from a rather small angle because the velocity of rotation within an eddy or vortex varies approximately inversely as the distance from the center. If the more rapidly whirling core of the eddy should happen to be split by the vane, there would be a short violent side slap which would appear to be a flow from some greater-than-average angle.

Such eddies as they move along the pipe would collide with other eddies and the path and velocity of whirl of the various particles of water would be affected. The causes of such events are so complicated that it can safely be assumed that they are a

matter of accident, and that at no two instants are conditions exactly the same, but over a period of time a certain average effect is produced. This would suggest the application of the law of probability which can be used to predict the frequency of accidental events if sufficient observations of past similar events are made. If some mathematical law such as the law of probability can be found which seems to fit actual test data, conclusions can be drawn from comparatively few tests and average effects computed.

Application of Probability to Angles of Flow.

Probability is defined as the ratio of the number of times which an event occurs to the number of chances of occurrence. If an event occurs in the same way at every trial, the probability is certainty or one. If the chances of occurrence and failure are even, the ratio of probability is one half. When the law is applied to events which may occur in an infinite number of ways, actual observations of a large number of events must be made; the greater the number of observations, the greater the accuracy of the results. The following statements are the basis of the application of the law of probability to angles of flow:

1 The angle of flow will lie between certain wide limits found by test, and the probability that the angle is within these limits is practically unity.

2 In a straight unobstructed pipe the chances that water will approach a vane from the left are equal to the chances of approach from the right, so that the probability of some left or right angle is one half, since the average angle in a straight pipe must be zero.

3 A study of other accidental events indicates that small angles of flow should occur more often than large angles. If angularity is caused by passing eddies, most of the water in the eddy is in the outer slower-moving part, and most angles of approach would be small. Only rarely would the rapidly whirling core hit the vane.

4 In a large number of tests, a particular angle of flow should occur about as frequently from the left as from the right which means the probability curve should be symmetrical.

If a small weightless vane were supported near the front edge so that it would be free to flutter in a turbulent stream, the vane would be constantly moving through varying small angles. If the fluttering motion were restrained on one side by the tail of the vane striking against an electrical contact, the number of times the contact was made in a given interval of time could be graphically recorded. Assume that the contact was placed on the right side of the vane. When the vane was pointed directly into the stream, the eddies pulsating against the vane from the left would cause a contact to be made, those coming from the right would cause the contact to be broken. According to the law of probability the contact should be made half of the time if the test interval were sufficiently long.

If the support carrying the vane and its contact were turned a small angle to the right, the majority of the impulses would come from the left and the vane would rest against the contact more than half of the time. Conversely, if the support were turned to the left, contact would be made less than half of the time. Thus, such an instrument would measure the probability of occurrence of all angles to the left of the support angle.

If the support be turned further and further to the right, the contact would be made over a greater percentage of the time until some angle would be reached where the vane would rest against the contact practically all of the time, indicating that the probability of an angle of flow being to the right of the vane angle was slight.

The mathematical probability curve is represented in Fig. 6 by curve A. The abscissa scale x is general for all probability curves. To find the particular curve which fits a given set of data, the abscissa x is replaced by a parameter $h\theta$, where the value of h is a constant multiplier determined by experiment for the particular set of test data.

The probability of occurrence of an angle to the left of an arbitrary angle θ, i.e., between $-\infty$ and θ, is represented by the shaded area under curve A, or by the probability integral. Curve B of Fig. 6 shows the integral of the probability curve, and the ordinate scale represents the probability of occurrence of the event x. The integral curve transformed into a straight line by a nonuniform probability-ordinate scale is shown by curve C.

The values of the probability integral at various positive values of x may be found in mathematical tables. When it is desired to use both positive and negative values of x, the desired probability P may be converted from the tabular value p, by the following simple formula

$$P = (p + 1)/2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

The mean abscissa of curve A irrespective of sign, representing the desired mean angularity, has a definite mathematical value and always occurs at a definite value of probability. The mean value of x equals $1/\sqrt{\pi}$ and occurs for positive values at $P = 0.7875$ and for negative values at $P = 0.2126$. To determine this mean value from a given set of data, it is only necessary to plot the test results on a straight-line probability chart and draw a straight sloping line best representing the average of the test values as curve C of Fig. 6. This straight line is taken as the probability - integral curve best fitting the test points. The mean value of the abscissa θ is read from the chart where curve C crosses the horizontal line at $P = 0.7875$.

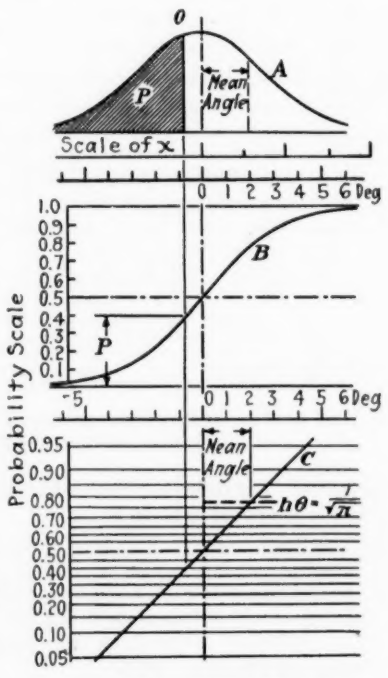

FIG. 6 PROBABILITY CURVES

If the zero of the instrument is not set correctly, curve C will be displaced from the origin. This does not affect the results, since the mean value of θ is represented by the abscissa distance between the curve intercepts of the chart lines at $P = 0.50$ and $P = 0.7875$. The slope of the line representing the average of the test points, determines the mean angle.

Description of Apparatus and Method of Test.

The first angularity indicator which was used for these tests was a plow-shaped vane made of brass shim stock 0.005 in. thick mounted on a shaft made of a common pin. The plow shape was preferred to a flat vane because unstable eddies were found to be set up on the low-pressure side of the flat vane. The indicator

was inserted through a hole in the top of the pipe so that there was no weight component influencing the results.

This angularity indicator was attached to the end of a Cole pitometer sheath which was equipped with a sliding stuffing box which could be screwed onto a $1^1/_4$-in. pipe nipple. The standard tips were removed; one piezometer tube of the sheath was used to bring out wires from the vane contacts and the other was taken up with a brass rod which turned the indicator through vertical angles. The details of construction are shown in Fig. 7.

The vane contacts were connected through a chronograph to a battery as in Fig. 8. A chart was moved at constant speed under two magnetically operated pens. When there was no flow of current in the vane contacts, the pens drew a continuous line on the chart; when one of the pens was actuated by a flow of current, a jog was made in its line. Each pen was connected to one of the indicator contacts. An interrupter was put into the circuit to give fairly rapid breaks in the current from the battery. This made the interpretation of data easier and reduced the troubles caused by polarization occurring at the contacts in the water.

The interrupter was driven by a synchronous motor to make and break the current supply five times a second so that the contact was closed 0.1 sec and open 0.1 sec.

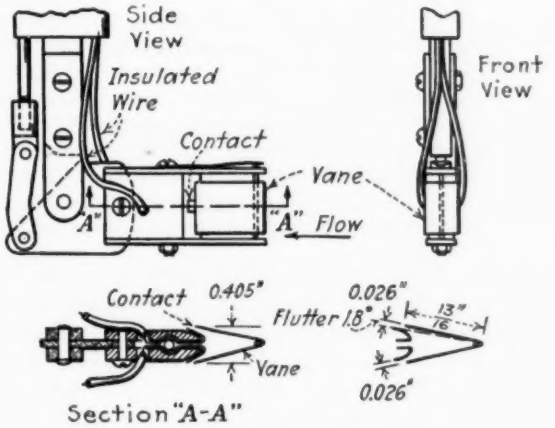

Fig. 7 Two-Contact Angularity Indicator

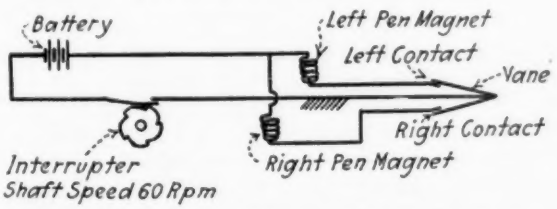

Fig. 8 Electrical Diagram of Angularity Indicator

It was necessary in constructing a practical instrument to have some movement of the vane between the left and right contacts, since the vane should not touch both contacts simultaneously. It was also necessary to space the contact from the vane sufficiently so that in the "off" position there would not be enough current leakage through the water between the contact and vane to operate the pen.

Micrometer measurements showed that the vane used could flutter through a total angle of 3.6 deg or 1.8 deg either side of center between the contacts. This effectively made the apparatus into two separate instruments the zero positions of which were 3.6 deg apart. In the early tests correction to the angles measured by the protractor for the flutter angle was made so that the data from both the left and right contacts would plot on the same curve. This was abandoned when it was found that

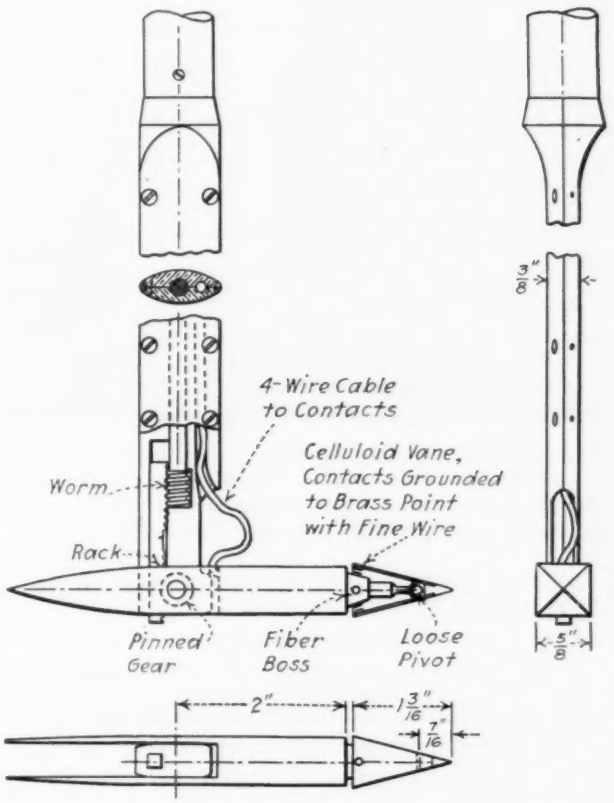

Fig. 9 Four-Contact Angularity Indicator

with the larger contacts required in the four-contact instrument, the measured flutter angle was modified by electrical leakage through the water.

In order that the angularity might be measured in a radial direction as well as tangentially, a four-contact instrument was constructed by the Pitometer Log Co., as shown in Fig. 9. This indicator was provided with a pyramid-shaped vane supported by a swivel near the point.

Since it was necessary that the vane should balance when in water, it was constructed of celluloid which is only slightly heavier than water and would require little correction. The point was of brass and so designed that the unbalanced weight of the celluloid and four contacts was neutralized. The contacts were made of platinum to avoid trouble with electrical corrosion encountered with brass or silver contacts.

A worm drive was provided so that the vane was adjustable through vertical angles. A gear connected to the top of the worm shaft was calibrated as a protractor to indicate the radial angular position of the vane. The tangential angular position with respect to the pipe axis was measured by a protractor attached directly to the shaft of the instrument.

The data and vane angle for a typical test run are shown in Fig. 10. Only a portion of a full run is shown; the usual number of possible contacts in a run was between 500 and 600. The number of possible contacts was determined by counting the number of jogs per inch of chart when one of the contact pens was actuated continuously. The chart speed was constant within 1 per cent so that it was only necessary to measure the length of chart for a particular test and multiply by the number of possible contacts per inch to calculate the total possible contacts. Although the support rod was pointed one degree to the right of the pipe axis, because of the flutter angle of 1.8 deg, the actual angle

of the vane with the pipe axis was 2.8 deg, when the right-hand contact was on, and —0.8 deg when the left contact was made.

In Fig. 10, the probability of an angle of flow to the left of —0.8 deg is 40/100 = 0.40. The probability of an angle of flow to the left of 2.8 deg is 1 — 15/100 = 0.85. These points may be plotted on the straight-line probability chart. The plot of a complete test of tangential angularity is shown in Fig. 11, and one of radial angularity in Fig. 12.

Tests were made with both the two-contact and four-contact instrument in pipes varying in diameter from 12 to 78 in. With the four-contact instrument, both the radial and tangential angularity were determined. The results of the tests are shown in Table 1. The conclusions drawn from them are the following:

1 No regular cycle of flow occurred.

2 The tangential and radial angularity were about equal.

3 The mean angularity was practically constant across the pipe, increasing only slightly toward the walls.

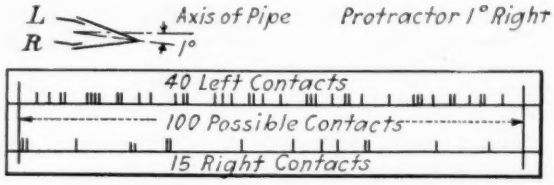

FIG. 10 SAMPLE CHART MADE BY ANGULARITY INDICATOR

TABLE 1 SUMMARY OF ANGULARITY TESTS

Pipe diam, in.	Mean velocity, fps	Pipe factor, mean velocity / center velocity	Wall surface	Mean angle at center line, deg	Mean angle off center line: Radius, in.	Mean angle off center line: Mean angle, deg	Mean angle off center line: Direction
12	5.9	0.78	Rough upstream	1.2	3	1.7	Radial
12	3.5 4.9 7.4	0.95	Smooth	1.6			
12	4.5	0.90	Smooth	1.3, 1.4			
12	6.2	0.87	Medium	0.65			
16-in. venturi throat	9.2	0.95	Smooth	0.50			
36-in. expansion below 28-in. butterfly valve	1.2			4.5, 5.5			
40-in. laboratory penstock	2.05	0.87	Medium	1.5	16.5	2.0	Radial
78-in. penstock at Rutland, Vt.	2.78	0.84	Smooth	1.3	31	1.5	Radial

4 The mean angularity was less than 3 deg and too small to cause an error in reading of the impact orifice of a pitot tube.

ANGULARITY AND THEORY OF TURBULENT FLOW

It was desirable to verify the results of the angularity tests by theory, if possible. Prandtl's theory of turbulent flow, as described by Professor Bakhmeteff (4), was found to have a direct application to angularity.

This theory was compared with test results obtained in the 40-in. diam riveted steel penstock at the Alden Laboratory. The test section was approximately 320 ft downstream from the head gates; the pipe walls were tuberculated and very rough for about 270 ft of this length. The remaining 50 ft just ahead of the test section had been scraped and coated with a waterproof paint which smoothed its surface somewhat, but there were still irregularities approximately $^1/_{16}$ to $^1/_8$ in. deep in the walls where the rust had been removed. The walls in the test section had a de-

cided pock-marked appearance. The tubercles in the 270 ft further upstream gave the appearance of rivet heads, from $^1/_4$ to $^3/_4$ in. high and spaced about as closely together as the tubercles can grow.

A velocity traverse was made across the test section with a Cole pitometer. The tests are shown in Fig. 15. The curve plotted through the test points was based on the general von Kármán equation

$$u = u_m - 5.75\ U \sqrt{(f/8)}\ \log_{10}(R/y) \quad \ldots\ldots\ldots [7]$$

The values of f necessary to make this equation fit the test points was 0.0184. For some reason, probably because of the change in roughness upstream from the test section, the portion of the velocity curve near the center was unstable and the center velocity appeared to be too low. The center velocity computed from the von Kármán equation which fitted the outer test points was 1.5 per cent greater than the measured center velocity. The velocities used in the following theoretical computations were taken from the smooth curve representing the von Kármán equation.

Prandtl's Theory Applied to Angularity.

The following notation is used:

- f = friction factor in Darcy pipe-friction formula
- l = Prandtl mixing length, see text for definition
- r = radius of inner cylinder
- R = radius of pipe
- y = radial distance of point in pipe from wall
- v = mean radial or cross velocity normal to axis of pipe over a long period of time
- u = velocity at any point parallel to axis of pipe
- u_1 = velocity parallel to axis of pipe, at mixing length from boundary of inner cylinder, radius $= r + l$
- Δu = acceleration from mixing length to boundary of inner cylinder $= u - u_1$
- u_m = maximum or center-line velocity parallel to pipe axis
- U = average or bulk forward velocity = discharge/pipe area
- θ = mean angularity of flow over a long period of time.

When there is turbulent flow in a pipe, the water is known to waver sidewise as it moves along the pipe. The degree of wavering at any instant varies greatly, but over a long period of time there is some average or mean amount of wavering from the axial motion which may be expressed by the mean angularity of flow.

Since the velocity varies across the pipe, from a maximum at the center to a minimum at the wall, any water which wavers from one layer to another has its forward velocity changed. Thus, water moving from an outer layer to an inner layer has its forward velocity increased. Prandtl realized that this increase in velocity given to the wavering particles of water would require a longitudinal force and would account for the friction force exerted by the water not in direct contact with the pipe walls.

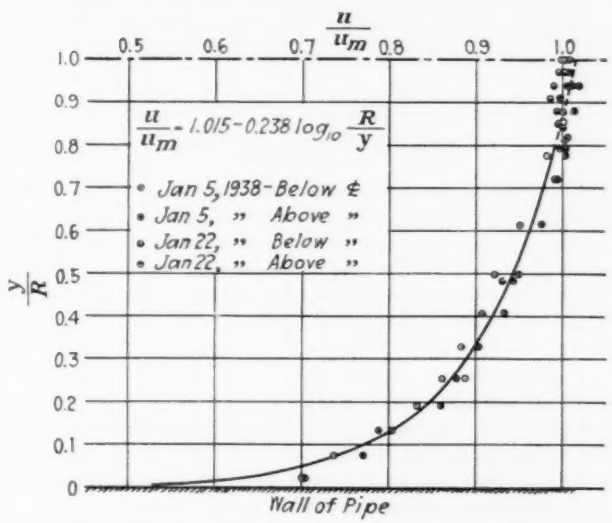

FIG. 15 PITOMETER TRAVERSE IN 40-IN. PENSTOCK WITH VON KÁRMÁN EQUATION

The longitudinal force exerted on an inner cylinder of the water in the pipe must be proportional to the mass per second of wavering water entering the inner cylinder and the increase in its velocity. Of course, when a small amount of water flows into the inner cylinder an equal amount of water is forced outward into the outer layer. This outward-flowing water can be neglected if what happens only in the inner cylinder is considered.

A diagrammatic sketch showing an inner cylinder of water flowing through the outer layer next to the pipe walls is shown in Fig. 16. Suppose that consideration be given to what probably happens at the boundary between these two cylinders.

The mass of water fluttering back and forth across this boundary is small compared to the main body of water in the inner cylinder, so that the entering water is quickly accelerated to the forward velocity near the boundary. Since the radial or cross flow indicated by the vector v in Fig. 16 is pulsating, the long-time

average of the flow into the inner cylinder must be used. This inward-flowing water is assumed to start from some point a distance l out from the boundary. Prandtl has given this dimension l the name mixing length.

Since the water entering the cylinder presumably does not start always from the same fixed point, the mixing length l prob-

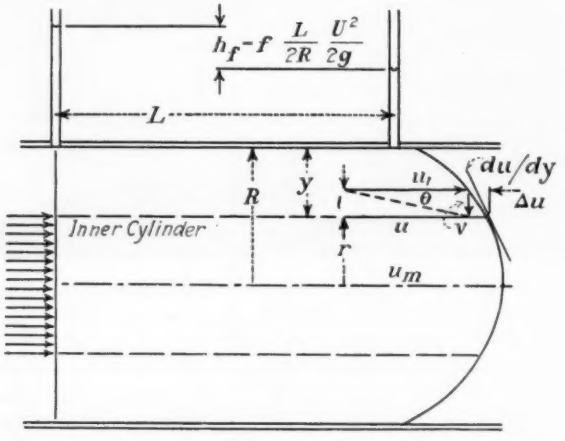

FIG. 16 DIAGRAM FOR THEORETICAL ANGULARITY IN PIPE

ably is a long-time-average distance. Referring to Fig. 16, the change in velocity, Δu, is equal to the forward velocity at $(r + l)$ subtracted from the forward velocity u at the radius r. The average true velocity of the water entering the inner cylinder would be made up of the components u and v, so that the tangent of the mean angle of flow would be v/u_1, or

$$v = u_1 \tan \theta \quad \ldots\ldots [8]$$

The experiments which have been described indicate that the value of this mean angle is about 2 deg all across the pipe. Thus, the value of the mean radial or cross velocity v is approximately 0.030 u_1, where u_1 is the forward velocity at a distance out from the boundary of the inner cylinder.

The volume of water per second which wavers into the inner cylinder is equal to the mean radial velocity multiplied by the boundary area of the cylinder, or

$$M = (62.4/g)\, v\, 2\pi r L \quad \ldots\ldots [9]$$

where M = mass, slugs per sec; Density of water = 62.4 lb per cu ft; g = acceleration of gravity; v = mean radial velocity, fps; r = arbitrary radius of inner cylinder, ft; L = length of section of pipe, ft.

Substituting for v its value $u_1 \tan \theta$

$$M = \frac{62.4}{g}\, u_1 \tan \theta \times 2\pi r L \quad \ldots\ldots [10]$$

The force required to accelerate this mass per second, an amount Δu fps, where $\Delta u = u - u_1$ is

$$F = M \Delta u = M(u - u_1) \quad \ldots\ldots [11]$$

The force equals the pressure difference acting on the inner cylinder multiplied by the area of the cross section. Since the pressure head is assumed constant across a plane normal to the axis of the pipe, from Fig. 16

$$F = 62.4\, \pi r^2 h_f \quad \ldots\ldots [12]$$

where hf is the head difference in the length L caused by friction. Using the Darcy formula for pipe friction

$$h_f = f \frac{L}{D} \frac{U^2}{2g} = f \frac{L}{2R} \frac{U^2}{2g} = \frac{fLU^2}{4Rg} \quad \ldots\ldots [13]$$

where f = friction factor, usually about 0.02; L = length of section of pipe, ft; R = radius of pipe, ft; U = average or bulk forward velocity, fps.

Then, from Equations [12] and [13]

$$F = 62.4\, \pi r^2 fLU^2/4Rg \quad \ldots\ldots [14]$$

Equating the force to the product of mass and acceleration, and using the values given in Equations [10], [11], and [14]

$$62.4\, \pi r^2 fLU^2/4Rg = (62.4/g) u_1 \tan \theta \times 2\pi r L\, \Delta u$$

or, eliminating common factors and rearranging

$$u_1 \tan \theta\, \Delta u = \frac{fU^2}{8} \frac{r}{R} \quad \ldots\ldots [15]$$

It was necessary to obtain a relation between the mean transverse velocity, v, and the acceleration, Δu. Since the flow is pulsating in an axial direction as well as across the stream, Prandtl assumed that the axial and transverse pulsations were proportional to each other at the same point in the pipe. But if a mass of water traveling with an axial velocity u_1 were suddenly moved transversely into a region where the velocity was u, then there would be a momentary negative axial pulsation proportional to $u - u_1$ while the mass of water was being accelerated to the velocity u. Thus, the acceleration Δu is proportional to the mean axial-velocity pulsation which in turn was assumed to be proportional to the mean transverse pulsation, v.

It may be seen from Fig. 16 that for small values of the mixing length, l

$$\Delta u = l\, du/dy = \text{constant } (v) = \text{constant } (u_1 \tan \theta) \quad \ldots [16]$$

If the value $l\, du/dy$ is substituted in Equation [15] for both Δu and $u_1 \tan \theta$ with the understanding that l no longer is a physical distance only, but also contains the constant of proportionality between Δu and $u_1 \tan \theta$; then Equation [15] becomes Prandtl's equation

$$(l\, du/dy)^2 = \frac{fU^2}{8} \frac{r}{R}, \text{ or } l = \frac{U\sqrt{\left(\frac{f}{8} \frac{r}{R}\right)}}{du/dy} \quad \ldots\ldots [17]$$

This enables l to be computed at various values of r/R. The mixing length for the 40 in. penstock is shown by curve A in Fig. 18. When l is known, Δu and u_1 can be determined from the velocity-traverse curve.

If Equation [15] be solved for $\tan \theta$, we obtain

$$\tan \theta = \frac{\frac{fU^2}{8} \frac{r}{R}}{u_1 \Delta u} \quad \ldots\ldots [18]$$

But from Equations [16] and [17]

$$\Delta u = l\, du/dy = U \sqrt{\frac{f}{8} \frac{r}{R}} \quad \ldots\ldots [19]$$

Substituting this value for Δu in Equation [18]

$$\tan \theta = \frac{U}{u_1} \sqrt{\frac{f}{8} \frac{r}{R}} \quad \ldots\ldots [20]$$

The theoretical angularity calculated from Equation [20] is shown by curve A in Fig. 17. The measured angularity shown by curve B in Fig. 17 agrees with the theoretical angularity in

magnitude but shows a more uniform distribution across the pipe. The probable reason for the discrepancy at the center of the pipe is that angularity near the center is induced by eddies away from the center and cannot be accounted for by the Prandtl theory alone.

The results of tests by Nikuradse, on page 53 of "The Mechanics of Turbulent Flow" (4) have shown that the velocity-traverse curve is more blunt at the center of the pipe than is indicated by the von Kármán Equation [7], and that the mixing length is finite at the center of the pipe. The mixing length as determined by Nikuradse for high Reynolds numbers is shown by curve *B* in Fig. 18, reproduced from Fig. 39, p. 54 of "The Mechanics of Turbulent Flow" (4).

The curve of Fig. 19 showing the cross velocity computed from tests plotted against distance from the wall indicated a nearly constant value of v. It seemed quite reasonable to assume that this curve was a horizontal line, or that the cross velocity was constant at a value of 0.0289 across the pipe. This assumption

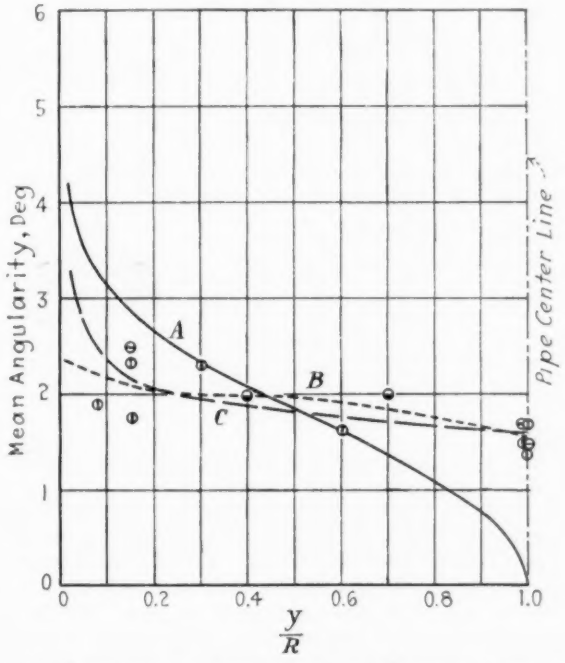

FIG. 17 COMPARISON OF THEORETICAL AND MEASURED ANGULARITY
(Curve *A*, theoretical angularity; curve *B*, mean of measured angularity; curve *C*, angularity computed using constant cross velocity of 0.0289 u_m.)

would give a means of computing the theoretical mean angle to check experimental values. Since it was necessary to have some method of computing the mixing length when the mean angle of flow was not known, the Prandtl Equation [17] was used. The value of f was taken as 0.0184. $U = 2.05$ fps, $u = 0.867u_m$. To compute the value of θ for a given value of r/R, substitution of r/R and du/dy are made in Equation [17] and the value of l obtained. This value of l when added to r gives the radius on the velocity-traverse curve at which u_1 occurs. Dividing the assumed-constant value of v, 0.0289, by the value of u_1 gives tan θ. Curve *C* of Fig. 17, showing the values of mean angle computed in this way, is in good agreement with the experimental values.

Fig. 20 shows the results of angularity tests in various pipes plotted against the pipe factor. The theoretical angularity, as computed from the von Kármán velocity formula for rough pipes, is also shown; the value of f was varied to obtain results at different pipe factors. The angularity was computed for a point midway between the center and wall of the pipe, since the tests in the 40-

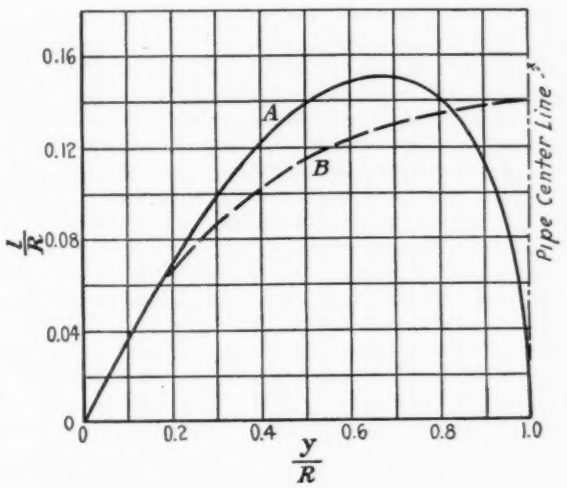

FIG. 18 MIXING-LENGTH CURVES

(Curve computed from the von Kármán velocity formula for rough pipes.)

in. penstock showed a close agreement between theoretical and experimental values at this point.

The comparison of the theoretical with the experimental values of angularity is close in most cases. There is sufficient evidence to indicate that there is a relation between turbulence and angularity and that angularity must necessarily be only a few degrees in stable pipe flow

PULSATION TESTS

In turbulent flow where the velocity at a point in the pipe constantly varies above and below the average, the manometer

connected to a pitot tube records a constantly changing pressure proportional to the velocity head. In computing the average velocity at a point in the pipe from a number of individual manometer readings, the arithmetic average of the manometer readings is used. Since the readings are proportional to the squares of the velocities, it is theoretically possible for the average velocity computed from the square root of the average pressure to be greater than the true average velocity. This would cause an error which would make the measured velocity appear too large, for the average of the square roots of a group of numbers is less than the square root of the average. The amount of error from this cause would depend on the magnitude and duration of the pulsations in velocity and pressure.

A system to measure pulsations was devised which utilized the principles of the law of probability in a manner similar to that described for the angularity tests. The piezometer in which pulsations were to be measured was connected to one side of a thin rubber diaphragm of 1 in. diam. The other side of the diaphragm was connected to an air reservoir in which the pressure could be varied at will. An electrical contact consisting of a strip of 0.005-in. shim-stock brass was laid on the air side of the rubber diaphragm so that when the pressure was slightly greater on the piezometer side, the diaphragm would bulge a few thousandths of an inch and the brass strip would be pressed against an insulated contact. The displacement of the diaphragm was estimated to be less than 0.001 cu in.

If the pressure pulsations varied constantly in an accidental manner so that they followed the law of probability, with a constant air pressure acting on one side, the variable pressure on the water side would cause the diaphragm to move and the electrical contact to be made and broken continually. If the air pressure were increased to an amount greater than the highest pressure pulsation, the diaphragm would always be held away from the contact and no record would be obtained. If the air pressure were reduced slightly, the contact would be made only by the highest of the pressure surges. The number of diaphragm contacts divided by the total possible contacts in a given test interval would determine the probability of a surge equal to or greater than the arbitrary air pressure.

The diaphragm contact was connected in series with an interrupter and chronograph pen exactly as in the angularity tests. By making tests at a number of different settings of the air pressure, it was possible to plot the results on a probability chart and the mean pulsation was determined in exactly the same manner as the mean angularity.

Fig. 21 shows the arrangement of the apparatus. In order that the pulsations would be modified as little as possible by friction and bulging of rubber hose, the diaphragm was connected close to the piezometer or pitot rod by a 2-in. length of $^1/_4$-in. high-pressure hose.

The air pressure was measured by an open mercury U-tube. An arbitrary zero was obtained by opening a by-pass between the air reservoir and the water side of the diaphragm, as this pressure was close to the average pressure. The by-pass was closed during the tests. The mercury deflection from the arbitrary zero was measured to 0.001 in. by a micrometer with a pointed rod which caused a flashlight to signal when contact with the mercury surface was made. The air pressure was varied by means of a small hand pump.

The tests shown in Fig. 22 were made with the diaphragm connected to the impact tip of a pitot tube located at the center of a 12-in. rough pipe and then to a wall piezometer of the same pipe. The center velocity in the pipe was 9.2 fps, and the mean velocity 7.2 fps. The results indicate that the mean pulsation is 0.048 in. of mercury or 4.1 per cent of the center-velocity head for both the wall piezometer and impact orifice. This amount of pulsation is too small to cause an appreciable error in the mean square root of deflection, since it can be shown that the mean pulsation must be about 25 per cent of the velocity head to cause an error of one per cent.

Dynamic Effect on Manometer Pulsations

It is well known that the dynamic force exerted by a jet impinging against a normal flat plate is equal to twice the force which would be exerted on the same area by the static head acting on the jet (5). Although the water in the jet cannot rise above

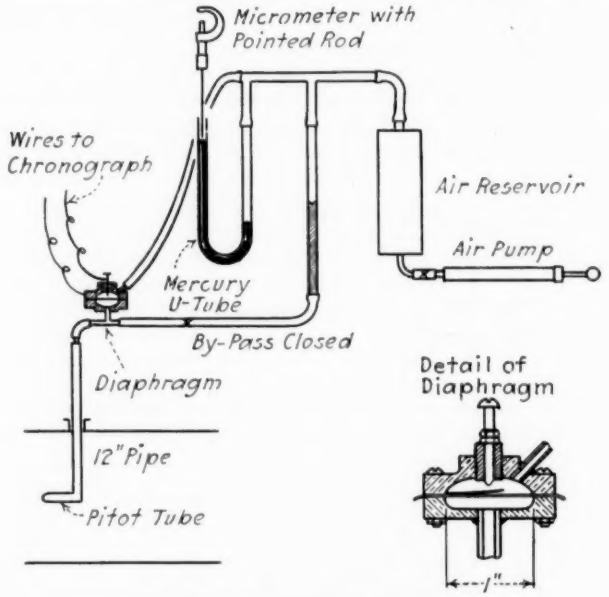

Fig. 21 Pulsation Apparatus

the level of the head causing flow, it can resist the tendency to flow of a more powerful opposing head.

In turbulent flow the pressure and velocity are not constant, but pulsating, so that the level in the manometer connected to the pitot tube is constantly shifting. After a positive surge, the water forced into the manometer must flow back through the pitot tube against the flowing water in the pipe. If this backflow is resisted by the dynamic effect of the stream in the pipe, then the tendency would be to emphasize the positive surges and to give too great an average deflection.

It was decided to test the backflow resistance by placing a pitot tube in a stream and measuring the rate of flow through the pitot tube at various artificially created surges. The pitot tip was mounted on a sliding frame so that a lengthwise traverse could be made of the jet discharging from a 4-in. orifice under a head of about 1.5 ft. The pitot support was so made that the tip could be projected through the jet 6 in. upstream from the plane of the orifice without seriously obstructing the flow. The pitot tube was connected by 5.5 ft of $^1/_4$-in. and 2.5 ft of $^1/_2$-in. rubber hose to a hook-gage stilling pot mounted on a firm support. The water level in the hook-gage pot was read by a standard hook gage to thousandths of a foot and estimated to half thousandths.

The brass pitot tip was 1 in. long, with a hemispherical nose of $^1/_4$ in. outside diameter and a $^1/_8$-in. hole drilled throughout its length. This tip was soldered to a support rod of thin brass tubing to which the hose was connected. Before the test the tip was plugged and the hook gage observed for 5 min to insure that there was no leakage between the tip and the hook-gage pot.

Before the tests were started, the discharge from the orifice was allowed to run for more than a half hour to insure constant condi-

tions. Hook-gage readings were taken for several minutes with the pitot tip at the vena contracta and also with it projected 6 in. into the forebay. With a head on the orifice of about $1^1/_2$ ft, the hook gage read 0.001 ft lower with the tip at the vena contracta than with the tip in the forebay. This close check was probably due to the fact that the edges of the orifice were rounded to about $^1/_8$ in. radius, causing little loss of head in the jet.

Excess water was poured into the hook-gage pot to create an artificial positive surge. The rate at which the level in the pot was lowered was obtained by timing a drop in level of about 0.020 ft with a stop watch. The rate of drop was a measure of the discharge through the pitot tube. In a similar manner the rate of rise after a negative surge could be determined by removing water from the hook-gage pot and allowing water to flow in through the

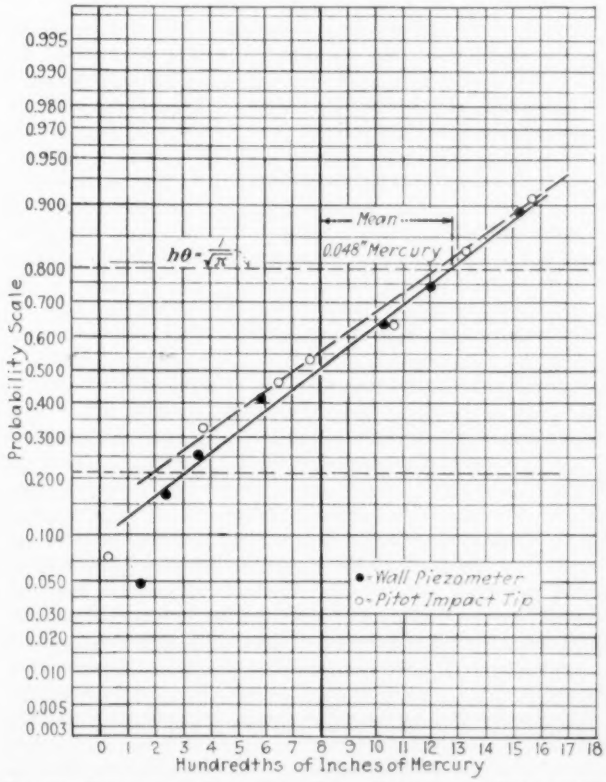

FIG. 22 RESULTS OF PULSATION TESTS PLOTTED ON PROBABILITY CHART

(Center velocity = 9.2 fps; velocity head = 1.165 in. mercury; mean pulsation = 4.1 per cent of velocity head.)

pitot tube. The results of tests with rising and falling hook-gage levels both in the vena contracta and in the forebay are shown in Fig. 23. Fig. 24 is a photograph of the apparatus.

If the dynamic effect of the stream caused a resistance to the backflow of a surge, then the discharge through the pitot tip should be less for a dropping head when placed in the vena contracta than for a rising head. Inspection of the test data in Fig. 23 shows the resistance to outward flow is slightly less than to inward flow. This indicated that there was no dynamic resistance tending to cause the impact tip to read too high in turbulent flow.

Tests similar to those just described in which the flow in and out of a wall piezometer in the side of an open flume was measured, showed no appreciable difference in flow through the piezometer. The velocity head near the piezometer was 0.25 ft. It is apparent that surges in the manometer do not affect either the impact-orifice or wall-pressure readings.

EFFECT OF PITOT-TUBE SUPPORT ROD ON VELOCITY READING

The essential measurement which must be made in order to determine the velocity of flow with a pitot tube is the difference between the dynamic head at the impact orifice and the pressure head in the fluid itself at the impact orifice. If, then, there is an

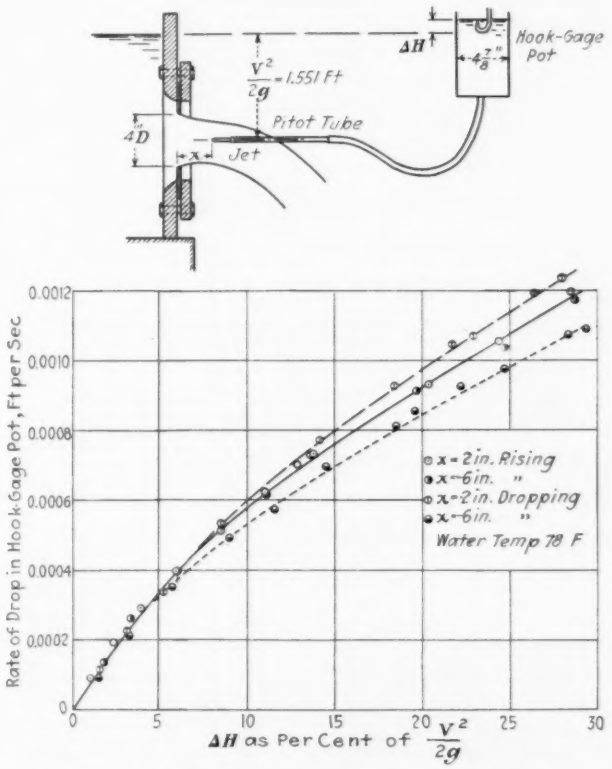

FIG. 23 TESTS TO DETERMINE DYNAMIC EFFECT ON MANOMETER PULSATIONS

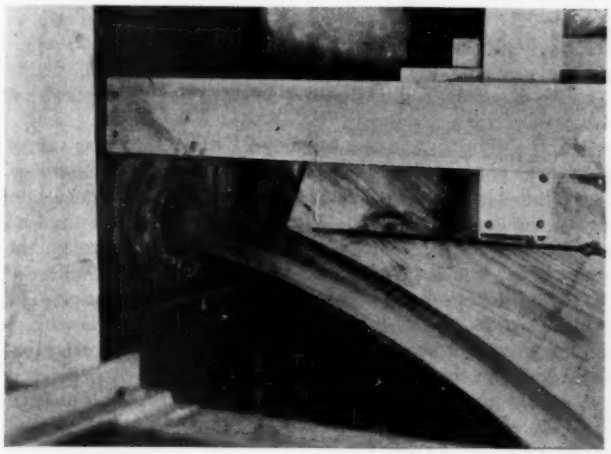

FIG. 24 ORIFICE AND PITOT TUBE USED TO TEST DYNAMIC EFFECT ON PULSATIONS

error in measurement of either the dynamic or the pressure head, the difference between them will be in error and the pitot tube will not register correctly.

In this paper a pitot tube is considered as an L-shaped tube. One leg, called the tip, points into the stream and has an orifice at

its upstream end termed the impact orifice. The other leg called the rod, is across the stream and serves to support the tip and provide a means of conducting the impact pressure outside the conduit. The rod usually passes through some form of stuffing box and allows motion of the tip across the pipe in traversing.

Tests were made to show whether the presence of the supporting rod behind the impact orifice would cause an error in reading. The apparatus and results of this test are shown in Fig. 25. The same tip used on the rotating boom (see Fig. 4) was mounted on a supporting pipe passing through a stuffing box so that the tip could be projected varying distances through a dummy rod without changing the flow. In order that small errors might be detected, the pitot tip was connected to a U-tube, the other side of which was connected to the upstream tip of a Cole pitometer. The pitometer tip was 0.2 ft away from the pitot tip and gave nearly the same deflection. With the pitometer tip fixed in position, the pitot tip was moved back and forth through the dummy rod over a distance of 3 in. One hundred readings of the U-tube deflection were taken at each position of the tip. The liquid used in the U-tube was monochlorbenzine having a specific gravity of about 1.10, so that the pressure difference between the pitot tips was magnified ten times.

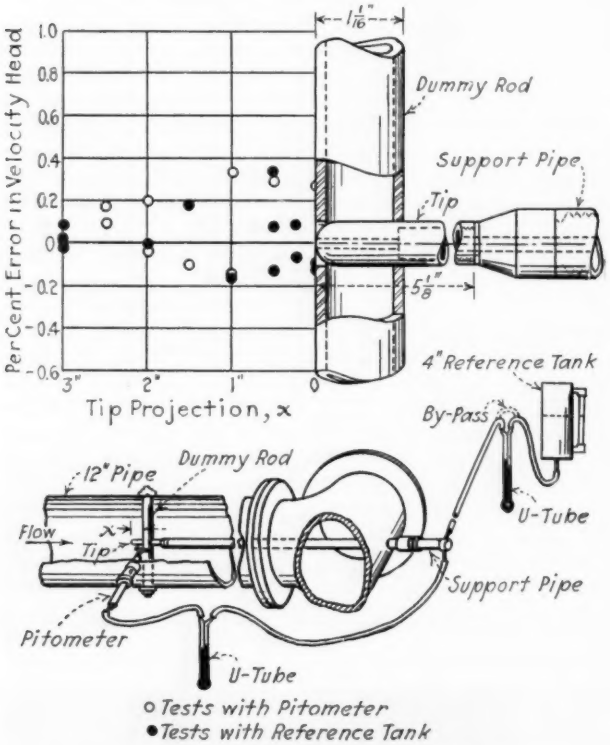

FIG. 25 EFFECT OF TIP LENGTH ON IMPACT-TIP READINGS

A second series of tests was made with the pitot tip connected to a U-tube which in turn was connected to a 4-in. reference tank having air trapped above the water surface. A by-pass was connected to the U-tube so that when the tip protruded 3 in. ahead of the dummy rod, the reference pressure could be made equal to the impact pressure. With the by-pass closed, the position of the tip was changed and one hundred readings of the U-tube deflection were taken. Monochlorbenzine was used in the U-tube. The inside diameter of the U-tube legs was $^5/_{16}$ in.

The results of these tests are shown in Fig. 25 and indicate that the length of the tip upstream from the rod has little effect on the impact orifice pressure. The tests were made at a mean velocity of 8 fps.

The previous tests have indicated that the impact tip has a coefficient of unity and is unaffected to any appreciable degree by the angularity or pulsations of turbulent flow or by the presence of the supporting rod. It seems, therefore, that any error in pitot-tube readings must be caused by an error in obtaining the correct pressure head.

Whereas the dynamic head at the impact orifice can be easily and accurately measured, it is practically impossible to measure the true pressure head at any point in the fluid. At the present time the only method of measuring pressure head in a pipe is by a piezometer in some solid surface. Such a surface cannot be placed in the stream without disturbing the flow and therefore affecting the pressure some unknown amount.

Ordinarily the pressure head is measured in one of two ways. For the simple pitot tube the pressure head is measured at the wall of the pipe by piezometers normal to the wall and abreast of the impact orifice. The second method is to have the pressure-head piezometers at some point on the tip itself, the instrument in this case being called a pitot-static tube. The errors in the reading of the pressure head will be described in a following section.

It is assumed for this discussion that the wall piezometer will be correctly made and that it reads the true pressure head at the point on the wall of the pipe where it is located. A complete discussion of the errors in wall piezometers will be found in the A.S.M.E. Transactions (6).

While traversing a pipe with a pitot tube it has been discovered, perhaps by many investigators, that the pressure reading of a wall piezometer changes with the position of the pitot tube as it is moved across the pipe. It is only natural to suppose that since the presence of the supporting rod reduces the cross-sectional area at the plane where it is inserted, the water must be speeded up as it passes the rod and the pressure at the wall be correspondingly reduced according to Bernoulli's theorem. Since the water cannot be accelerated instantly, it is necessary to find how far upstream from the plane of the supporting rod a wall piezometer should be located to avoid this reduction in pressure. It is also necessary to investigate how far around the circumference of the pipe from the point of insertion of the rod the piezometer should be located to avoid extreme local effects caused by the presence of the rod.

The errors caused by the rod were expected to be small, and the difficulty of making two or more piezometers which would read exactly alike was fully appreciated. It was, therefore, decided to determine the effect of a movable dummy rod with respect to a particular piezometer called the test piezometer. This method would eliminate the errors between several piezometers due to in accuracies of construction, since the change in the reading of a particular piezometer due to change in position of the rod could be measured. The change in reading of the test piezometer would be observed by measuring the difference in pressure between the test piezometer and a reference piezometer which read nearly the same pressure. The reference piezometer would have to be located reasonably close to the test piezometer so that the pressure difference would be small, but sufficiently far away so that its reading would not be affected by changes in position of the dummy rod near the test piezometer.

Apparatus.

A convenient section of an existing 12-in. line was selected for the tests. The section selected had several advantages. At the head end of the line just downstream from the connection to the penstock was a 16 × 8-in. venturi meter which could be readily calibrated by diverting the discharge through the test section into a 50,000-lb weighing tank, assuring accurate measurement of

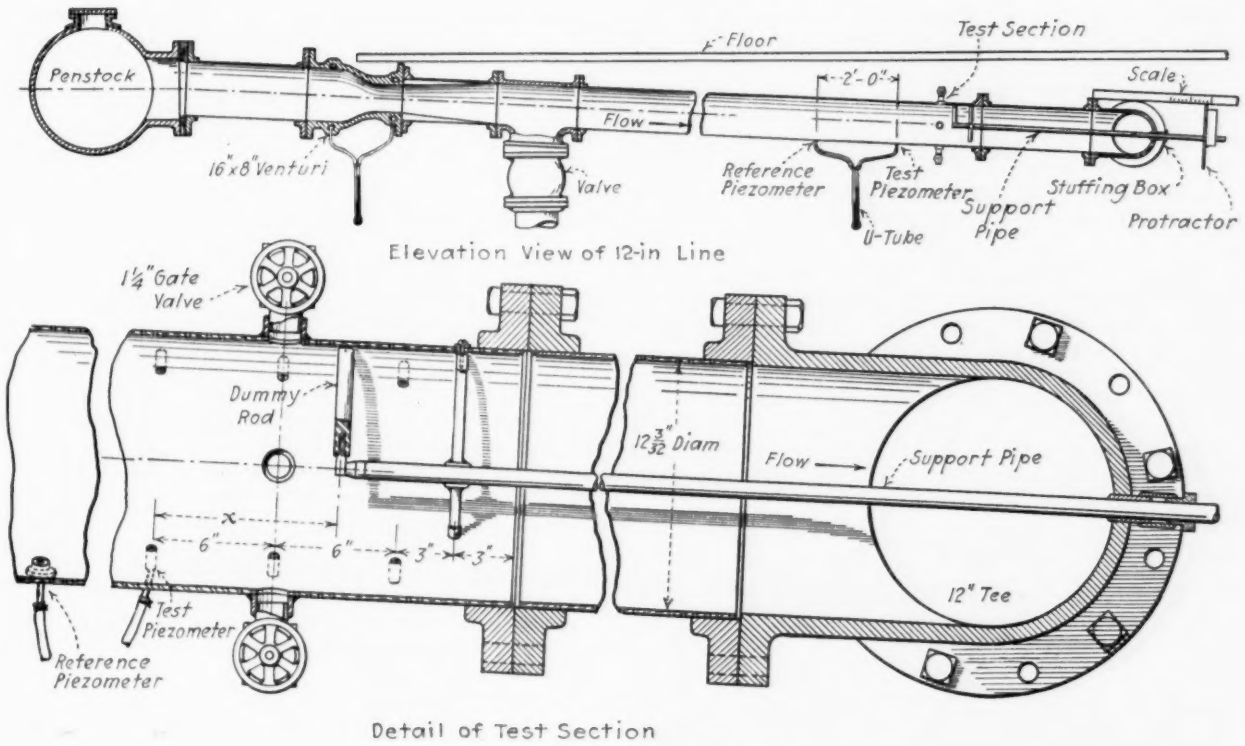

FIG. 26 DIAGRAM OF 12-IN. TEST PIPE

flow. Just downstream from the point selected for the test section was a short length of pipe which could be easily removed to make changes in the test section located near the end of a 15-ft length of pipe. The test section was close to a 12-in. tee so that apparatus for holding and moving the dummy rod could be easily set up. Because of the arrangement of the meter and piping turbulent flow unquestionably existed. The test section is shown in Fig. 26.

The 15-ft length of pipe containing the test section was painted with a smooth waterproof paint to prevent rusting and change of surface roughness while tests were in progress. Twelve brass piezometer plugs with $^1/_8$-in. holes were installed in three rings of four, 6 in. apart. These piezometers were carefully located at the ends of 45-deg diameters, but not exactly in line with the corresponding piezometers of the other two rings. They were carefully lined up and finished flush with a small portable grinder mounted on a wooden jig. All burrs and scratches were removed and the final inspection made with a magnifying glass. Although these piezometers were made with all possible care, the error shown by comparing one with the other eleven was about 1 per cent of the mean velocity head. It is obvious that the construction of the wall piezometers is important.

A reference piezometer was constructed by inserting a bronze plug $2^1/_2$ ft upstream from the center of the test section. This piezometer was too far from the end of the pipe to be finished in place, but its error was found to be constant and its value as an arbitrary reference was not impaired. The details of the piezometers and test section are shown in Fig. 26.

Four tapped connections 90 deg apart but 45 deg from the piezometers were installed in the test section. These connections were made by brazing half a $1^1/_4$-in. pipe coupling to the wall of the pipe. The connections were accurately lined up so that rods could be inserted through them from opposite directions if so desired.

A spider having three legs of $^1/_8 \times ^1/_2$-in. flat iron was accurately centered at the downstream end of the test section. This spider supported a $^1/_2$-in. brass pipe used to hold the dummy rod. The supporting pipe projected through a stuffing box in the 12-in. tee so that a protractor 19 in. in diam could be clamped to it. A suitable fitting was attached to the upstream end of the support pipe to receive the various dummy rods. This fitting was so made that the rods could be changed quickly by inserting them through one of the $1^1/_4$-in. tapped connections and screwing them into place. The rods were carefully finished to clear the pipe walls by not over $^1/_{32}$ in.

The piezometer used for most of the tests was one near the bottom of the pipe in the upstream ring. This ring was farthest from the spider and would be least influenced by it. A glass U-tube was connected by rubber hose between this test piezometer and the reference piezometer located 2 ft upstream from it. The liquid used in the U-tube was monochlorbenzine having a specific gravity of approximately 1.10. The specific gravity of the U-tube liquid was checked each day of test. Care was taken that the U-tube liquid had perfect menisci, otherwise the readings would be in error due to surface tension. To prevent sticking of the meniscus to the glass, the liquid was removed and filtered after each series of tests and the U-tube cleaned and filled with dilute nitric acid.

The flow was measured by the calibrated 16 × 8-in. venturi meter. The meter coefficient had been determined with an accuracy of about 0.25 per cent.

Description of Tests.

A complete test with a given size of dummy rod at a fixed velocity was performed as follows: The desired discharge was set and the deflection of the venturi meter measured and recorded against time of day. Ten readings were taken of the piezometer U-tube with the rod at an angle of 180 deg from the test piezometer and 0.95 ft downstream from it to obtain the initial deflection. The dummy rod was then moved to another position

and the effect on the wall piezometer determined. At each station tests were made at a sufficient number of angular positions to enable a smooth curve to be drawn through the test points.

A complete test occupied about an hour so that the room temperature affected the liquid in the U-tube and slightly changed its specific gravity. The change was gradual so that by taking all readings against time of day and correcting them to standard conditions before computing results, little trouble was encountered from this source. The rate of flow stayed constant during the test.

Tests showed that the presence of the dummy rod exerted no influence on the test piezometer when in the initial or far position. The effect of the rod at any other position, therefore, was taken as the change in the U-tube reading at the new position. Thus, if the difference in pressure between the piezometers were 13 per cent of the mean-velocity head with the rod at the initial position and 14 per cent at some other rod position the effect of the rod at its new position would be a change in pressure at the test piezometer of 1 per cent of the mean-velocity head.

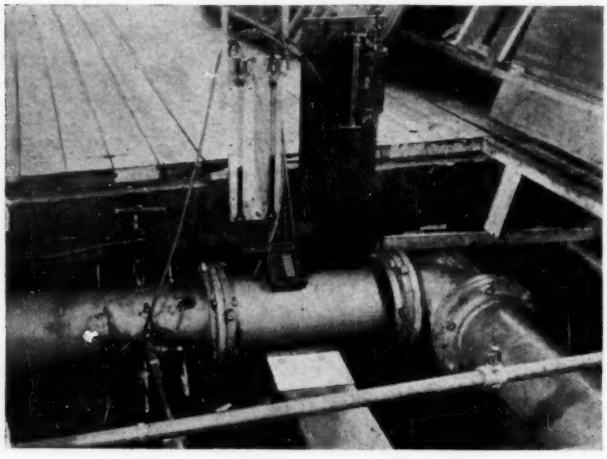

FIG. 27 TEST SECTION OF 12-IN. LINE

Tests were run with dummy rods having diameters of $^1/_2$, $^3/_4$, and $1^1/_{64}$ in. in the 12-in. pipe. Each of these sizes of rod was tested at two or three velocities. A test was also run at two different velocities with no rod which showed that the effect of the support alone was negligible.

Results of Tests.

Examination of the test data showed that the change in the test-piezometer reading was dependent on the relative position of rod and piezometer for a given size of dummy rod. For the same relative positions this change was apparently a constant percentage of the velocity head at all velocities.

In order that the data for different sizes of rods might be correlated, the assumption was made that the piezometer error, as a percentage of the mean-velocity head, was proportional to the reduction in the stream cross-sectional area for two different rods at the same position.

According to Bernoulli's theorem the pressure abreast of the rod should differ from the pressure just upstream from it by the difference in mean-velocity heads. The mean velocities at the two sections are to each other inversely as the cross-sectional areas. Thus, if the pipe area were 1 sq ft and the projected area of the rod a sq ft, then the net stream area abreast of the rod would be $(1 - a)$ sq ft. The mean velocity V_1 in the plane of the rod would be $1/(1 - a)$ times the mean velocity just upstream.

The difference in pressure between the two sections would be

$$h - h_1 = (V_1^2 - V^2)/2g \quad [21]$$

but

$$V_1 = V[1/(1 - a)] \quad [22]$$

then

$$V_1^2 = V^2[1/(1 - a)^2] \quad [23]$$

$$h - h_1 = \frac{V^2}{2g}\left[\frac{1}{(1-a)^2} - 1\right] = \frac{V^2}{2g}\left[\frac{2a - a^2}{(1-a)^2}\right] = K\,\frac{V^2}{2g} \quad [24]$$

For ratios of projected rod area to pipe area less than 0.05 the term a^2 becomes small and the term $(1 - a)^2$ is close to unity, so that K is practically equal to $2a$.

The percentage error for three different sizes of rods at the same location was divided by the factor K, and the result was called the relative percentage error. The relative percentage error was not the same for the different rods at the same location, but appeared to be the same if they were compared on the basis of axial distance in terms of rod diameters. Thus the same relative effect on the test-piezometer reading was obtained with a 1-in. rod 5 in. downstream from the piezometer as was obtained with a $^1/_2$-in. rod $2^1/_2$ in. downstream, when both rods were at the same angular position relative to the piezometer.

In order that all the tests for all sizes of rod and at all velocities might be plotted on the same sheet, the relative percentage errors are plotted as contours on the development of half the pipe wall. These results are shown in Fig. 28.

For convenience in plotting the data for various sizes of rod the piezometer errors were expressed in terms of the mean-velocity head. Essentially, we are more interested in the error in deflection, or what is desired is the apparent coefficient of the pitot tube combined with wall piezometers.

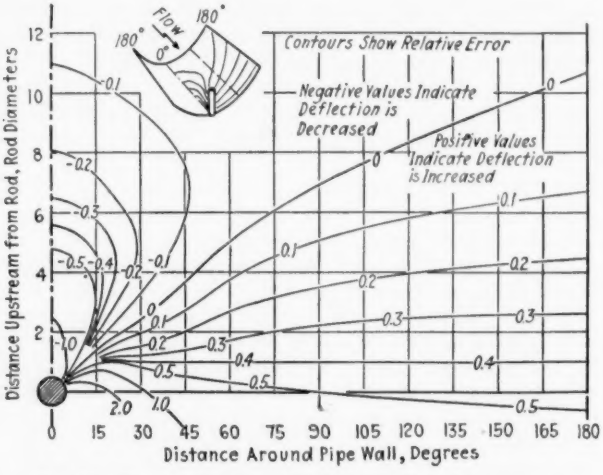

FIG. 28 EFFECT OF SUPPORT ROD ON WALL PIEZOMETER

In all the tests the dummy rod has simulated a pitot rod projecting half across the pipe with the tip at the center of the stream. The ratio of areas then has a simple relation to the ratio of diameters of rod and pipe. If the rod diameter be expressed as d, and the pipe diameter as D, the projected area of the rod will be $Dd/2$ and the area of the pipe will be $\pi D^2/4$. The ratio of areas will be $2Dd/\pi D^2 = (2/\pi)(d/D) = a$. The piezometer error in deflection is proportional to $2a$. Because of the square-root relation between velocity and deflection, the error in velocity is very closely one half the error in deflection. Thus the percentage error in velocity is proportional to a. Then the wall-piezometer error in per cent of mean velocity should be equal to the contour value in Fig. 28 multiplied by $2d/\pi D$.

As an example, suppose that a simple pitot tube having a rod 1 in. in diam is to be used in a 12-in. pipe. What would be the effect of the rod if the wall piezometers are situated 90 deg from the stuffing box and $1^1/_2$ in. upstream from the rod center line?

Fig. 28 shows that a relative error between 0.3 and 0.4 or about 0.36 exists when the piezometer is located 90 deg and $1^1/_2$ rod diameters upstream. The error in mean velocity would then be $0.36(2d/\pi D) = 0.36(2/12\pi) = 0.019 = 1.9$ per cent of the mean velocity.

If the pipe factor is 85 per cent, the piezometer error will be 0.85×1.9 or 1.6 per cent of the center velocity.

The effect of the rod on the wall piezometers will cause the indicated center velocity to be 1.6 per cent too large.

It is apparent from these tests that the wall piezometer should be located at a point little affected by the presence of the pitot rod. If two piezometers are connected together, they should be located so that the rod affects both an equal amount.

Pressure Piezometer of Pitot-Static Tube

In the combined or pitot-static tube one or more pressure piezometers are located on the tip itself. Research performed by Merriam and Spaulding (9), of the Worcester Polytechnic Institute on pitot-static tubes with air shows that the pressure along the tip is affected by the presence of the supporting rod and by the nose of the tip itself. This work was performed in the jet of a 20-in. wind tunnel. The pitot tube recommended by Merriam and Spaulding based on their tests, was one with a tip twenty-four times as long as its diameter, and with the pressure-head orifices located eight diameters back from the hemispherical nose. Thus, for a tube of $^1/_2$ in. diam, the tip would be 12 in. long. Such a tube would be satisfactory for measuring the flow of gases, but would be much too awkward to use with liquids flowing in pipes under pressure.

In the Merriam and Spaulding tests the pressure piezometers varied from two to eight arranged in a ring around the tip. With the shorter tip, more convenient for work in pipes, the pressure at each piezometer would vary greatly and the average would be appreciably affected if some should become clogged.

It was, therefore, decided to study the effect of the supporting rod on a single tip pressure piezometer in a manner similar to that used for the wall piezometers. The test section was located in the 12-in. pipe shown in Fig. 26. The test piezometer hole, $^3/_{32}$ in. in diam, was carefully drilled through the side of a $^1/_2$-in. brass pipe. A solid hemispherical nose was soldered to the upstream end of the $^1/_2$-in. pipe. The downstream end of the brass pipe which projected through the stuffing box in the 12-in. tee was capped and a connection made through the cap for a $^1/_4$-in. rubber hose. The brass pipe rested on a fixed dummy rod which was accurately shaped to receive it. With a large 360-deg protractor fastened to the projecting end, it was possible to rotate and slide the small pipe so that the piezometer was moved with respect to the dummy stem.

The effect of the hemispherical nose of the tip, as determined by Merriam and Spaulding's tests, is shown in Fig. 29. In order that the pressure at the piezometer might not be modified by this effect, the piezometer was located 11.5 diameters back from the nose.

The arrangement of the apparatus is indicated in Fig. 31. The brass piezometer pipe was connected to one side of a differential U-tube, and the other side of the U-tube was connected to a wall piezometer 12 in. upstream from the dummy rod. The U-tube contained a liquid which magnified the difference in pressure ten times.

Tests were made with a center velocity of about 8 fps. The piezometer was moved axially with respect to the dummy rod and also rotated through angles from 0 to 180 deg from the plane of the rod. The change of U-tube deflection with position of the pipe piezometer was a measure of the rod effect.

In computing the results of these tests, there was evidence that the reference pressure measured by the wall piezometer was not constant, but changed with the axial movement of the brass pipe. The dummy stem was removed and the brass pipe supported by a spider located 2 ft downstream from the reference wall piezometer. A U-tube containing monochlorbenzine was connected between the wall piezometer and the reference piezometer 2.2 ft upstream

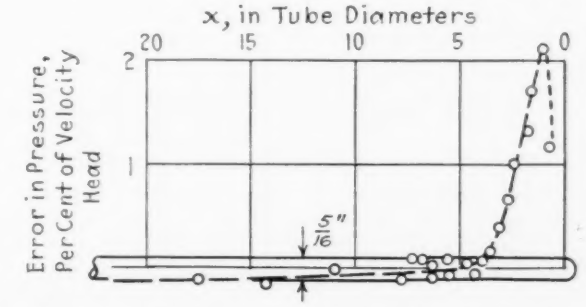

Fig. 29 Effect of the Nose on Pressure Piezometer Located on the Tip

(Flow around nose causes low pressure readings. Tests by Merriam and Spauld ng.)

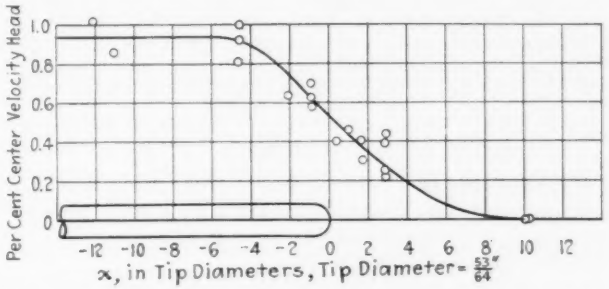

Fig. 30 Effect of Tip on Wall-Piezometer Pressure in 12-In. Pipe

(Venturi effect causes wall piezometer to read low.)

as used in the wall-piezometer tests. (See Fig. 26.) When the brass pipe was moved by the wall piezometer, the U-tube deflection was affected.

The change in the reference wall piezometer corresponded with the increase of velocity due to the presence of the $^1/_2$-in. pipe. The outside diameter of the brass pipe was 53/64 in., and the projected area equal to 0.47 per cent of the area of the 12-in. pipe. The change in wall-piezometer reading caused by moving the pipe abreast of it, was 0.94 per cent, exactly corresponding to the venturi effect obtained by reducing the area. The results of this test, shown in Fig. 30, indicate that when a large pitot tube is used in a small pipe a correction for the projected area of the tip should be made.

The results of the tests to determine the effect of the support rod on the tip piezometer are shown in Fig. 31. These results have been corrected for pipe friction between stations and venturi effect caused by the presence of a large tip. The error in pressure reading is shown in per cent of center velocity head. Because of the square-root relation, the error in velocity would be one half the error in deflection. It is apparent from Fig. 31 that piezometers located within 2 or 3 diameters of the rod will be unstable and, therefore, inaccurate. To obtain a stable coefficient near unity, the tip should be at least 10 diameters in length with the pressure piezometers located 5 diameters back from the nose.

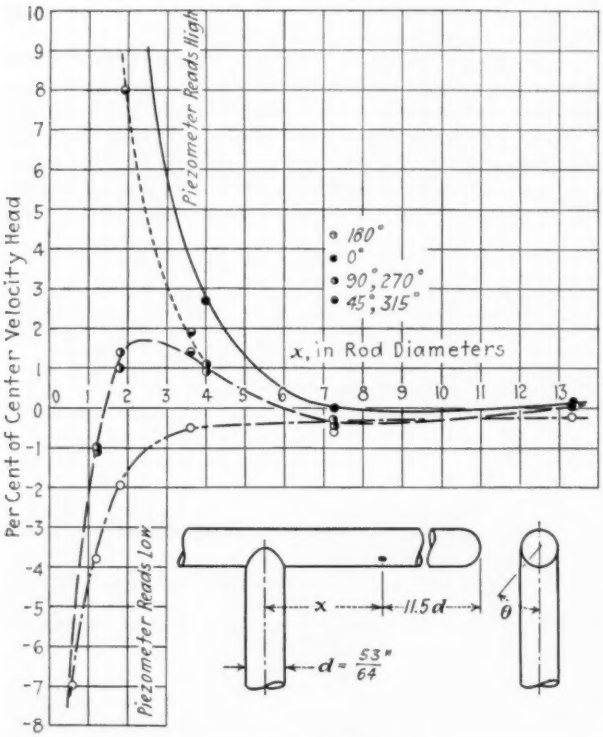

FIG. 31 EFFECT OF DUMMY ROD ON PRESSURE PIEZOMETER ON TIP OF PITOT-STATIC TUBE

CONCLUSION

If a pitot tube does not measure the true velocity head at a point in a turbulent stream, either the impact orifice reads the dynamic head incorrectly or the pressure piezometer does not read the true pressure head, or both.

The tests made in still water with the rotating boom show that the impact orifice registers the true dynamic head within one part in a thousand. If this perfect registration is changed by turbulent flow in a pipe, the change must be caused either by the turbulence or by the confining action of the pipe walls. The only conceivable ways in which turbulence can affect the reading of the impact orifice is by the angularity with which the water approaches the tip or by causing an error in registration of the average of pressure and velocity pulsations. The confining action of the pipe might possibly cause the rod to influence the pressure at the impact orifice.

Angularity. The results of the tests show that none of these effects is sufficiently great to cause an appreciable error, for in the case of angularity:

1 The mean angle of approach is less than 3 deg.
2 It is nearly constant across the pipe.
3 The radial and tangential angularity are equal.
4 There is no noticeable regular cycle.
5 The angularity is independent of the size of pipe.
6 The measured angularity agrees well with the Prandtl theory of turbulent flow.

Pulsation. The mean pulsation measured in a 12-in. rough pipe was only 4 per cent of the velocity head. It can be shown that a mean pulsation of 25 per cent of the velocity head is required to cause a 1 per cent error in velocity due to averaging deflections instead of their square roots.

The mean pulsation was the same for both impact orifice and wall piezometer.

Dynamic Effect of Stream. The dynamic pressure of the stream against the tip does not resist outward flow from the tip and cause surges to be incorrectly averaged.

Support Rod. The support rod does not affect the reading of the impact orifice.

It is concluded from these facts that the impact orifice correctly registers the true dynamic head in both smooth and turbulent flow.

Wall Piezometers. The errors obtained by experienced engineers when using the pitot tube must then be caused by an incorrect measurement of the pressure head. The results of the tests show that when the pressure is measured by wall piezometers: The rod causes an error in pressure reading.

It is obvious that if, for any reason, the pressure is not constant across the pipe, the wall piezometer does not measure the pressure head which exists at the tip of the pitot tube.

Tip Piezometers. If the pitot tube is the combined type in which the pressure head is measured by tip piezometers:

1 The pressure reading is affected by the relative size of tip and pipe, causing a venturi effect which is appreciable if the tip is too large for the pipe.

2 The pressure reading is affected by both the shape of the nose of the tip and by the support rod. These effects are not serious if the piezometer is at least 5 tip diameters back of a hemispherical nose and 5 or 6 tip diameters ahead of the support rod.

The conclusion drawn from these tests is that the most reliable pitot tube is one of the combined type using a tip-pressure piezometer. This piezometer or group of piezometers should be located on the tip at a point where the rod effect is stable and affects all piezometers in the group about the same amount. Such an instrument may not read the true velocity head, but its error will be constant for all ordinary velocities and sizes of pipes, so that it is capable of being calibrated and used under different conditions of flow if necessary. Special types of combined pitot tubes such as the Pitometer having both the impact and reference orifices on the instrument itself give accurate results since both orifices are calibrated together.

Grateful acknowledgment is extended to Mr. Julien White and Mr. Shaw Cole for their assistance in making some of the tests and to Mr. E. S. Cole for his kindness in providing the four-contact angularity indicator. The helpful suggestions and criticism given by Prof. C. M. Allen, Prof. L. J. Hooper, Prof. W. S. Pardoe, and others is also acknowledged.

Discussion

R. W. Angus.[3] The experiments recorded in this paper are of unusual interest and give quantitative values for the ideas long held regarding the nature of hydraulic flow. The author has used a most ingenious method for getting the average angle of flow of the particles within the pipe.

The writer is not surprised at the statement that the impact orifice in the pitot tube correctly registers the dynamic head, for his own experience is that the tube gives remarkably accurate results. Errors may easily result in the use of the tube due to the incorrect readings of the differential manometers used to indicate the velocity head, for if rubber hose is used between the tube and manometer, air may easily collect in it in such volumes as materially to affect the specific gravity of the fluid in the hose. This may be readily avoided, of course, if water is frequently blown through the connecting hose, but sometimes the pressure of the water being measured is low and then water cannot be blown through quickly enough.

The writer has not used the wall piezometer for the pressure element of the pitot tube, but would expect some inaccuracies due to it, because it is unusually difficult to measure pressures very accurately. Any irregularities in the pipe wall around the measuring holes will vitiate the readings. In order to study this problem, the writer made a careful series of experiments some years ago and published the results.[4] In this case, the writer primarily wished to know the accuracy with which pressure readings, measured at the outlet end of an elbow, could be taken. Additional studies were also made. The pipe was 6-in. standard steel pipe supplied with water from a tank 8 ft square, there being straightening vanes at the pipe entry. Four piezometer openings were made in the downstream flange of the elbow, two of the holes being in the plane of the bend and two on the other diameter. In all cases the holes were carefully drilled normal to the pipe wall. All holes were drilled $^1/_8$ in. with the inner end rounded to $^1/_{16}$ in. radius. Four open-topped glass tubes enabled the pressure at each piezometer opening to be read with accuracy. The water was delivered by the elbow into a 6-in. pipe attached by flange to the elbow.

Traverses by pitot tube, on two diameters of the supply pipe above the elbow, showed a good velocity distribution for pipe velocities varying from 6 fps to 17 fps. The four piezometer tubes showed considerable differences in pressure, the one in the plane of the bend and at the outside of it usually showing the greatest pressure. For a long-radius elbow the hole diametrically opposite the former (that is, on the inside of the bend) gave the next highest reading, while those at the sides of the bend gave the lowest readings. The average of the four readings differed by 0.2 ft from the true pressure at high velocities.

To measure the effect of obstructions close to the piezometer openings, the pipe into which the elbow delivered was first set concentrically with the opening in the elbow, the face of the elbow connected to the pipe being $^1/_2$ in. downstream from the piezometer openings. This was the condition for the above readings. When the eccentricity was $^1/_4$ in. there was a variation between the extreme piezometers of 4.5 ft, for a mean pipe velocity of 17.29 fps (for which the velocity head is 4.65 ft) as against a corresponding variation of 1.5 ft under the same flow when the pipe was concentric. These experiments proved that, even when the piezometer openings were carefully made, any irregularities in the pipe wall, even below the openings, would cause considerable errors in the pressure readings. By the same reasoning the ordinary roughness of the pipe wall would affect the reading to some extent.

With a pipe velocity of 6 fps the velocity head is 0.56 ft. Even if the impact opening of the pitot tube gave a correct reading, an error of 0.028 ft in the pressure reading would correspond to an inaccuracy of 5 per cent in velocity head. The writer's experience is that pressure measurements on the ordinary pipe wall cannot be read much more closely. Wherever the pitot tube is used the writer believes that the pressure element should be close to the impact element and on the same tube with it. This naturally enlarges the whole tube, but there is no difficulty in keeping the outside diameter of the tube down to a small proportion of the pipe diameter in cases occurring in ordinary practice.

The author might well have included in his bibliography a reference to a paper by A. Fage.[5]

J. E. Christiansen.[6] The author has answered many questions regarding the behavior of pitot tubes in pipes that have long remained unexplained. Especially noteworthy are his unique methods of studying the different characteristics of pitot tubes, as ordinary tests on pitot tubes are of little value in this respect.

The characteristics of pitot-static tubes in a wind tunnel were thoroughly studied by Ower[7] at the National Physical Laboratory, London. He found that the pressure determined by piezometers along the tip of a pitot tube was too low for a considerable distance back from the nose, but that the error became small in about 6 diam. He also found the rod to have the opposite influence on the piezometer pressure and for even a greater distance along the tip. These conclusions were later substantiated by the work of Merriam and Spaulding (9),[8] referred to by the author. Marks[9] has also contributed valuable data concerning the characteristics of pitot tubes, including the first published data that had come to the attention of the writer concerning transverse pitot tubes. All of these studies, however, have dealt primarily, or wholly, with the flow of air. Can the conclusions reached in these studies be broadly transferred to the case of flow of water in pipes, where confining boundaries, incompressibility of fluid, different density, and viscosity may have an influence on the magnitude of the effects produced by different pitot-tube designs? For example, does the influence of the nose or rod on the piezometer pressure of a combined tube extend as far along the tip in the case of water in a pipe as it does in air? The author has only partly answered this question.

The agreement between the measured velocity distribution across the pipe and the von Kármán equation (Fig. 15) is very good, considering that this equation is derived by dealing only with the distance from one wall. In the central region of the pipe the velocity distribution is undoubtedly also affected by the opposite wall. One should expect a velocity-distribution curve across the pipe that is continuous and symmetrical with respect to the center line; i.e., that du/dy at the center must be zero. This is not true of the von Kármán equation which indicates a finite value of du/dy at the center, and therefore an abrupt break in the curve at this point. A very good discussion of this subject is presented by Rouse (10), who comments that the von Kármán equation, "is valid for the wall regions in either case (referring

to both smooth and rough walls) and, moreover, gives good results over the entire central portion of the flow."

Regarding curve *A* Fig. 18, stated to be computed from the Prandtl formula, Equation [18], should not this read Equation [17]? If du/dy is assumed to approach 0 as the center is approached (as evidenced by the author's test points as well as measurements by Nikuradse), the mixing length l need not become zero according to Equation [17] and may have a finite value, as indicated by curve *B* Fig. 18. There appear to be no physical reasons for assuming $l = 0$ at the center. In fact, there are good reasons why it should have a finite value, probably a maximum value at this place.

The writer has been primarily interested in the pitot tube as an instrument for measuring the flow from irrigation pumping plants, especially farm turbine pumps with horizontal discharge pipes ranging from 6 in. to 12 in. diameter. Pitot tubes more nearly approach the ideal instrument for this purpose because (*a*) they can be used in nearly all cases encountered, (*b*) they are readily portable and easily installed for test purposes, and (*c*) they are sufficiently accurate for most practical purposes.

Since the inauguration of a free pump-testing service by the major power companies in California, pump companies are depending more and more upon these tests as acceptance tests on pumps sold under performance guarantees. For such tests accuracy is essential, and differences of 2 or 3 per cent in computed efficiencies may mean the acceptance or rejection of a pump. Accuracy within these limits is difficult to obtain with field tests where conditions are frequently far from ideal for testing.

Transverse pitot tubes are widely used for testing irrigation pumps, although little has been published concerning them. With limited testing facilities available, studies were undertaken at the College of Agriculture, University of California, Davis, to determine some of the characteristics of transverse pitot tubes in pipe lines. The preliminary results of these studies have been published.[10] In these tests, the mean velocities determined with transverse tubes were compared with those computed from the flow measured with a free-flowing orifice which previously had been calibrated by volumetric measurements. In addition to transverse tubes in sizes ranging from $^1/_8$ in. to $^5/_{16}$ in. diameter, a number of other kinds of pitot tubes have been tested. Of particular interest are the tests of a conventional-type pitot tube made according to the suggestions of Ower,[7] who claims such a tube to have a coefficient of unity. This tube was made from $^5/_{16}$-in. diameter brass tubing, has a hemispherical nose, and six piezometer holes on the tip 6 diam from the nose and 8 diam from the rod. This tube can be inserted through a $^9/_{16}$-in. drilled hole, tapped for a $^3/_8$-in. pipe-thread stuffing box. The flow determined with this instrument from a 10-point traverse, each point representing equal areas, at a position in the pipe line about 20 diam below a partly opened gate valve and about 7 diam above the free-flowing orifice, averaged from 2 to 3 per cent greater than that determined with the orifice. Traverses have been made in horizontal, vertical, and both diagonal directions with consistent results. Extreme care was taken to set the tube at the correct position for each point. A water-air manometer was used in all of the tests.

At a position in the pipe about 6 diam below the partly opened gate valve, the flow determined with this pitot-static tube averaged from 6 to 8 per cent greater than for the orifice. This is explained by the fact that for the extremely turbulent flow the transverse currents produce a negative piezometer pressure, and therefore increase the indicated head. At this position, the velocity distribution across the pipe was unsymmetrical, the velocity being greatest near the top and to one side, whereas the gate opening was at the bottom.

Similar tests were made with a $^5/_{16}$-in-diameter transverse tube with two orifices exactly opposite each other. The flow determined with this instrument, based on 10-point traverses in two directions, averaged about 2 per cent greater than indicated by the orifice, but there was no difference in results, 6 diam or 20 diam from the valve.

Earlier studies of transverse tubes with single orifices showed that the velocity head obtained with the orifice facing upstream agreed very closely with that obtained with a conventional-type pitot tube and, therefore, indicated the true velocity. With the orifice in the downstream position, the mean velocity computed from the negative head agreed very well with the mean velocity past the net section, the area of the pipe less the projected area of the tube, even in the exaggerated case of a $^5/_{16}$-in. tube in a 1-in. pipe. The total indicated head for a transverse tube with both impact and trailing orifices is, therefore, slightly greater than twice the true velocity head for the full pipe section. The mean velocity determined from a traverse across the pipe agrees very well with the average velocity corresponding to an area equal to the area of the pipe less half the projected area of the tube, considering the manometer head equal to twice the velocity head. This correction, when applied to tubes of different sizes, brings the results into almost perfect agreement. It was therefore applied to all tests with transverse tubes.

In field work, where it has been necessary to use the instrument close to the pump head (elbow) it has been noticed that the conventional pitot-static tube indicates an appreciably greater flow than the transverse tube. As the result of these studies, the writer believes the transverse pitot tube to be a more reliable instrument for field tests than a conventional pitot-static tube. A transverse tube is not sensitive to direction and can be rotated about 10 deg from the correct position before any effect on the velocity head is noted. Upon further rotation, the manometer head decreases rapidly, becoming negative at approximately 63 deg.

The writer is in full agreement with the author's conclusion that it is easy to measure accurately the true dynamic head with the impact orifice, but that "it is practically impossible to measure the true pressure head at a point in the fluid." This applies also to a transverse tube. Nothing seems to affect the velocity head produced by the impact orifice, but the trailing orifice is extremely sensitive and the negative head is appreciably affected by the position of the stuffing boxes with respect to the inside of the pipe wall. When the stuffing box is back in the pipe wall, the cavity around the tube at the wall produces some disturbance that creates a large negative head near the wall and a lower negative head nearer the center of the pipe. This effect, illustrated in the paper,[10] was completely eliminated by soldering couplings to the outside of the pipe for the stuffing boxes and drilling holes through the pipe wall the size of the tube. The burrs on the inside of the pipe were carefully removed. Stuffing boxes protruding slightly into the pipe have very little effect on the trailing orifice. The true velocity distribution, across the pipe, however, cannot be obtained with a transverse tube with both impact and trailing orifices but can be determined by using only the impact orifice and wall piezometer.

Incidentally, where one has access to the inside of the pipe, very satisfactory wall piezometers can be made by soldering or brazing small pipe couplings or nipples to the outside of the pipe, and then drilling a small hole (about $^1/_8$ in.) through the pipe wall, being very careful to remove completely the burr on the inside of the pipe. For field tests, however, one seldom has access to the inside of the pipe, and a combined form of pitot tube is essential.

[10] "Characteristics of Transverse Pitot-Tubes," by J. E. Christiansen and O. C. French, *Agricultural Engineering*, vol. 18 (1), January, 1937, pp. 21–24.

E. Shaw Cole.[11] Distrust of the accuracy of pitot tubes in measuring the flow of water in pipes has grown in recent years because there seemed to be no law of variation of the coefficients less than unity which were obtained in pipe calibration.

It has long been known that the impact tip does not correctly register the cosine component of velocity when the water approaches the tip of angles greater than five or ten deg. The most frequent explanation of the low coefficients obtained in pipes has been the existence of angular flow, caused by turbulence.

When the author's method of measuring the mean angularity of turbulent flow indicated even less angularity than was reported by E. S. Cole in 1935 (8), it was apparent that some other explanation for the discrepancies in simple pitot-tube coefficients must be found. A study of the author's investigation of the effect of the support rod shown by his Fig. 28 did not explain Prof. W. S. Pardoe's and Prof. W. B. Gregory's results as reported in their discussion of "Pitot Tube Practice" (see Table 2), although the value of the rod correction studies reported in 1934 by Cole were confirmed.

TABLE 2. PITOT-TUBE COEFFICIENTS OBTAINED IN VARIOUS SMALL PIPES HAVING DIFFERENT PIPE FACTORS, AT UNIVERSITY OF PENNSYLVANIA AND TULANE UNIVERSITY

Experimenter	Size of pipe, in.	Pipe factor	Tube coefficient
W. S. Pardoe	8	0.971	0.995
W. S. Pardoe	8	0.875	0.980
W. S. Pardoe	4	0.858	0.982
W. B. Gregory	10	0.83	0.976

Pardoe in his discussion gave the results of calibrations of three different shapes of impact tips combined with wall piezometers in an 8-in. pipe. These tips are shown in Fig. 32. The counterbored tip showed a change in coefficient from 0.980 to 0.995 when the 22-ft length of test pipe was reversed so that the pitot station was located just downstream from a converging section. The wall piezometers were so located that the rod effect in the author's Fig. 28 did not apply.

It was, therefore, decided to test Pardoe's tip shapes in the same 12-in. pipes used by the author in order that some correlation might be obtained. In addition to the four different tip designs shown in Fig. 32, a single pitometer tip was also tested as a simple pitot tube. The standard pitometer using the customary impact and trailing tips was used to represent the combined form of pitot tube. A sketch of the pitometer is given in Fig. 5 of the author's paper.

The calibrations presented in Fig. 32 were made in three different types of flow in 12 in. pipes. The smooth pipe was the same as used by the author in his "Rod Effect Studies" and is shown in Fig. 26 of his paper. This pipe had been painted with a smooth waterproof paint which caused the pipe factor (ratio mean to center velocity) to have the rather high value of 0.925. The same test section was used for the rough pipe tests, the pipe being lined ahead of the test section with $^1/_8$-in. mesh wire screen (see Fig. 34) for a distance of 12 ft. The lining of screen terminated 2 ft 3 in. upstream from the pitot test section. The pipe factor in this pipe was 0.774. The third section was located in another pipe line which was located along the west wall of the laboratory. This pipe had a pipe factor of 0.874 which was intermediate between the smooth and rough sections described above.

In all cases for the simple pitot-tube test the wall piezometers were located at 45 deg to the axis of the pitot tubes and 6 in. upstream from the test section so that all "rod effect" would be avoided. The piezometers were carefully finished according to the recommendations of Allen and Hooper in their paper "Piezometer Investigation." (6)

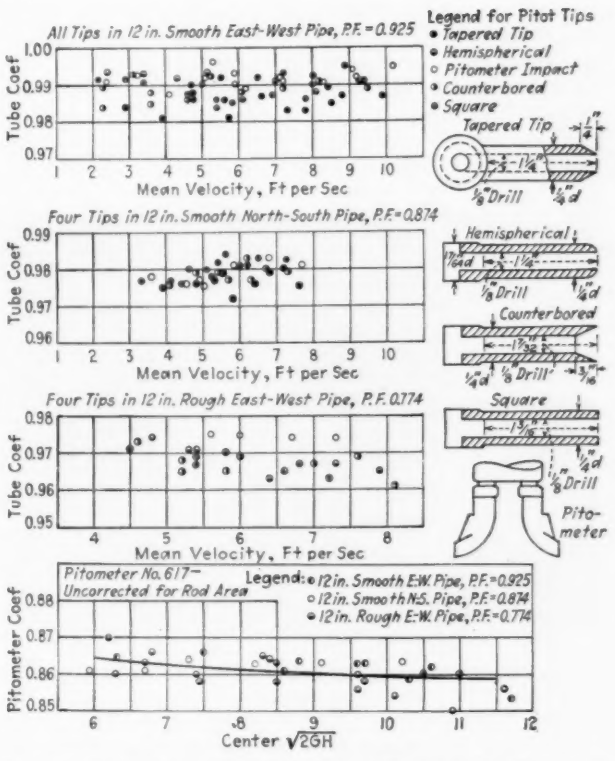

Fig. 32 Pitot-Tube Calibrations of Various Tip Shapes in Three Different 12-In. Pipes

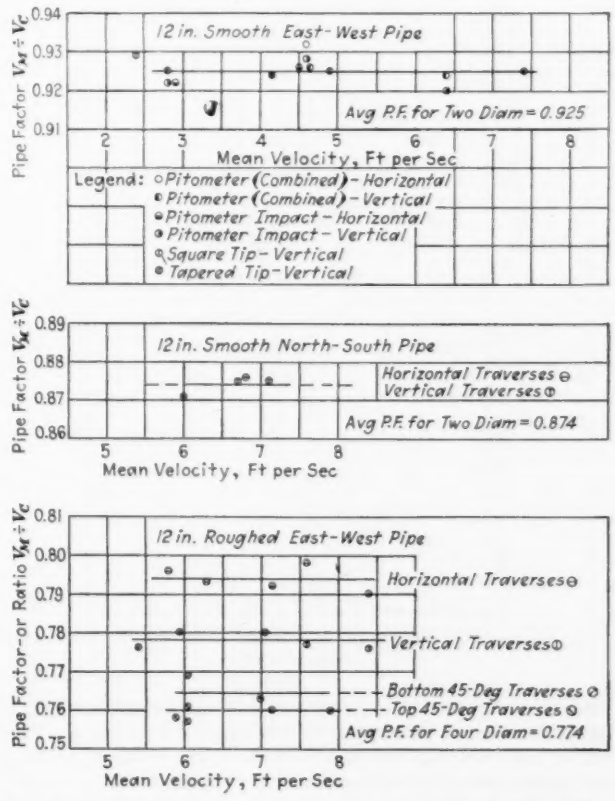

Fig. 33 Pipe Factors ($V_M \div V_C$) for Three Different 12-In. Pipes

Traverses to determine the pipe factors shown in Fig. 33 were made in all three test sections at several rates of discharge with both the simple pitot tubes and the pitometer.

These traverses, samples of which are plotted in Fig. 35, were made on two diameters 90 deg apart except for the case of the rough pipe, when irregularities in the screen lining made it necessary to traverse on four diameters 45 deg apart. In traversing,

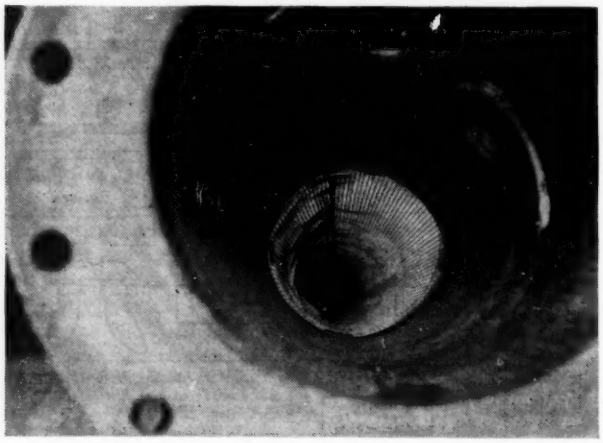

FIG. 34 VIEW LOOKING UPSTREAM IN 12-IN. ROUGHED EAST-WEST PIPE

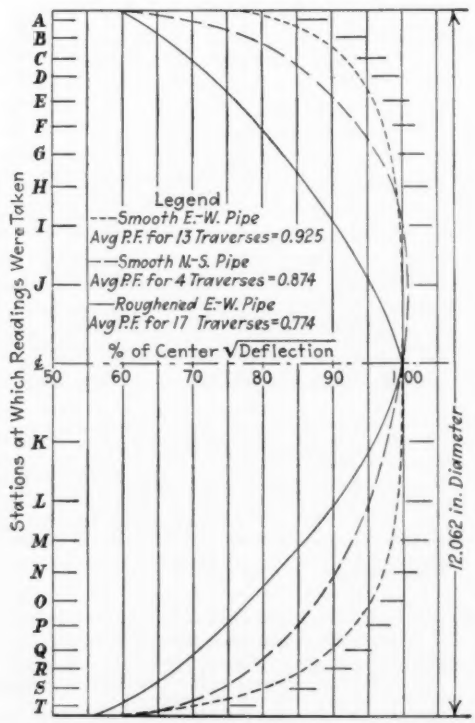

FIG. 35 SAMPLE VELOCITY TRAVERSES FOR THREE DIFFERENT 12-IN. PIPES

readings were made at 20 points on each diameter, these points being situated at the centers of ten rings of equal area. Five sets of forty readings were taken at the center of the pipe during the traverse of a single diameter.

The flow was measured by calibrated venturi meters which could be checked by a 40,000 pound weighing tank while the pitot tests were going on. Several check tests were made on these venturi meters.

These tests involved a large number of individual readings. The total number of readings in the smooth-pipe tests was more than 5000. In the rough pipe the traverses and calibrations at the center required more than 7000 readings. About 1600 readings were required for the traverses and tests at the center of the third or intermediate test section.

RESULTS

Results. The results of the calibrations are presented in Table 3 and Fig. 36 which presents a plot of pitot-tube coef-

ficients against pipe factor. It will be seen in the case of simple pitot tubes, Fig. 36*A*, that five tips of widely different design gave practically the same coefficient under similar flow conditions. On the other hand, the coefficient for each type of flow became smaller as the pipe factor decreased so that for a pipe factor of 0.774 the tube coefficient was 0.967. In addition the coefficients obtained at the University of Pennsylvania and at Tulane University were plotted with the others after computation had been made of the sample traverse curves presented in the discussion (8). The remarkable agreement of these points, as shown in Fig. 36*A* leads to the conclusion that simple pitot-tube coefficients in pipes vary directly with velocity distribution.

Wide experience in gaging the flow of commercial pipes and penstocks has demonstrated that the pipe factor for a straight run of pipe usually lies between 0.86 and 0.79. Referring to Fig. 36*A* it will be seen that these values correspond to pitot-tube coefficients ranging from 0.973 to 0.978, which have been so often reported in engineering literature.

Fig. 36*B* also presents the calibration results obtained with a combined form of pitot tube such as the pitometer. It will be seen that practically the same coefficient was obtained for all three types of flow distribution. The fact that the pitometer coefficient did not vary with the type of flow pattern demonstrates that no appreciable angularity was present in these three different types of flow.

Conclusion. Although the simple pitot-tube coefficient changed in pipes of different flow pattern, Fig. 36*A* shows that the pitometer coefficient remained constant in all three of the 12-in. pipes. Since about three quarters of the pitometer deflection is caused by the impact tip, if the change in the pitot coefficient were caused by pulsation effects, then the pitometer coefficient should have changed nearly as much as did the pitot-tube coefficients in the different pipes. Furthermore, if the change in coefficient had been caused by angularity effects the pitometer coefficient should have changed more than the pitot-tube coefficients. It can only be concluded, therefore, that the variation in pitot coefficient with change in pipe factor was due entirely to a decrease in the wall pressure reading, this decrease apparently depending on the type of flow distribution, caused by the pipe roughness, or the location of the gaging point.

The writer wishes to acknowledge gratefully the help and interest extended by Professors C. M. Allen, C. W. Hubbard, and L. J. Hooper.

E. A. Hitchcock.[12] To the writer certain of the discussions implied a vague knowledge of the early uses of the pitot tube. The following results obtained over a period of twelve years, 1900 to 1912, in the use of the pitot tube in measuring the flow of air and natural gas may therefore be of value.

From a partially written paper of the writer's, commenced more than thirty years ago but never completed, the following is quoted: "The first application of the pitot tube for natural-gas measurements in this country was made by Prof. S. W. Robinson, during the year 1886, when the gas wells opening up in Ohio had so high a capacity as not to admit of measurement by means of the gas anemometer which had been in use previous to that time. In 1890 the Ohio Geological Report contained a chapter written by S. W. Robinson on the Measurement of Natural Gas wherein is illustrated his first form of instrument for pipe-line flow, having what he called the combined static and dynamic tip.

"There were two forms of Robinson instruments, differing only in the design of tips, to be inserted in the line; i.e., the combined or expert pitot tip where both static and dynamic openings are in a combined form and the permanent or double-tip type, each tip of such a length as to reach the center of the line. The static tip was a duplicate in shape of the dynamic one but end closed and with parallel sides having the static openings."

Professor Robinson exhibited a setup of the application of the two forms to pipe lines at the Chicago Columbian Exposition of 1893. This display was accorded a Certificate of Award.

Years of commercial use and experimental work with the pitot tube convinced the writer that its accuracy depended largely upon an intelligent application and use. For example, the Robinson expert combined form, as furnished by a supply company, was found to give results 13.9 per cent too high. On the other hand a test pipe 2.1 in. in diameter, equipped with separate tips made of $^1/_4$-in. OD brass pipe, reaching to the center, and placed in a line 38 diameters or more from a fitting, gave correct results under accurate calibration by known quantities of air. Thirteen tests of this pitot pipe requiring over five hundred readings gave an average deviation from the true value of 0.1 per cent with a plus or minus of 1.45 and 1.88 per cent, respectively. The writer used this form of test pipe in the Ohio and Canadian gas fields extensively, in connection with commercial processes. For main gas-line work with lines up to 12 in. diameter, the writer used a traversing dynamic tip with a separate static tip, 6 in. following and $1^1/_2$ in. from the pipe wall. This tip was of $^1/_4$ in. outside diameter brass tubing, tapered to a point $2^1/_2$ in. upstream with $^1/_8$-in. static openings 2 in. from the point. In no case did he ever use an opening in the pipe wall for static pressure on account of pipe roughness. The above arrangement permitted a velocity curve for every case investigated.

It was in 1908 that Eugene Coste, Toronto, Canada, and the writer were called upon by the Union Natural Gas Company of Pittsburgh to determine the coefficients for three drawn-brass test tubes or pipes having 2 in., 3 in., and 4 in. diameters, each 12 ft in length. The static openings were in the side wall 9 ft 4 in. from the entering ends, and the dynamic tips, made of $^1/_2$-in. outside diameter steel pipe were located 10 in. beyond. The pipe interiors were exceptionally smooth. The calibrations were done by natural gas, the measuring element being a gas holder about 81 ft in diameter and having a net capacity of 5246.5 cu ft per ft of rise. All trials were carried on during the night in order to obtain constant temperatures about the holder. In all, 30 runs were made during the nights of June 3, 4, and 5, 1908, and the pitot pipe coefficients obtained were as follows:

TABLE 4 PITOT-PIPE COEFFICIENTS

4-in. tube	3-in. tube	2-in. tube
5134	3036	1345
5203	3073	1353

5190	3054	1355
5155	3061	1357
5156	3055	1362
Average 5171	3043	1381
	3067	1345
	3038	1369
	3044	1384
	Average 3051	1372
		Average 1363

These coefficients are tabulated in the order of gas flow from minimum to maximum which were as 64, 150, and 100 per cent, respectively, for the three tubes. These coefficients were determined by the following formula and are for cubic feet of natural gas per hour at a flowing temperature of 40 F, storage at 50 F, and 16.3 lb per sq in. absolute pressure. The specific gravity of the gas was 0.668.

$$\text{Coef} = \frac{\frac{5246.5}{16.3} \times L \times (Br \times p) \frac{510}{T_2} \times \frac{60}{\text{Time}}}{\sqrt{h(Br + P) \frac{500}{T_1}}}$$

L = lift of holder, ft
Br = pressure by barometer, lb
p = pressure in holder, lb
T_2 = temperature absolute of gas in holder, F
h = dynamic head of water, in.
P = pressure of flowing gas, lb
T_1 = temperature absolute of flowing gas, F

These pitot tubes or pipes were then used for standardizing the permanent pitot installations at measuring stations, a system in quite common use at that time.

L. J. HOOPER.[13] The experimental work mentioned in the discussion by E. Shaw Cole suggested that the variation in coefficient of a simple pitot tube might be caused by the fact that the wall piezometers do not measure the mean pressure existing in the test cross section. This might conceivably arise from several causes such as faulty construction of piezometers or a variation in pressure across the traverse.

Piezometer errors were checked in a 12-in-square tilting flume 22 ft long. The entrance of the flume was made bell mouthed and a roof was provided for a length of 3 ft to obtain smooth flow conditions. A sliding gate at the downstream end of the flume was used as a backwater control. In operation the slope of the flume was adjusted for each discharge until the water surface and the bottom of the flume were parallel. The piezometer section was located 5 ft from the downstream end of the flume. The piezometers were made up in brass plates 3 in. wide inset into the flume wall so that the resulting wall surface was flush. Five piezometers were located in the bottom plate and three each in the two side plates. The orifices were made $^1/_8$ in. in diameter and the construction followed the recommendations made in a previous investigation.[14] Each piezometer was connected to a 3-in. stilling well. The water surface elevation in the wells and in the flume was measured by a traversing-point gage, mounted on a horizontal straightedge.

Thirteen series of tests, separated into three groups, were made with mean velocities ranging from 3.0 to 7.05 fps. For the first group of tests, the entire inside surface of the flume, including piezometers, was covered with galvanized-iron-wire screening of $^1/_2$ in. mesh. The average piezometer error as compared to the mean water surface was found to be —0.4 per cent of the mean velocity head. In the second group of tests, the wire screen was cut away for a radius of $^3/_4$ in. around each piezometer. The average piezometer error was found to be 0.8 per cent of the mean velocity head. In the third group of tests, the wire screening was entirely removed, leaving the flume walls smooth painted surfaces. The average piezometer error was found to be 0.7 per cent of the mean velocity head. Therefore, these tests indicated that the piezometer errors alone would not account for the low coefficients of simple pitot tubes as reported by E. Shaw Cole.

A number of tests were made to try to compare the pressure at the center of the pipe with that measured by a wall piezometer. A comparative calibration was made between a pitometer and a pitot tube in the 12-in. flume when running open and, with a roof on, as a pipe. The test results were inconclusive because of the difficulty of computing the rod-area correction factor for the open flume. Then a piezometer was mounted in a disk on the end of a rod and the 12-in. flume and a 12-in. pipe were traversed. It was found that the velocity errors of the rod were much larger than any differences of pressure that were present. The same was found to be the case for a traversing rod, equipped with a pair of piezometers in a wedge-shaped tip. Finally, a set of three geometrically similar pitot reference tubes was made up. The tips were 0.25 in., 0.54 in., and 0.84 in. in diameter and were mounted on the same $^1/_2$-in. traversing rod. A 12-in. pipe was traversed at various velocities with each rod. It was hoped that the test results would plot in a consistent manner so that a curve could be extrapolated to zero tip diameter but such was not the case. A study of the results indicated that the performance of the tip was affected by the point velocity past the tip, the change in area, and the change in velocity distribution during a traverse, so that the results contained variables which could not be readily evaluated.

These tests indicate that the measurement of pressure within a flowing fluid is a most difficult task. Either more refined instruments must be developed or a different approach used, before it can be proved experimentally that the pressure across a section of pipe is constant and equal to the wall pressure, as measured by a piezometer.

The fact should be emphasized that, even if it is found the indications of the wall piezometer differ from the mean pressure in the cross section by an amount sufficient to account for the reduction in the coefficient of the simple pitot tube, the amount of the error is still small and only important when the piezometer is used in a way that does not permit of calibration with the instrument. For instance, an error of about 5 per cent of the mean velocity head would be required to account wholly for a pitot coefficient of 0.975. If an error of 5 per cent of the mean velocity head were made in measuring the head on a water wheel, it would be negligible, since the entire velocity head only represents about 1 per cent of the total head acting on the wheel. However, this does not detract from the importance of solving this entire problem concerning simple pitot-tube coefficients.

It was believed possible that the diameter of the impact orifice might have an appreciable effect upon the velocity indication of the tube. For instance, in pipe flow the change in velocity is very rapid near the walls of the pipe so there can be a difference of velocity of several per cent across the diameter of a relatively large impact orifice. In such a case an average pressure effect is communicated to the manometer but it may well be that this does not represent the true average velocity for that interval.

Therefore, traverses at three different velocities were made in a 12-in. pipe with impact tips of three different diameters. The length of the tip was made the same in each case and the same support rod was used for all three tips. Two reference piezometers were used located 6 in. upstream and at 45 deg and 135 deg with the traverse diameter. The results of these tests are presented in Table 5.

TABLE 5 RESULTS OF TESTS IN 12-IN. PIPE AT THREE VELOCITIES AND WITH THREE DIFFERENT TIPS

Impact tube			
Outside diam, in.	Bore of tip, in.	No. of traverses	Pipe factor
0.094	0.063	6	0.810
0.297	0.258	3	0.811
0.540	0.490	3	0.816

NOTE: Pipe factor is the ratio of the mean velocity to the center-line velocity.

Thus it is seen that a $^1/_4$-in. impact tip used in a 12-in. pipe will give a value for the pipe factor which is within 0.2 per cent of the figure given by a tube of zero diameter. From this it appears that the size of the impact orifice has little effect upon the accuracy of the traverse for pitot tubes of normal design and reasonable size.

In conclusion, the tests mentioned in this discussion show that:

1 Properly constructed piezometers provide pressure indications which check the elevation of the free water surface within 1 per cent of the mean velocity head in an open channel.

2 Present laboratory technique and equipment do not allow the pressure within a moving fluid to be measured accurately.

3 The accuracy of the traverse is within 0.2 per cent for pitot impact orifices of normal design and reasonable size.

A. A. KALINSKE.[15] The writer is particularly interested in the information presented by the author regarding turbulence. The use of the angularity indicator is ingenious, and if it responds to the small velocity fluctuations should prove to be a useful instrument for the measuring of mean turbulence. The author's as-

sumption that the angles of flow are distributed according to the normal-error law has been checked by the writer in a photographic study made of the transverse velocity component at a point in a turbulent fluid.[16] Whether the indicator will respond and indicate accurately rapid velocity fluctuations, needs further investigation; this probably can be done by comparing results given by it to those obtained by the photographic method.

The author's derivation of the equations relating angularity and the velocity fluctuation components to pressure loss in circular pipes is not exactly correct. First it should be pointed out that the von Kármán equation of velocity distribution for turbulent flow in a circular pipe does not apply at the center of a pipe. Von Kármán pointed this out, when he introduced his assumption of similarity of the turbulent-flow pattern, in deriving the velocity-distribution equation.[17]

The author's Equation [14] for the shearing force on a cylindrical element of fluid is an expression for the average force. Actually, this force varies from instant to instant. If the expression for the average force is to be used, an expression must be found for the force at any instant and then the whole expression averaged. The elements composing that expression, such as the fluctuating velocity components v and Δu should not be averaged individually, but rather their product is averaged as it occurs in Equation [15]. The Reynolds equation for unit shear stress due to turbulence is

$$\tau = -\overline{\rho u v} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [25]$$

ρ = unit density

The terms, u and v, are the longitudinal and transverse velocity components due to the turbulence (the term u corresponding to the author's Δu). In Equation [15] if both sides are multiplied by the density ρ, we have the equation for average unit shear. However, the quantity, $(u \tan \theta \Delta u)$, must be averaged as a product and not by individual terms.

The average shear at the center of the pipe is zero, since the mean velocity gradient is zero. This means that the mean product, $(u \tan \theta \Delta u)$, is zero; however, none of the individual terms needs necessarily be zero. Experimental data have verified this, particularly the data of Wattendorf.[18]

It should be pointed out that Equation [17] for the mixing length only plots as curve A in Fig. 18, when von Kármán's velocity-distribution Equation [7] is used to compute the mean velocity gradient. We know that this equation is not valid in the center of the pipe. Equations [18] and [20] are valid only for giving the general order of magnitude of $\tan \theta$, since the product $(u \tan \theta \Delta u)$ cannot be split and the mean value of each individual term used alone. At the center of the pipe v and Δu are uncorrelated, thus the mean product $(\overline{v \Delta u})$, becomes zero. Also, the term Δu need not always be positive near the center; thus near the pipe center Equation [18] for $\tan \theta$ is quite invalid.

The curve in Fig. 19, showing the distribution of cross velocities in a circular pipe, does not correspond to the data obtained by others. Wattendorf[18] for instance obtains, by means of hot-wire experiments in air, a curve that has a maximum value in the region of y/R equal to 0.1 to 0.2, and the data indicate a much more pronounced variation in the mean cross velocity between the center and a point near the wall. Experiments by the writer, in water using photographic methods to record the magnitude of the cross velocities, check in general the data of Wattendorf.

Regarding the effect of the pulsation of the manometer, it should be pointed out that, if the resistance to flow, in the manometer and connections thereto, in one direction is materially different from that in the other direction, an error can be introduced which might be larger than the error due to averaging the squares of the velocities instead of the actual velocities. Another way of indicating what effect the fluctuating velocity has on the manometer reading is to note that the reading at any instant is proportional to $(U + u)^2$, where U is the mean velocity and u is the variation, either plus or minus, about the mean. The arithmetic-mean value of u is zero, therefore, the average manometer reading is proportional to $(U^2 + \overline{u^2})$. If the value of $\sqrt{\overline{u^2}}$ is about 15 per cent of U, then the average value of the velocity as computed from the average reading of the manometer will be 1.011 U, or about 1 per cent too large. The value of $\sqrt{\overline{u^2}}$ hardly ever gets over 5 per cent of U, in ordinary pipe flow.

Regarding the use of tip piezometers on pitot tubes the writer wishes to refer to work done by Goldstein[19] and Fage [20] on the measurement of static pressure in a turbulent fluid. The reading of the manometer connected to tip piezometers is effected by the magnitude and frequency of the cross velocities in addition to being effected by the design of the tip and the number, size, and arrangement of the static-pressure holes. Fage shows that the static-pressure manometer reading is equal to

$$H = \bar{h} + K/g\,(\overline{v^2} + \overline{w^2}) \quad \ldots\ldots\ldots\ldots\ldots [26]$$

where $\bar{h}$ = the true static head
K = experimental constant
$\overline{v^2}$ and $\overline{w^2}$ = mean square cross velocities

For a circular pipe, Fage's experiments indicated the value of K as being about 0.28.

Since the longitudinal velocity fluctuation as measured by $\overline{u^2}$ tends to increase the reading from the impact orifice, and the cross velocities $\overline{v^2}$ and $\overline{w^2}$ tend to increase the reading from the pressure orifices, when the two readings are subtracted in order to obtain the true velocity head, the effects produced by the fluctuating velocities due to turbulence tend to cancel. Therefore, the author's conclusion that a properly designed combined type of pitot tube is the most reliable seems to be quite in order.

K. G. Merriam.[21] In a paper,[22] presented before the Society in 1903, written 173 years after the invention of the pitot tube, W. B. Gregory stated in his opening paragraph: "The object of this paper is to call attention of the members of the Society to a simple, efficient instrument for measuring the velocities of fluids."

Despite the alleged simplicity of the instrument, which, as described, is now termed a pitot-static tube, there seemed to exist some confusion of thought in respect to its performance. For example, in the paper mentioned (quoting from the reply to a discussion of a paper by Williams, Hubbell, and Fenkell, presented before the American Society of Civil Engineers in 1902) is found the following statement:

"Regarding the question of the proper formula for the pitot tube, the writers are not yet entirely satisfied and, while fully

appreciating Frizzell's effort to clear the matter up, they yet prefer to leave the question where they left it before, that, practically, it makes little difference in reduction of results whether a tube reading actually is $V^2/2g$ or V^2/g. The discussion presented by Seddon gives excellent reason to believe that there is a large account of internal forces to be balanced before the laws of flow will be fully understood, and until these forces have been more fully investigated, too rigid laws had best not be laid down."

Although thirty-five years later, the time is not ripe to balance the account and lay down too rigid laws, the coefficient of ignorance pertaining to pitot-static tube performance becomes smaller. The investigations which have illuminated the subject have been performed in several countries, using both water and air as fluid media. Much of the stimulation for these investigations came from the airplane and the ventilating fan. From necessity rather than from choice, air-flow problems associated with these devices have involved the use of the pitot-static tube as a basic instrument. Hence the vital need for a knowledge of its performance, especially in air applications.

Attempting to supply this knowledge, many experimenters have labored. In the Reports and Memoranda of the British Aeronautical Research Committee and in the N.A.C.A. Technical Reports, Notes and Memoranda, are numerous papers on the subject. In a valuable treatise by E. Ower[23] much space is devoted to pitot-static tube design.

From what has been written and, also considering the fact that experiments are generally conducted more conveniently and quickly with air than with water, one might infer that the author's work could consist only of verification of conclusions already arrived at as a result of wind-tunnel and air-duct research.

To a slight extent only is this true, although most of the tests described could have been performed with air. The author's ingenious and painstaking experiments, particularly those relating to turbulent flow, represent a valuable contribution to aerodynamics and general fluid mechanics as well as to hydraulics.

LEWIS F. MOODY.[24] The writer recommends this paper to students as a model of the way experimental research should be carried out and presented. Few experimenters in the hydraulic field are able to command the facilities for such a thorough investigation covering so large a number of tests of so many phases of a problem, with the assistance of so able a group of observers and on apparatus of ample capacity; but the method of analysis and manner of presentation can be followed by others to advantage. The author has not only given us clearly the physical results, answering by established facts the questions he has propounded, but he has analyzed the problem rationally and compared the results with well-digested theories.

The use of probability plotting in analyzing turbulence in flowing water is in itself a striking use of a mathematical tool admirably suited to the problem. The same method has been found most useful in hydrology in plotting duration curves of runoff, for instance, and in analyzing errors of observation in surveying. There are often occasions for using it in other engineering problems dealing with quantities controlled by so great a number of indeterminate factors that they are said to be governed by chance. Here the fact that the frequency summations of obliquity of flow actually plot on straight lines on probability paper substantiates the validity of the application.

The writer approves this paper and its conclusions in full realization that it considerably modifies his own early conceptions as to the magnitude of turbulence effects under ordinary flow conditions. At one period investigators, including the writer, were greatly concerned with errors in pitot tubes due to turbulence in the stream and carried out rather elaborate tests to find the effects; but there were few attempts to answer the difficult problem of how much turbulence usually exists, except by comparing over-all results of quantity measurements. Here few opportunities were found for full-scale comparisons, and then only with inexact or indirect means.

Although the author has convincingly demonstrated that the usual degree of turbulence in a good measuring conduit with stable flow is of a lower order than some of us had realized, so that the reduction of the pitot coefficient below unity cannot be justified on this ground alone, it cannot be concluded that a flow measurement by pitot tube should employ unity coefficient. The results of these investigations appear to absolve the pitot impact tip itself from suspicion of appreciable error due to either obliquity of flow or pulsations, but do not definitely account for the cause of the reduction of coefficient which must be applied to the flow measurement as a whole, in order to make it agree with a simultaneous determination of the discharge by an absolute method or one of established accuracy. Whether the reduction is due to a combination of factors or mainly to a particular factor has not been fully answered, but suspicion is directed pointedly to the static-pressure piezometers. This phase of the problem offers a fruitful field for a continuation of this line of research.

The discussion of the paper presented at the 1938 Annual Meeting of the A.S.M.E. contained some valuable supplementary material to which the writer would call particular attention. Professor Hooper has discussed the behavior of the piezometers and possible sources of error due to them and has described some significant experiments. Mr. E. Shaw Cole has analyzed the variation of the over-all coefficient applicable to a pitot measurement using a wall piezometer, as well as that applicable to measurements using Cole pitometers. His discovery of a simple and consistent functional relation between coefficients applicable with wall piezometers and the so-called "pipe factor" or ratio of mean to center velocity, is a notable contribution which brings order out of confusion. The curve representing this relation, which is simply an inclined straight line, seems to supply exactly the information which is needed to reestablish this method as a dependable means of water measurement, and should prove of great assistance, for example, to those A.S.M.E. Power Test Code Committees dealing with hydraulic prime movers and centrifugal pumps.

The value of this paper goes beyond the immediate purpose of the investigation, to analyze and evaluate pitot-tube errors, and extends into the field of the phenomenon of turbulence. One of the most convincing features to my mind is the comparison of the results with the Prandtl and von Kármán theories. Dr. von Kármán has expressed to the writer his dissatisfaction with his own theory as a final solution, with respect to its requiring zero mixing length at the pipe axis and a discontinuity in the velocity curve at this point. This limitation is clearly discussed by Professor Bakhmeteff (4). The methods and results of these experiments may throw further light on such fundamental questions. The writer suggests that by continuing this line of experimentation useful and far-reaching conclusions may be possible.

W. J. RHEINGANS.[25] Some of the author's tests confirm the results of previous investigations and conclusions, while others present entirely new ideas. He found that the coefficient of the impact tube is unity in quiet water, which confirms the results of

[23] "The Measurement of Air Flow," by E. Ower, Chapman and Hall, Ltd., London, 1927.

numerous tests on impact-tube coefficients originated by Dr. W. M. White in 1901.[26]

The interesting feature of the present test is that a round-nosed impact tube was used. This confirms the theory advanced by Dr. White that any impact tube whose impinging surface is one of revolution will have a coefficient of unity. It would have been of added interest if the author had made a test on the effect of angular flow on the round-nosed type of impact tube.

The determination of the angle of flow in a pipe line was extremely interesting. However, the writer calls attention to the fact that while the mean angle was found to be only about 2 deg, there were momentary maximum angles of 8 to 10 deg. Since the impact coefficient for angular flow is not a straight-line function of the angle but approaches unity asymptotically, the average error for angular flow is slightly greater than the error at 2 deg.

Equally interesting were the author's tests on the effect of support rods on wall piezometers. Unfortunately in the analysis of these tests he omitted a clear definition of the symbol a which he used in Equations [21] to [24]. In the text he states that a represents the projected area of the rod in sq ft. If the reader accepts this statement and if the author used this definition in his work, it can readily be shown that K in Equation [24] is not $2a$, and that Fig. 28 is therefore in error.

However, if the author assumes that a is the ratio of the rod area to the pipe area, then his subsequent formulas and Fig. 28 are correct. Since no original data are given, it is impossible to tell from the text which definition of a was used in arriving at Fig. 28. There is a clew in a subsequent paragraph as to what the author probably intended a to represent. It would have eliminated confusion if he had definitely defined a as being the ratio of rod area to pipe area and then simply stated that the wall-piezometer error is equal to the contour value in Fig. 28, multiplied by the ratio a for the rod and pipe under consideration.

In attempting to use Fig. 28, further confusion arises from the interchangeable use of relative error and relative percentage error by the author. For nstance, the contours in Fig. 28 supposedly show relative errors. However, the text immediately following states, "the wall-piezometer error in per cent of mean velocity should be equal to the contour value in Fig. 28 multiplied by $2d/\pi D$." What the author apparently means is that the contour value in Fig. 28 multiplied by $2d/\pi D$ multiplied by 100 will give the piezometer error n per cent of mean velocity. Since no original data are given, it s impossible for the reader to check back and determine which is correct.

The above observations may seem hypercritical, but Fig. 28 is of such potential value in the determination of possible errors in pitot-tube tests that all doubts as to the exact values should be eliminated.

Although Fig. 28 indicates that the support rod affects the reading of the wall piezometer, this does not necessarily mean that the measured deflection between the pitot-tube point and the wall piezometer is in error by an equal amount, nor do any of the author's tests definitely show that this might be the case. Fig. 28 indicates that due to an increase in velocity near the support rod, the pressure at the wall piezometer drops. Now there are several theories supporting the assumption that, when the pressure at any point in a cross section of a closed conduit changes, there is a similar change at all other points in that cross section. If the pitot-tube impact point is located in the same section as the wall piezometer, any change in pressure at the wall will be accompanied by a similar change in pressure at the pitot-tube point and thus tend to eliminate any error in deflection.

On the other hand, Fig. 28 indicates an apparent increase in pressure on the wall piezometer for certain locations of the support rod in relation to the piezometer. Just why this is true is not immediately apparent. Is it possible that the support rod lowers the velocity of flow immediately upstream and for a short distance on either side; that this lower velocity causes an increase in pressure, and that this increase in pressure is not transmitted across the entire section? It would seem that further investigations along this line would be advisable in order to get a true explanation of the varying piezometer readings.

The writer calls attention to the fact that the piezometer errors indicated in Fig. 28 are of relatively small magnitude when the size of the support rods is kept within practical limits, and if the method usually applied to traverses in large pipes is used, which consists of inserting the pitot-tube rod from the opposite sides of the pipe up to the center only. The author's subsequent example, for instance, indicates an error in center velocity of 1.6 per cent. However, in measuring the flow in a circular pipe the center velocity has relatively small influence on the mean velocity. Thus, as the support rod is pulled back toward the wall of the pipe, where the greatest amount of flow occurs, the projected area of the rod is reduced. The author has shown no data indicating the effect of a reduced rod area on the piezometer error, where the reduced area is occasioned by a shorter support rod; i.e., a rod not reaching to the center of the pipe. However, since he has plotted the piezometer errors on the basis of the ratio of the rod area to the pipe area, it is natural to assume that the error is proportional to the percentage rod area, even when the rod is partly withdrawn.

Making this assumption, it can be shown that the actual traverse error due to piezometer error would be in the neighborhood of 0.60 per cent instead of the 1.6 per cent indicated for the center velocity for the conditions assumed in the author's example. Furthermore, in an actual test it would be more in line with actual practice to use a $^1/_4$-in. streamlined rod in a 12-in-diameter pipe than the 1-in-diameter rod used in the author's example. With a $^1/_4$-in. rod, the wall-piezometer error for a complete traverse, as obtained previously and for conditions and location of piezometer similar to that used in the author's example, would be less than 0.2 per cent. In fact, a 1-in-diameter support rod would be feasible in a 6-ft-diameter pipe, in which case the piezometer error for the foregoing conditions would be less than 0.1 per cent.

Thus, while at first glance the piezometer error indicated by the author and by Fig. 28 may seem of considerable magnitude, in actual practice it is negligible.

The author concludes from his tests that the most reliable pitot tube is one of the combined type using a tip pressure piezometer, and that special types of combined pitot tubes such as the pitometer having both the impact and reference orifices on the instrument itself, give accurate results, since both orifices are calibrated together. This conclusion does not quite check with other statements made by the author. For instance, he states that it is apparent that "piezometers located within 2 or 3 diameters of the rod will be unstable and, therefore, inaccurate."

Also, the author's Fig. 25 indicates that, with the impact tube close to the support rod, erratic results are obtained. For instance, with the impact tube 1 diameter from the support rod variations of 0.5 per cent were obtained. The illustration shows that the impact tube should be at least 3 (rod) diameters from the support rod to give consistent results.

Since most pitot tubes of the combined type, especially the pitometer, have both the impact orifice and the piezometer orifice located near the support rod, it would seem, according to the author's own statements and tests, that these types are subject to inaccurate results in spite of their calibrations. Furthermore,

[26] "The Pitot-Tube; Its Formula," by Wm. Monroe White, *Journal of the Association of Engineering Societies*, vol. 27, July-Dec., 1901, pp. 35–79.

it would seem that pressure orifices located on the support rod are subject to the same type of errors as indicated for the wall piezometer in Fig. 28 because, if the support rod introduces a change in the pressure at the wall, why should there not be a similar change in pressure at different points across the cross section?

It is also hard to understand why it should be easier and more accurate to measure pressures in the center of a pipe than it is to measure them with wall piezometers. Certainly angular flow, turbulence, etc., must have varying effects on piezometer orifices located within this flow, which is not taken care of by calibrations on combined pitot tubes in quiet water.

It would therefore seem that this divergence of opinion suggests several further lines of investigation, as follows:

1 The effect of angular flow and turbulence on the static pressure orifices of combined types of pitot tubes. (Although Cole has made tests along these lines[27] further tests are needed to obtain more detailed information.)

2 Determine whether pressure orifices located on support rods in the flowing stream or wall piezometers will give the most consistent and accurate results.

3 The effect of a short support rod (such as when measuring velocity near the walls of a conduit) on wall-piezometer readings.

In conclusion, the writer calls attention to the fact that the entire paper indicates that the pitot tube, if properly used, is an accurate means for measuring flow of water.

HUNTER ROUSE.[28] Pitot tubes, like piezometers, have long been used and misused, and often subjected to analytical and experimental scrutiny. Not until the rise of modern aerodynamics, however, did the pitot tube take on the aspects of a precision instrument. The requirements of fluid research in this field have led to very careful studies of pitot-tube characteristics for a wide variety of shapes and flow conditions. The author will find, for instance, an excellent résumé of results, similar to many of those which he now reports, in a translation of a German work by Peters.[29]

Although the tests described in this and similar aeronautics publications were conducted in air, pitot-tube performance in water should obviously be similar to that in air under dynamically similar flow conditions. In this regard, however, one must not lose sight of the geometric scale relationship between the dimensions of the instrument and the dimensions of the turbulence in the measured flow. For instance, the degree of wind-tunnel turbulence is usually expressed by the ratio of mean absolute velocity of fluctuation to the mean velocity of flow, a factor akin to the angularity discussed by the author. Nevertheless, research men in aerodynamics do not ignore the fact that the linear scale of the turbulence, i.e., the "mixing length," or the size of the eddies involved, is also of fundamental importance. The angularity caused by the turbulent mixing process can have an appreciable effect upon a measuring instrument only if the linear scale of the turbulence is at least of the same order of magnitude as the scale of the instrument; likewise, an instrument can correctly measure such angularity only if its scale is far smaller than that of the turbulence.

[29] "Handbuch der Experimentalphysik," vol. 4, part 1, by L. Schiller: Translation in manifold copy form of section from vol. 4, part 1, entitled, "Pressure Measurement," by H. Peters, in which static-pressure and dynamic-pressure instruments are discussed. Copies are on file at the Engineering Societies Library, at the National Hydraulic Laboratory, and at the United States Waterways Experiment Station.

The author has devised an intriguing type of apparatus for measuring angularity. Such equipment is particularly needed in the study of liquid motion, for the hot-wire anemometer, so valuable in the study of turbulence in air, does not lend itself so readily to use in water. The angularity indicators described by the author must be considered commendable first steps in this direction; but they cannot always be expected to yield accurate quantitative results. That is, while the best hot-wire anemometers used in wind tunnels are but a small fraction of a millimeter in size, the author has developed an indicator with vanes approximately 1 in. long for use in pipes where the eddies are often much smaller.

With respect to the author's analysis of the turbulence mechanism, certain amplifications are in order. The equations of Prandtl and von Kármán to which the author makes reference are specifically means to an end, namely, the formulation of simple, usable, and fairly general expressions for velocity distribution and resistance, and not rigorous statements describing at once the internal mechanism of flow at all parts of the cross section. The pipe measurements presented in this paper, as well as in the references cited, include three distinct portions of the flow section—the boundary zone, the central zone, and a zone between the two. Prandtl's equation for the velocity distribution was developed for the boundary zone (this zone is not to be confused with the very thin boundary layer). That this equation also yields good velocity results nearly to the center of the section in no way insures the validity of the mixing-length distribution curve derived therefrom (curve *A*, Fig. 18) for more than the boundary zone. Von Kármán's similarity hypothesis (i.e., constant correlation between radial and longitudinal velocity fluctuations) has been shown by hot-wire measurements to be correct only for the intermediate zone. The resulting equation (Fig. 15) does not apply near either the wall or the central axis. The fluctuations show no correlation at the axis of the pipe, approaching in this zone the random nature typical of isotropic turbulence in the developed wake of a rack or grid; at the axis, moreover, the mixing length should attain its maximum value.

Evidently, these velocity relationships may be expected to yield the probable distribution of the mixing length and the velocity of fluctuation only in the zones for which they were originally developed. A better indication of true conditions over the cross section was found by Nikuradse through determining the values of l and of $\epsilon = vl$ from measured velocity profiles by means of the following relationships

$$l = \sqrt{\frac{\epsilon}{\frac{du}{dy}}} \qquad \epsilon = \frac{\frac{\tau}{\rho}}{\frac{du}{dy}}$$

$$\frac{\tau}{\rho} = \frac{\tau_0}{\rho}\left(1 - \frac{y}{R}\right) \qquad \frac{\tau_0}{\rho} = \frac{8U^2}{f}$$

In the diagram Fig. 37 will be found dimensionless plots of l, ϵ, and $v = \frac{\epsilon}{l}$ determined in this manner, containing, to be sure, the unknown proportionality constant mentioned by the author. As was shown in Fig. 18, this curve for the mixing length agrees with that found from Prandtl's velocity equation only in the boundary zone for which the equation was developed. It will also be noted that the magnitude of v increases steadily toward the boundary, contrary to the author's measurements in Fig. 19. One must recall, however, that Prandtl's original assumption upon which these curves are based $\left(\text{that } v \text{ is proportional to } l\frac{du}{dy}\right)$ is approxi-

mate, but not exact, and cannot be expected to hold even closely at the wall or at the axis.

Nevertheless, actual hot-wire measurements of the root-mean-square velocities of fluctuation[18] also indicate that these velocities continue to increase toward the wall, the form (though not the absolute position) of a measured distribution curve being shown by the broken line. It will be noted that v changes only slightly in the central (isotropic) zone and increases almost linearly throughout the intermediate zone of constant correlation. Indications are that it reaches a maximum a short distance from the wall, then drops off rapidly. More recent measurements in the wind

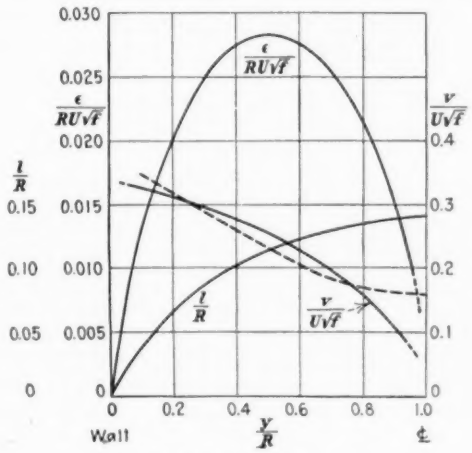

FIG. 37 CURVES FOR l, v, AND ϵ

tunnel, as well as an analysis of older studies in the Mississippi River,[30] prove the general validity of this trend.

It should be evident that the author's "theoretical" curve for angularity Fig. 17 shows the greatest discrepancy, even according to sound theoretical analysis, at the central axis, while his measurements are probably closer to the actual values in this region than in any other. Since the mean velocity decreases radially, moreover, it follows that the angularity must increase toward the wall even more rapidly than does the velocity of fluctuation, and not remain essentially constant as the author's measurements would seem to indicate. Finally, one cannot well state that any given mean angularity is typical of flow in pipes; for fully developed turbulence, the form of the v/U curve would seem to be constant, while that of the u/U curve definitely is not, varying with both the Reynolds number and the relative roughness.

The failure of the author's measurements to agree with actual conditions can be traced directly to the fact that his angularity indicator is too large to be affected by the average eddies in all but the central regions of flow. In other words, although the angularity increases steadily toward the pipe wall, the indicator is not sensitive to such variation because the average size of the eddies decreases toward the wall in direct proportion to the mixing length. Obviously, however great the angularity, it will have no marked effect upon either an angularity indicator or a pitot tube so long as the instrument is enough larger than the eddies involved.

The writer does not mean to disparage the author's development of such an instrument. Indeed, he considers the effort to perfect a device of this nature by far the most valuable portion of the investigation now under discussion, for the research world will be everlastingly indebted to the man who produces satisfactory equipment for measuring the degree of turbulence in flowing water.

[30] "Turbulence," by Th. von Kármán, *Journal of the Royal Aeronautical Society*, vol. 41, 1937, pp. 1136–1137.

R. B. SMITH.[31] The author's creditable study of pitot-tube characteristics points to the fact that difficulty with instruments of this type is generally associated, as is frequently the case in hydro and aerodynamics, with the measurement of static pressure.

The problem of static-pressure measurement has been attacked numerous times but, generally overlooked in this country, is the very interesting work of Fuhrmann,[32] who investigated the in-

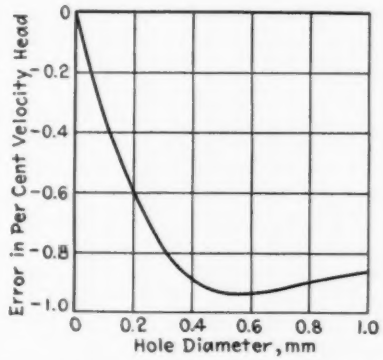

FIG. 38 EFFECT OF HOLE SIZE ON STATIC PRESSURE MEASUREMENT

fluence of static hole size. The results, Fig. 38, indicate that for nearly all commercial holes, the static-pressure reading is too low by about 0.8 per cent. This conclusion applies to all hole sizes larger than $^1/_{16}$ in. and is not in contradiction to the work of Hooper and Allen (6) inasmuch as the studies by them were made comparatively, with holes larger than $^1/_{16}$ in. Inasmuch as the head and velocity vary in a quadratic relation, an error of 0.8 per cent in head is sufficient to explain a pitot-tube coefficient of 0.996.

W. M. WHITE.[33] The determination of the coefficient of the pitot-tube point seems to have been carefully done. It is a long way from the formula for the pitot tube given in Kent's Handbook in 1900 as $V = \sqrt{gh}$ to the present-day accuracies.

In 1900 the writer determined that the pitot-tube point had a coefficient of unity by submerging the point in front of a boat traveling at known velocity. Reference has been made to a paper[26] by the writer. It was shown by the paper that the pitot-tube point would read correctly without unity coefficient, provided the point was a surface of revolution in respect to the axis of the pitot-tube point.

The second section of the author's paper is particularly interesting since he has shown that angularity of flow is of such small magnitude as not to affect seriously the coefficient of the point of the tube.

The section on pulsation tests is of particular interest, because possible errors in the reading of the pitot tube, due to the pulsating effect have been known. In pitot-tube work, where great accuracy was required, we have inserted in the connections between the pitot-tube point and the glass gage, a small double-ended venturi meter having a small hole of say $^1/_4$ the diameter of the hole in the tube itself, the shape at each end being the same, so that the pulsation effect on the reading of the tube was thus eliminated.

The section of the paper dealing with the effect of the rods or supports, which are necessary to be used inside the pipe upon the reading of the pitot-tube point and piezometers, is an excellent contribution to the art. It is unfortunate, however, that an error has been made in the formula on which the results in Fig. 28 are based. This error was discovered by Rheingans who has suggested a correct formula. When Fig. 28 is corrected and is properly used in connection with the obstructions actually used in making pitot-tube tests on 12-in. pipe and larger, the correction to be applied is so small as to be negligible.

It is unfortunate that the author used such a large rod in the 12-in. pipe to arrive at the results plotted in Fig. 28. Probably a small rod comparable to the actual rods used in pipe would have shown such small deflections as to be unreadable. If we step up the 1-in. rod in the 12-in. pipe to a test in a 10-ft-diameter pipe, we should then have a 10-in. pipe for supporting our pitot tube which, of course, is absurd. When we apply the corrected data for Fig. 28 to tests which we have heretofore made by pitot tubes using point and pipe piezometers and taking into consideration the actual supports used, together with the locations of the piezometers, we compute from Fig. 28, the effect on the readings to be less than 0.25 per cent.

The writer is interested in the conclusions to which the author has been led by his tests, and particularly his statement: "To obtain a stable coefficient near unity in a tip-pressure tube, the tip should be at least 10 diameters in length with the pressure piezometers located 5 diameters back from the nose."

This conclusion confirms the writer's long held opinion that the heretofore used tip-pressure pitot tubes were liable to sources of considerable error. In fact, the unreliability of this type of tube, which was used by the writer in 1899, led to the investigation resulting in the paper.[36] It is certainly comforting to know that the careful data secured by the author leads us to a more rational design of a tip-pressure pitot tube.

The writer is not in accord with the conclusion drawn by the author in respect to the tip-pressure tube, and cannot see from a consideration of the observed data, how he can make the statement: "The conclusion drawn from these tests is that the most reliable pitot tube is one of the combined type using a tip-pressure piezometer. This piezometer or group of piezometers should be located on the tip at a point where the rod effect is stable and affects all piezometers in the group about the same amount. Such an instrument may not read the true velocity head, but its error will be constant for all ordinary velocities and sizes of pipes, so that it is capable of being calibrated and used under different conditions of flow, if necessary."

The writer agrees with the author that the source of error lies in the securing of a proper pressure reading. This pressure reading should be secured in a region where the velocities are least, which is at the walls of the pipes and not by piezometers on the tube itself in the high velocities, especially at the center of the pipe. The piezometer 5 diameters in front of the rod will be influenced by the position of the tube in the pipe, particularly in the vicinity of the pipe wall, where the area is of considerable moment in determining quantity. Its coefficient must be affected as a greater and greater amount of rod is introduced into the pipe in traversing a diameter of the pipe.

The author has certainly given enough data to eliminate from further serious consideration those types of tip-pressure tubes which have the pressure opening in line with or downstream of the supporting rod.

The coefficient as determined for the pitot tube with wall piezometer was seriously affected when the wire mesh was inserted in the pipe, due to the location of the wall piezometers within the influence of the sudden enlargement from the diameter of the pipe with the wiring mesh to the normal diameter.

Everything the author has developed confirms the writer's opinion that the most reliable method of making quantity determinations by means of the pitot tube is by that method described in the A.S.M.E. Hydraulic Prime Movers Power Test Code, approved June, 1938.

Author's Closure

The author is indebted to those who have discussed this paper and added so much useful information to it.

The comment by Mr. Christiansen concerning a correction for the area of the rod in small pipes is interesting in the light of tests on the pitometer reported by E. S. Cole (8).

The discussions by Mr. Kalinske and Professor Rouse concerning the method of deriving the equations for the so-called theoretical angularity are enlightening. However, the author attempted what was intended to be a simpler if less exact derivation of the theory of turbulence which would form a framework for those who have not had the time to study the subject of turbulence in detail.

Mr. Rheingans and Mr. White have called attention to the section of the paper dealing with the effect of the support rod on the wall-piezometer reading. While the wording may not be clear, there is no mistake in the equations as given in the paper. The use of the relative errors as given in the example explains the method of correction. These tests were intended to show where piezometers should be located with respect to the rod to minimize the rod influence and therefore are exaggerations of what would be considered good practice for field work. It is unfortunate that lack of space made it necessary to omit the cross plots of the original test data from which the curves of Fig. 28 were derived. The tests at three different velocities with three sizes of rod checked within 1 per cent of the velocity head.

Professor Rouse's comments add greatly to the theoretical discussion of turbulence. He may have been led to doubt the measured angularity in the 40-in. pipe by the fact that the wall roughness was not constant along the whole pipe, so that the tests were made in a section where the flow conditions were in the process of transition from rough to smooth pipe. As described in the paper, the upper portion of the pipe was extremely rough, the portion just above the test section was comparatively smooth. It is possible that the higher turbulence generated in the rough section persisted at the center well into the smooth section, while the turbulence near the wall in the rough section had decreased to a lower value after entering the smooth section. This led the author to draw the conclusion that in large pipes the angularity is nearly constant across the pipe.

Recently the author has made tests with a smaller vane in 12-in. pipes. While this vane appears large when compared with the hot-wire anemometer used in air measurements, its dimensions are only 2 per cent of the diameter of the 12-in. pipes in which the tests were made, or about twice the impact-orifice diameter of most of the pitot tips which were used.

This smaller vane was made of cork, $^1/_4$ in. high by $^5/_{16}$ in. long. Its shape and mounting are shown in Fig. 39. The weight of the grounded platinum contact on the vane was sufficient to make the whole movable element weightless in water. The testing was simplified by connecting the platinum contacts behind the vane, one at a time, to a commercial electric stop clock having a clutch action capable of moving in 0.005 sec. The stop clock integrated the total time in which a particular contact was "made" in a given measured time interval, usually taken as 2 min. The mean angularity was computed from plots on probability graphs as described in the paper. With this instrument, approximately one third the size of the one described in the paper, the results obtained checked well with the tests originally reported. The tests, which are shown in Fig. 40, show an increase in angularity

toward the pipe wall, but not enough to influence the reading of a pitot impact tip.

With the present knowledge of turbulence it is difficult to establish relations between turbulence, wall roughness, and velocity distribution across large pipes, for most pipes in which tests have been made do not have a sufficiently long uniform straight section for the flow conditions to become stable. For example, the

FIG. 39 SMALL ANGULARITY VANE

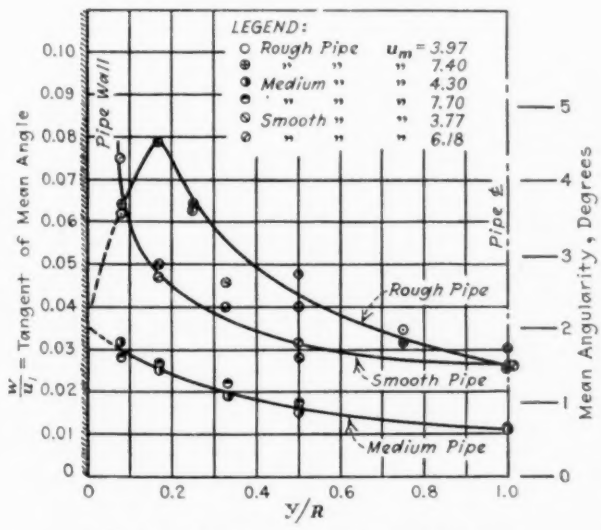

FIG. 40 MEAN ANGULARITY IN 12-IN. PIPES
(Measured with 1/4 × 5/16-in. vane.)

measured angularity in the smooth 12-in. pipe is greater than would be expected with the high pipe factor found by traversing. This may be caused by the venturi meter only 15 diameters upstream from the test section as shown in Fig. 26. The rough pipe, which was the same pipe lined with wire screening, has the same turbulence at the center, but increased turbulence near the walls. The sharp reduction in turbulence close to the wall in the rough pipe was probably due to the fact that the wire screening terminated about one foot upstream from the test section. The medium pipe, which had an intermediate pipe factor, showed the least turbulence of all. This may have been caused by straightening vanes located in an elbow approximately 30 diameters upstream from the test section.

The interesting results of the tests reported by Mr. Cole in his discussion certainly add much to the information concerning pitot tubes, although the exact reason for the variation of the wall-piezometer reading with pipe factor is not evident. The apparent reason is that turbulence varies uniformly with the pipe factor, but the angularity measurements of Fig. 40 made in the same pipes do not show this to be so.

The author has recently made tests in the same pipes that were used by Mr. Cole, both with a pitometer and also with a pitot-static tube constructed according to the recommendations mentioned in the conclusion of the paper. Mr. Cole's pitometer results were checked within 0.5 per cent, although some of the pipe factors had changed because of roughening of the pipe walls. However, it was disconcerting for the author to find that the coefficient of the pitot-static tube varied from 0.956 in the center of the rough pipe to 0.992 in the medium pipe. The pitot-static tube was calibrated in the center of each of the three pipes.

It was finally found that a small tight-fitting ring placed ahead of the pressure or static orifice on the tip of the instrument not only changed the coefficient of the pitot-static tube, but in certain positions reduced the discrepancy between the coefficients obtained in the various pipes. In fact, with the ring immediately ahead of and tangent to the upstream edge of the pressure piezometer, a nearly constant coefficient of about 0.89 was obtained in all the pipes. The results of tests with and without the ring are given in Table 6. The pitot-static tip with the ring moved away from the piezometer is shown in Fig. 41.

TABLE 6

12-in. pipe	Pipe factor	Mean angle at center, deg	Average pitot-static coefficient	
			Without ring	With ring
Rough	0.77	1.56	0.956	0.889
Medium	0.83	0.70	0.992	0.897
Smooth	0.92	1.65	0.980	0.885

Tests made at velocities of from 4 to 8 fps at center of pipe.

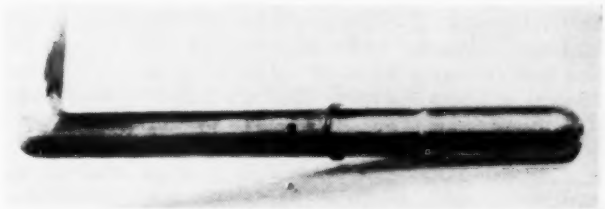

FIG. 41 PITOT-STATIC TIP WITH RING

The coefficients obtained in each pipe were constant within 1 per cent over the velocity range tested. There does not seem to be any consistent relation of the coefficient to either the pipe factor or the measured turbulence. The results certainly do not agree with the formula proposed by Fage given as Equation [26] in Mr. Kalinske's discussion.

Thus far only the velocity pulsations across the stream have been measured in connection with these tests. Since the turbulent pulsations have three degrees of motion, it is possible that some of these phenomena will be explained when measurements of the velocity surges in the direction of flow as well as the cross pulsations are made.

The information given in this paper and the discussions show definitely that the error of the impact orifice of a pitot tube is negligible in ordinary turbulent flow. The errors occur in measuring the pressure head or some other reference pressure. These errors are not a constant function of the velocity head, but are associated in some manner with turbulence. The coefficient of

the instrument is therefore likely to change in different conditions of flow.

The effect of the support rod on pressure piezometers can be largely avoided. However, until more has been learned about the effect of turbulence on pressure measurements, it will be necessary to use the coefficients for simple pitot-tubes suggested by Mr. Cole as given in Fig. 36 of his discussion. If a combined form of instrument such as the pitometer, or the pitot-static tube with a break in the surface near the pressure orifice as suggested by the author is used, then the instrument should be calibrated in at least two different types of flow conditions to insure that it has a reasonably constant coefficient. It is hoped that further research will suggest one or several forms which will have the same coefficient in all sizes of pipe under all ordinary kinds of flow conditions.

Changes in a High-Pressure Drum to Eliminate Recurrence of Cracks Due to Corrosion Fatigue

By ALBERT E. WHITE,[1] ANN ARBOR, MICH.

This paper gives the results of an investigation which was undertaken for the purpose of determining the cause of the cracks found in the No. 5 boiler at the Edgar Station of the Boston Edison Company. It also discusses the cause of the cracks found in the water columns and in certain of the superheater fittings and headers of this same boiler. The boiler in question is one of the first high-pressure units installed in this country and, therefore, it was quite essential that the cause of the cracks be determined and suitable steps be taken to prevent their recurrence. The study sets forth the changes which were made.

As a result of the investigation it was not felt that any of the difficulty could be attributed to faulty metal. The material was of the proper chemical composition and had suitable physical properties.

The primary cause of the cracks was believed due to corrosion fatigue resulting from stresses set up by changes in temperature on the surface of the metal in combination of a relatively low pH value of the water which was at times in contact with the metal that developed cracks.

As a result of the removal of the cracked metal and the changes in design which would prevent fluctuating temperatures on the surface of the drum at the boiler feedwater inlet, as well as other design changes which would raise the pH value, particularly in the water columns, it is not anticipated that further cracking will take place.

WHEN BOILER No. 5 at the Edgar Station of the Boston Edison Company was removed from service in February, 1938, for rebuilding after being in almost continuous operation since September, 1927, it was carefully examined to determine the extent it had been affected by operating conditions. This boiler had operated for approximately 60,000 hr at a rating of from 180,000 to 220,000 lb of steam per hr. It was one of the first high-pressure units installed in this country operating at 1400 lb pressure and 725 F steam temperature. It was suspected that cracks would be found in certain parts of the unit because in September, 1936, cracks were found in the feedwater connections in No. 3 boiler which is similar to No. 5 boiler.

The cracks which were found in No. 3 boiler at the time it was again examined in 1937 were not of such magnitude as to require the removal of the boiler from service. In fact, with the approval of the boiler inspectors, it was again placed in operation for a period of 6 months, after which time it was then again examined and returned to service for another 6 months, as there had been no visible increase in the extent of the cracks.

The cracks in No. 5 boiler were of greater magnitude than those in No. 3 boiler and, in consequence, a thorough investigation was made for the purpose of determining the cause and extent of the cracks, and likewise for the purpose of arriving at a decision as to what should be done.

The cracks which were found were in the walls of the boiler drum forming part of the feedwater inlets, in the lower connections of the water columns, and in the forged-steel tee fittings at the inlet and outlet of the superheater, as well as in the flanges of the inlet and outlet superheater headers.

In presenting this subject, reference is first made to a sectionalized view of No. 5 boiler which shows the drum, the feedwater inlet, the water columns, and the superheater inlet and outlet headers. These are all shown in Fig. 1.

Boiler Drum

A cross section of the boiler drum and the feedwater and water-column connections is shown in Fig. 2. Attention is called to the fact that the feedwater enters through a forged-steel nozzle which is attached to the boiler drum by stud bolts, then passes through a hole in the drum to the internal feedwater distributing pipe, which pipe is in turn attached to the inside of the drum by stud bolts. This arrangement results in the bore in the drum becoming part of the channel through which the feedwater enters. This is an important point, as the major cracks which were found existed on the face of the bore. One of the problems, therefore, was to determine the cause of these cracks and arrive at a decision with respect to repairs and changes to prevent a recurrence of the condition. Also in this general connection, it was necessary to arrive at a similar decision on cracks found in the lower water-column connections and in the superheater inlet and outlet headers and fittings.

As the first step in the investigation, the cracks were examined briefly and records taken of their appearance by photographs which are presented in the section headed Visual Examination. The metal around some of the cracks was then removed so that a metallographic examination might be made to determine the manner in which the cracks proceeded into the metal, and to arrive at some conclusion as a result of such an examination as to their nature and cause.

This phase of the examination is discussed under Metallographic Examination. It showed that the cracks were transcrystalline, relatively narrow at least at their ends and, in some cases though not all, were terminating in a snub-nosed section in the center of the crystal. This finding precluded the possibility

Professor White received his B.A. degree from Brown University in 1907 and his Sc.D. degree in 1925. After graduation he served a few years with the Jones and Laughlin Steel Company, Pittsburgh, Pa. He has been at the University of Michigan since 1911, with the exception of two years spent with the Ordnance Department, U. S. A., during the World War.

Contributed by the Power Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, New York, N. Y., December 5–9, 1938.

Discussion of this paper closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

that the cracks were due to caustic embrittlement, because cracks due to caustic embrittlement are intercrystalline rather than transcrystalline. They were not due to corrosion alone, for had they been they would have taken on more the character of zones of corrosion. Yet because of their snub-ended structure, it was evident that corrosion was a factor. In fact, the metallographic examination showed that the cracks resulted from accelerated corrosion accompanied by stress and, because of the sharpness of the cracks, especially at the lower ends, it was evident that the stress was of a repeated character.

In arriving at the conclusion that failure was due to corrosion fatigue, it was necessary to find some explanation for a stress which would be of a repeated character. This was found in the boiler operation itself; that is, the temperature of the surface of the metal in the feedwater inlets varied from 250 F to 587 F with an average temperature of 350 F. This was due to the fact that the temperature of the boiler feedwater usually varied from 250 F to 350 F. There were times, however, when the feedwater regulator shut off and on such occasions the temperature of the water at the inlet would be the temperature of the water in the drum, 587 F. Therefore, by using the bore of the drum as part of the channel for the boiler feedwater, the surface of the drum, used as the channel, was subjected to repeated heatings and coolings at a rapid rate which, on an estimated basis of ten such

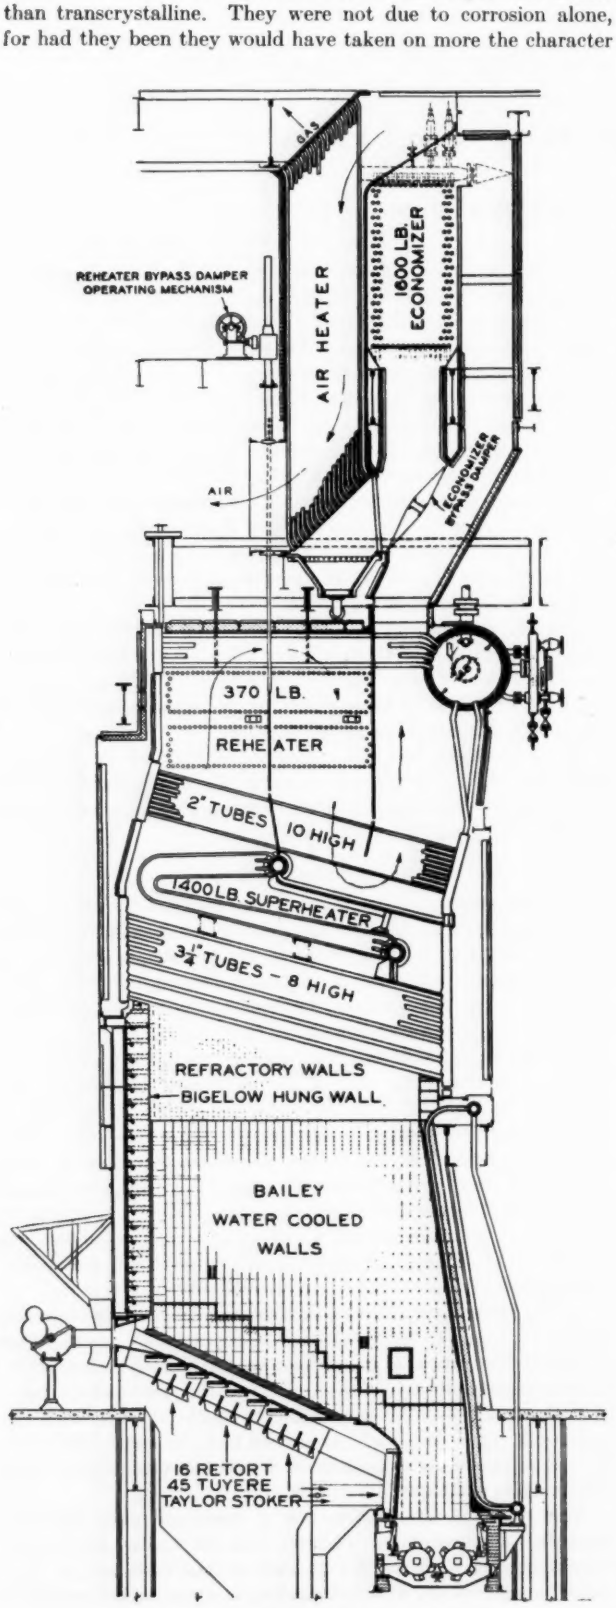

FIG. 1 CROSS SECTION OF NO. 5 BOILER

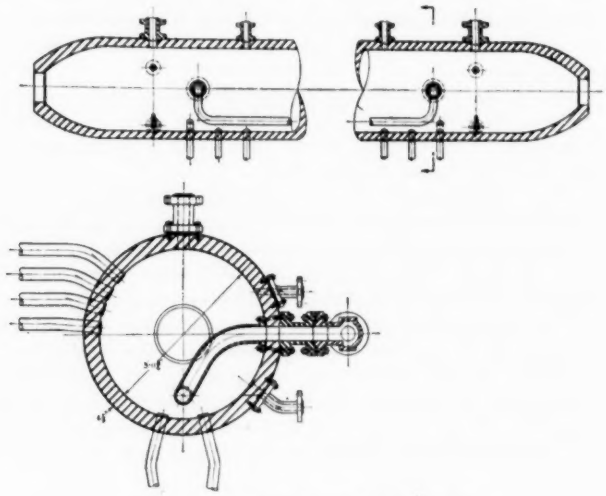

FIG. 2 CROSS SECTION OF BOILER DRUM

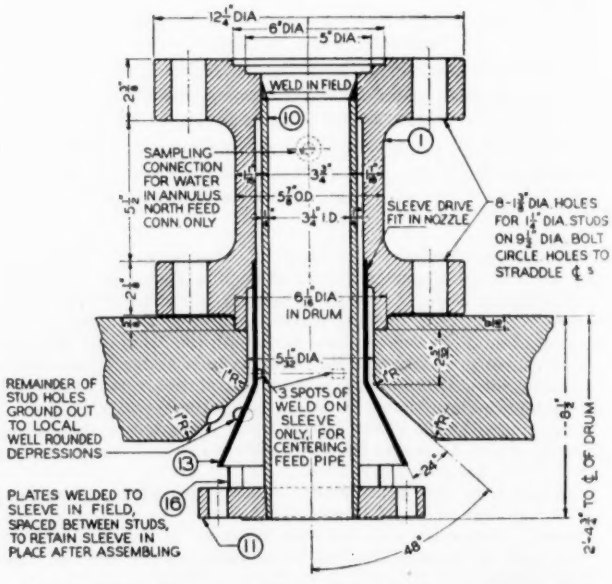

FIG. 3 CROSS SECTION OF NEW INLET FOR BOILER FEEDWATER

changes per hour, would amount to as much as 600,000 changes during the operating life of the boiler. These changes in temperature would introduce stresses into the surface of the metal which as they were repeated, would result in surface cracks and, with continued temperature changes, would cause them to grow and develop to the extent found when the boiler was examined.

In view of these conditions, it was felt that the solution to the problem involved changes in design so that the metal in the drum would not come in contact with the boiler feedwater during its passage into the drum and, therefore, not subject metal surfaces in the drum to changing temperatures, resulting in fluctuations in stress.

The design, shown in Fig. 3, was developed to accomplish this purpose. It, of course, required the boring out of the cracked sections of the drum. Essentially, it consisted in attaching a tube to the outside flange of a new nozzle in such a manner that the walls of this tube would not come in contact with the walls of the drum. Also, to prevent any possible drip from the outside wall of this tube onto the wall of the drum, an apron attached to the inside of the nozzle was installed. In this way, the boiler feedwater enters the drum without coming in contact with any part of the drum wall and, in consequence, removes the possibility of the stress conditions due to changes in temperature resulting from the variations in temperature of the boiler feedwater.

Attention is particularly called in this new design to the fact that, because of the space between the apron and the drum wall

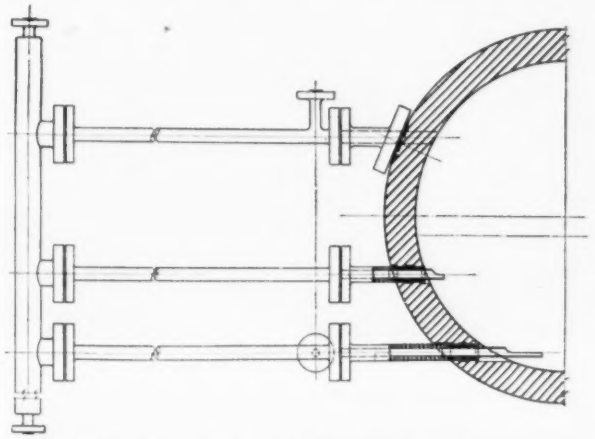

FIG. 4 CROSS SECTION OF NEW WATER-COLUMN CONNECTIONS

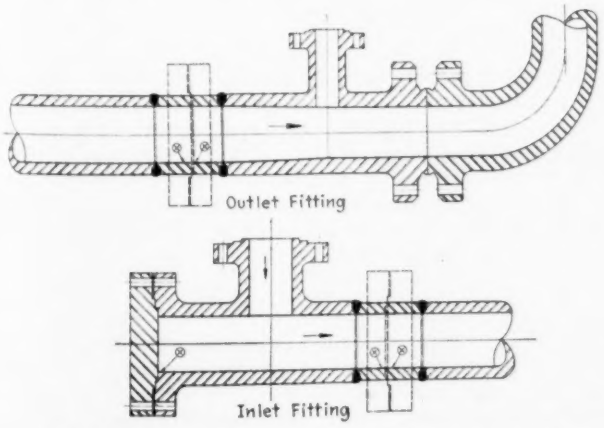

FIG. 5 SECTION OF SUPERHEATER FITTINGS AND HEADERS
(Above, outlet fitting; below, inlet fitting.)

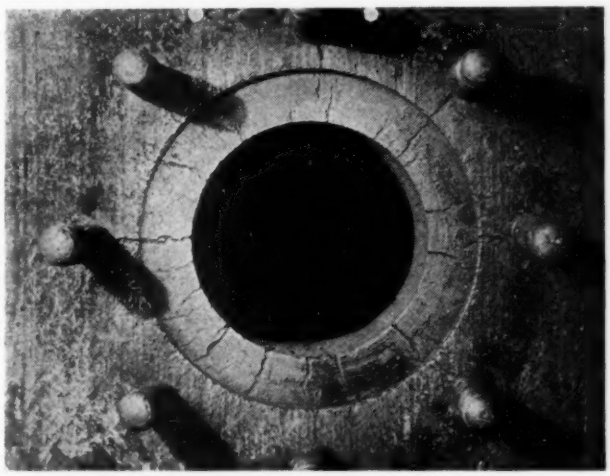

FIG. 6 FEEDWATER INLET, INTERIOR OF DRUM

FIG. 7 FEEDWATER INLET, EXTERIOR OF DRUM

and the space between the tube, and the apron and the nozzle, the temperature in the drum wall should be relatively constant and at the temperature of the water in the drum. Due to the space between the tube and the nozzle, the nozzle will be at practically the same temperature as the drum and therefore there will be no cooling action on the outside surface of the drum.

One of the possible contributing factors to the corrosion was the fact that the pH value of the water as it entered the drum varied from 6.9 to 7.2, while the water in the drum itself showed a pH value varying from 11.0 to 11.7. The change in design to reduce temperature stress also resulted in freeing all sections of the boiler drum from contact with water with a low pH and substituted alkaline water with a pH value from 11.0 to 11.7.

WATER COLUMNS

The corrosion-fatigue cracks which were first found in the base of the water columns in 1935, and in the boiler connection of the water columns of No. 5 boiler in 1938, were believed due to the same causes as those which produced the cracks in No. 5 boiler drum. To correct this condition, the inside edges of the male and female joints were rounded off for the purpose of removing stress concentrations. The major change, and what is believed to be the most important one, was the installation of a new connection

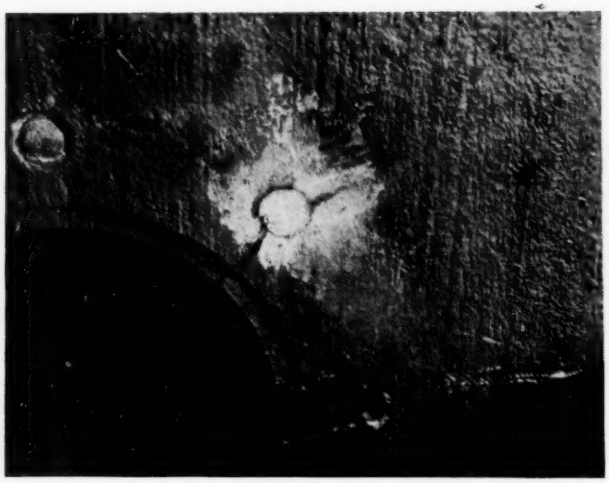

FIG. 8 INTERIOR, INLET BORED TO $5^1/_{32}$ IN.
(Note crack extending beyond stud hole.)

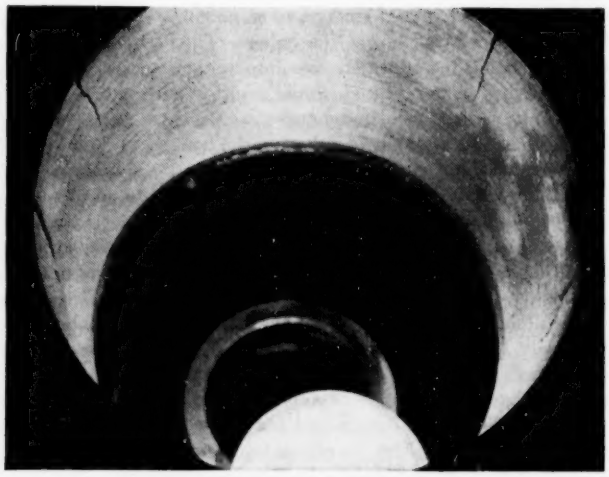

FIG. 9 INTERIOR, INLET BORED TO $5^1/_{32}$ IN.
(Showing cracks in upper half of inlet hole.)

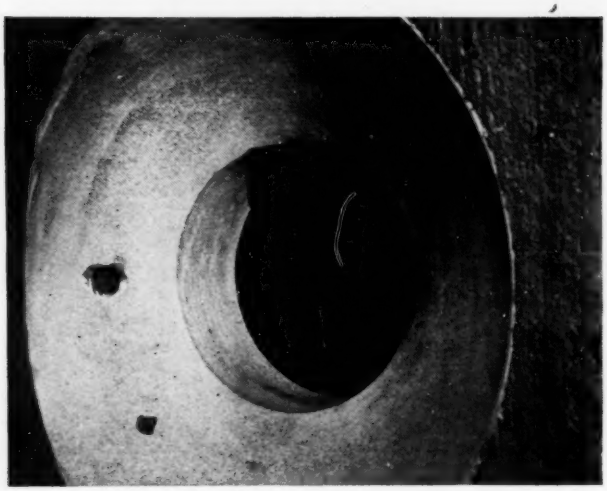

FIG. 10 INTERIOR, NORTH SIDE OF COMPLETED HOLE AFTER POLISHING, ETCHING, AND MAGNAFLUXING

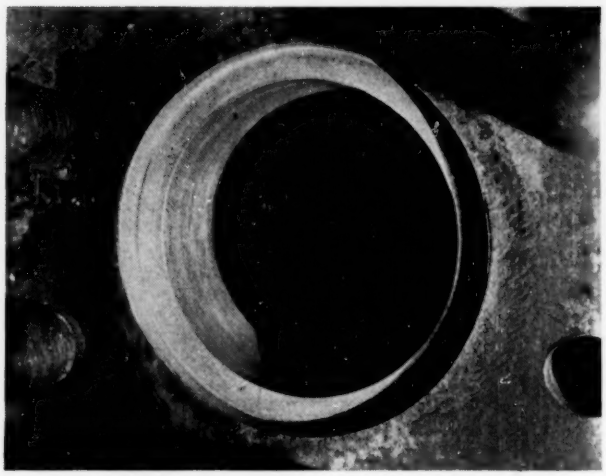

FIG. 11 EXTERIOR, SOUTH SIDE OF COMPLETED HOLE AFTER POLISHING, ETCHING, AND MAGNAFLUXING

12 in. above the lower connection to provide a continuous circulation of the water in the lower connection. With this arrangement, shown in Fig. 4, the pH value in the lower section of the water column and in the connections to the water column would be raised from values as low as 6.0 to values substantially the same as found in the drum, namely, values ranging from 11.0 to 11.7.

This change would also bring about a relatively constant temperature in the lower connections approximating that found in the boiler, namely, 587 F. Therefore, because of the changes made, overcoming troubles due to repeated changes in surface stress resulting from fluctuating temperatures, amplified by the presence of water with too low a pH value, it is not expected that further cracks will be found in the water columns.

SUPERHEATER FITTINGS AND HEADERS

Small cracks were found in some of the flanges in certain of the forged-steel tee fittings on the inlet and outlet superheater headers and also in the flanges of the headers themselves. It was believed that these cracks were due to stress reversals in the presence of condensed steam. At these points there were pH values of probably less than 7.0 which would produce a corrosive condition.

The original design of these parts is shown by the dashed lines in Fig. 5.

It was felt that the correction for this problem would be a change whereby there would be no possibility of the collection of condensed steam, accompanied by the removal of stresses by changing from a flanged to a welded construction. This opinion also was substantiated by the fact that on the outlet-tee-fitting end, jointed by a Sargol joint, there was no evidence of cracks.

Therefore, forged-steel filler pipes were welded between the two fittings and their respective headers, after the flanges had been eliminated, as shown in Fig. 5.

VISUAL EXAMINATION

The cracks which were found in the feedwater inlets of No. 5 boiler, in the lower connections of both water columns, and in the inlet and outlet superheater tee fittings, as well as in the superheater inlet and outlet headers were carefully examined visually. The cracks in the fittings and headers were not pronounced. Also, no cracks were found on the end of the outlet tee that

formed part of the Sargol joint, or in the side outlets of both of the tees. These latter were in a vertical position.

The cracks in the feedwater inlets into No. 5 boiler drum were present in both the north and south inlets. In each case, they were distributed more or less uniformly over all the exposed drum metal in the inlets. Some of them extended into the drum metal to a depth of about 2.5 in. A crack of this depth was found on the inside of the drum. The cracks were much deeper on the inside than on the outside.

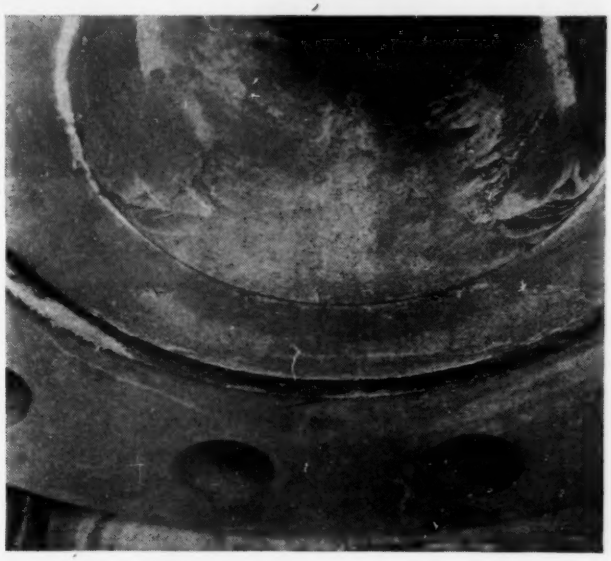

FIG. 15 SUPERHEATER-INLET STEP-JOINT T-FITTING, HEADER END

Photographs showing the nature and character of these cracks are given in Figs. 6 and 7.

Photographs showing the appearance of the inlets during and after machining are given in Figs. 8, 9, 10, and 11.

Fig. 8 shows the extent of a crack in the north feedwater inlet after boring had been completed to $5^{1}/_{32}$ in.

Fig. 9 shows the cracks in the upper half of the bore of the same connection after boring to the same diameter.

Fig. 10 gives the appearance of the hole after polishing, etching, and magnafluxing.

Fig. 11 gives the appearance of the finished bore from the outside.

Figs. 12 and 13 give the appearance, respectively, of the bottom of the lower connections in the boiler drum for the south water column before and after removal of the cracks. The appearance of the lower connection of the north water column was similar.

The inlet superheater tee fitting showed small cracks on the flanges forming the run of the tee as shown in Figs. 14 and 15. Also, as shown in Fig. 16, small cracks were found on the flange of the inlet superheater header.

The outlet superheater tee also developed cracks on one of the flanges forming the run of the tee as well as on the flange of the header which faced this flange. See Figs. 17 and 18.

CHEMICAL COMPOSITION

In connection with the examination that was made of the No. 5 boiler, it appeared desirable to ascertain if there were any irregularities with respect to the chemical composition. Table 1 gives the composition of the metal in the drum as obtained from mill analyses and from the analyses of drillings from the actual metal in the drum.

FIG. 19 TYPICAL UNETCHED SECTION FROM DRUM METAL SHOWING A MODERATE NUMBER OF INCLUSIONS, ×100

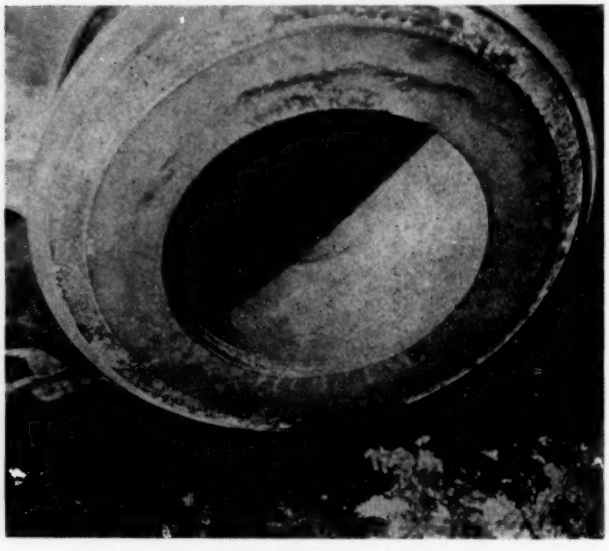

FIG. 18 SUPERHEATER OUTLET HEADER
(Facing flange shown in Fig. 17.)

FIG. 21 SAME SECTION AS FIG. 19, ETCHED, ×100

FIG. 22 ANOTHER SECTION OF DRUM METAL, ETCHED, ×100

FIG. 23 SAME SECTION AS FIG. 22, ×1000

These analyses show that the metal in the drum was made from killed steel. The chromium and nickel contents which were found are of no significance. They represent residuals which are oftentimes found in steel. The analyses show that from a chemical-composition standpoint, the metal was of excellent quality and conformed closely to that which was desired.

Also, there is satisfactory agreement between the analyses taken at the mill and the analyses taken from drillings from the drum itself.

TABLE 1 ANALYSES OF DRUM METAL

	Mill analyses, per cent	Analyses of drillings, per cent
Carbon	0.26	0.25
Manganese	0.53	0.52
Sulphur	0.024	0.036
Phosphorus	0.03	0.022
Silicon	0.22	0.27
Chromium	..	0.05
Nickel	..	0.14

Physical Properties

An examination was made of the physical properties of the metal in the drum to determine its characteristics. Tests were made on specimens taken from the drum and compared with tests made at the mill. Results of these tests are given in Table 2.

TABLE 2 PHYSICAL PROPERTIES OF DRUM METAL

	A.S.M.E. Code S-4	Tests at mill, longitudinal sections		Tests on drum specimens, radial cores

[a] Test at University of Michigan.
[b] Test by Babcock & Wilcox Company.
[c] Not secured. Yield point would be higher than reported yield stress.

It would appear as if there were little agreement with respect to the physical properties between the core specimen tested at the University of Michigan and that tested by the Babcock &

Fig. 24 Crack in Boiler Drum, ×100

Fig. 25 End of Crack Shown in Fig. 24, ×1000

FIG. 26 CRACK IN BOILER DRUM, ×100

Wilcox Company, or the longitudinal specimens tested at the mill. The difference, however, is easily explained by the following interpretation which is based on the manner in which the specimens were secured.

The core obtained from the steam drum has its longitudinal axis parallel to and 9 in. from the horizontal center line of the drum. The testing of a cylinder in such a direction is unusual as it places the stress during the tensile test at right angles to both the longitudinal and the hoop stresses which are developed in operation and parallel to the direction in which the operating stress is zero. It is well known that minute laminations frequently occur in both plate and forgings and the plane of such laminations is parallel to the faces of a plate or the cylindrical surfaces of a forging; hence, it can be seen that, in a tensile coupon prepared as were these coupons, small laminations, if they are present, are at right angles to the longitudinal axis of the tensile coupons and hence they are planes of weakness within the coupons. Under these conditions, it is not unusual for such coupons to develop physical properties that are somewhat abnormal as compared with coupons cut longitudinally from the same material.

This was found to be the case with respect to the specimen which was tested at the University of Michigan, although it was not the case with respect to the specimen which was tested by the Babcock & Wilcox Company. That is, in examining the photomicrograph of Fig. 20, taken from the drum metal subjected to the physical test at the University of Michigan, a zone was found

FIG. 27 END OF CRACK SHOWN IN FIG. 26, ×1000

in which there were a considerable number of inclusions. The test specimen broke in such a zone because of these inclusions and therefore, resulted in the low values secured. On the other hand, it is believed that the test coupon broken by the Babcock & Wilcox Company happened to be in a section which was free from such inclusions or planes of weakness, or free to the degree shown in Fig. 19, and therefore their test coupon showed superior physical properties.

It is appreciated that the test values on the coupons, because of the fact that they were radial rather than longitudinal or transverse, are of no significance and contributed in no manner to the cracks that were found.

Physical tests were also made on specimens taken from each of the superheater headers. These both showed metal of a good quality. The results are given in Table 3.

TABLE 3 PHYSICAL PROPERTIES OF SUPERHEATER HEADERS

Metallographic Examination

A metallographic examination was made of sections from the drum for two purposes: One was to determine the character of the metal in the drum itself, and the other was undertaken for the purpose of determining, in so far as these examinations would disclose, the nature and character of the cracks.

Quality of Metal in Drum. Figs. 19 to 23 show metallographic structure of the metal in the drum. Fig. 19 is an unetched section at 100 diameters, representative of the specimen under examination. It shows a relatively small number of inclusions. Fig. 20 shows another portion of the same surface in which a considerable number of inclusions are shown, although there are no more of these than are frequently found in metal of this mass. It is an unetched section at 100 diameters. Fig. 21 is an etched section corresponding to the unetched section in Fig. 19. It shows the metal to be of low carbon content which is confirmed by the analyses. It shows a number of dull-gray particles which represent the inclusions in the unetched section. The grain size is somewhat irregular, due without doubt to the influence of forging. Fig. 22 shows the metallographic structure of an etched section at 100 diameters of another specimen from the drum. This shows a somewhat cleaner metal than was disclosed in Fig. 21 and a more uniform grain size. Fig. 23 shows the structure disclosed in Fig. 22 but at 1000 diameters. It is made up of ferrite and sorbitic pearlite. All of these photomicrographs show the material to be of an acceptable quality, as disclosed from a metallographic examination. The same is especially true with respect to the structure of Figs. 22 and 23.

Nature and Character of Cracks. Figs. 24 to 27, inclusive, are given for the purpose of showing the nature and character of the cracks.

Fig. 24 shows a crack in its entirety at 100 diameters. It indicates clearly that the cracks are transcrystalline.

Fig. 25 shows the end of this crack at 1000 diameters. It shows also that the crack not only passes through the crystals themselves but even directly through the carbide-carrying zones.

Fig. 26 shows the appearance of another crack. It too is transcrystalline.

Fig. 27 shows the end of this crack and brings out more clearly its transcrystalline characteristics.

Attention is called to the fact that all of these cracks are transcrystalline and blunt-nosed. The blunt-nosed condition is generally indicative of a crack which has been affected by corrosion. Also, all of these cracks are transcrystalline, which is a condition found in cracks resulting from fatigue. In fact, there is no evidence that any of these cracks are due to caustic embrittlement because, if they had been due to this cause, they would have been intercrystalline rather than transcrystalline.

Though no metallographic examination of the cracks in the failed water column and superheater fittings and headers was made there is no doubt but that they would have been of the same character and type as the cracks found in the boiler drum.

Therefore, in view of the evidence shown by this metallographic examination, there can be no other conclusion reached than that these cracks were the result of corrosion fatigue.

Conclusion

As a result of the studies which were made, none of the difficulty could be attributed to faulty metal. The material was of the proper chemical composition and had acceptable physical properties.

The primary cause of the cracks was believed due to corrosion fatigue resulting from stresses set up by changes in temperature on the surface of the metal in combination with a relatively low pH value of the water in contact with the metal.

As a result of the changes which have been made in design, it is not anticipated that further cracking will take place.

Acknowledgment

Participating in this investigation were also: W. C. Schroeder, U. S. Department of the Interior, Bureau of Mines; Babcock & Wilcox Company; Hall Laboratories, Inc.; Mutual Boiler Insurance Company of Boston; and Boston Edison Company.

Discussion

M. K. Drewry.[2] Because 100 F temperature difference of component steel parts causes 20,000 lb per sq in. stress, there seems a probability that the 337-F rapid temperature changes mentioned in the paper caused drum cracking from simple stress alone. Attaching more significance to thermal stresses and less to corrosion fatigue seems possibly more helpful in this and other similar cases.

The original 1300-lb per sq in. pressure boiler at Lakeside, with 325 F feedwater directly contacting the 5-inch-thick drum, has operated 70,000 hr without developing any cracks at any point. Feedwater-flow rate is always coincident with steam-flow rate, being regulated manually with the aid of water-flow steam-flow meters, thus preventing sudden metal temperature changes.

The lower half of all high-pressure water columns has been insulated since learning of drum-cracking troubles, in order to increase return-water temperature from 50 F below boiling temperature to within 10 F, so that thermal stresses from once-per-shift blowdown are rendered unimportant. No need of raising alkalinity of column returns appears necessary, for in addition to the apparent unimportance of corrosion, data and experience are available showing that high alkalinity is not as favorable to preserve protective coatings as is low alkalinity.

S. C. Hollister[3] and G. J. Schoessow.[4] This is a progress report of an investigation under way to determine the reduction in bursting strength of a cylindrical pressure vessel due to a circular hole cut in its side.

[4] Engineer in Charge Mathematical Analysis in Design, The Babcock & Wilcox Company, Barberton, O. Mem. A.S.M.E.

The investigation thus far has included three materials; fully annealed steel, cold-drawn brass, and Pyrex glass. The tubes had a nominal outside diameter of 1 in. and a length of $7^1/_2$ in. Specimens have been tested with holes varying in diameter from $4^1/_2$ per cent to about 28 per cent of the outside diameter of the tube. In each case, the bursting strength was compared to that of a tube of the same size and material without a hole.

The tests were made on the tubes without closing the ends. Stresses, therefore, were due to hoop tension only. Hydraulic pressure was applied to the tube which was lined with a rubber sack. Closure of the ends was made by the use of close-fitting plugs which were prevented from moving outward by a yoke frame around the specimen. Closure of the hole in the side of the tube was made by inserting, from the inside, a small plug having a head conforming to the inner surface of the tube at the periphery of the hole. The rubber sack bore directly against this head. A thin rubber washer was used between the plug head and the tube to absorb any small irregularity in the fit. Pressure was supplied by means of a simple plunger pump placed in a standard testing machine. Fig. 28 shows the specimen in the partially assembled yoke with the end closures and the closure for the hole already in place, and with connection made to the pump. Fig. 29 shows the entire assembly ready for testing.

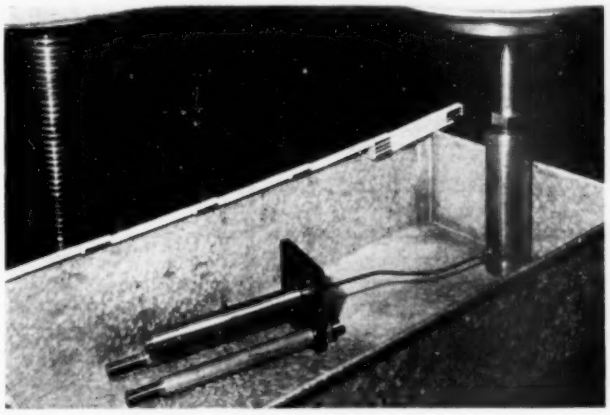

FIG. 28 SPECIMEN IN PARTIALLY ASSEMBLED YOKE WITH END CLOSURES AND CLOSURE FOR HOLE IN PLACE AND PUMP CONNECTION MADE

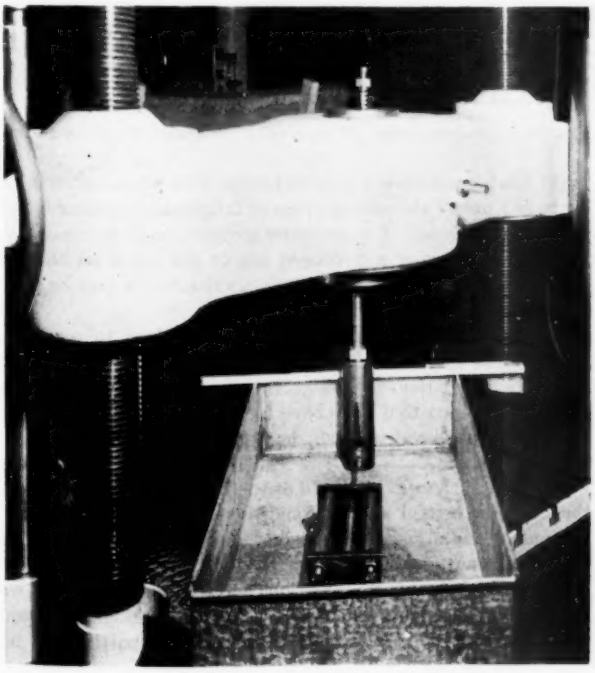

FIG. 29 ASSEMBLY READY FOR TESTING

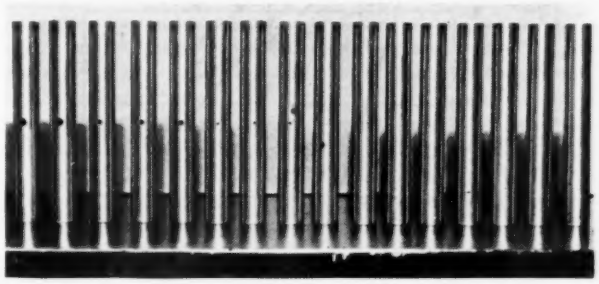

FIG. 30 TYPICAL SERIES OF TUBES BEFORE TESTING

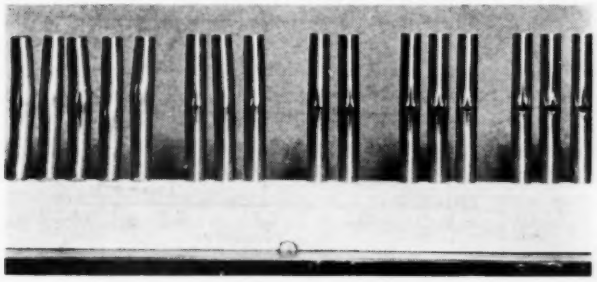

FIG. 31 SAME SERIES OF TUBES IN REVERSE ORDER AFTER BURSTING

Fig. 30 shows a typical series of tubes before testing, while Fig. 31 shows the same tubes after bursting.

Four thicknesses of steel tubing were used, varying from $2^1/_2$ per cent to $8^1/_2$ per cent, approximately, of the outside diameter of the tube. The brass tubing had a thickness of approximately 4 per cent of the tube outside diameter, while the Pyrex-glass tubing had a thickness approximately 6 per cent of the outside diameter of the tubing.

The results of the pressure tests on the various tubing samples are shown in Fig. 32, in terms of the reduction of bursting pressure (hence reduction in efficiency) caused by the hole, when compared to that of a solid tube of the same material. It will be noted that the ductile materials are grouped relatively close together at the top of the diagram, while the results of the tests on the glass specimens are much lower.

If one were to draw a 45-deg line downward and to the right from 100 per cent efficiency at 0 hole diameter, such a line would pass through 90 per cent efficiency at 10 per cent hole diameter; 80 per cent efficiency at 20 per cent hole diameter, etc. Such a line represents a value somewhat below the average of the metal specimens so far tested. It suggests a simple method of determining the efficiency of a vessel with a hole in the side. If, for example, a hole with a diameter 10 per cent of the outside diameter of the vessel reduces the efficiency in hoop tension by 10 per cent it suggests that one may use for efficiency the ratio $(D - d)/D$ where D is outside diameter of vessel, and d, diameter of hole. The diagram Fig. 32 shows that such an approximate relation holds up to hole diameters of 28 per cent of the outside diameter of the vessel, with thick walls lying well above such diagonal and thin walls lying somewhat below it.

The tests made thus far indicate that the results with glass

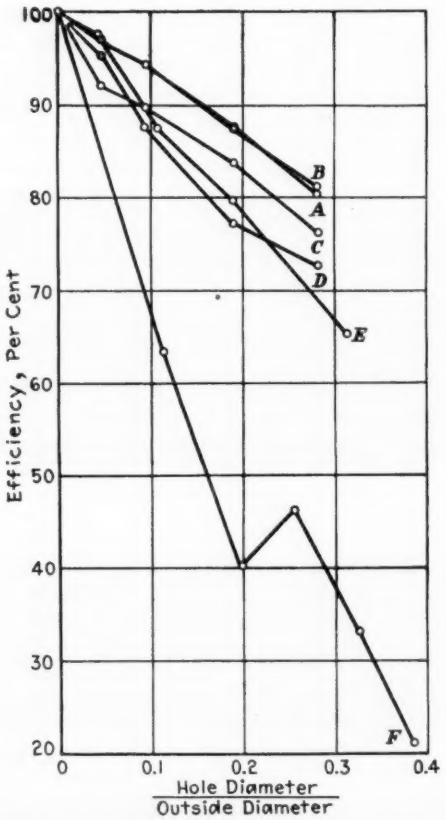

FIG. 32 RESULTS OF PRESSURE TESTS ON TUBING SAMPLES

A, 1.005 in. OD × 0.084 in. thick × 7½ in. long seamless steel tubing fully annealed
B, 1.003 in. OD × 0.068 in. thick × 7½ in. long seamless steel tubing fully annealed
C, 1.000 in. OD × 0.042 in. thick × 7½ in. long seamless steel tubing fully annealed
D, 1.004 in. OD × 0.026 in. thick × 7½ in. long seamless steel tubing fully annealed
E, 0.938 in. OD × 0.037 in. thick × 7½ in. long seamless brass tubing cold drawn
F, 0.979 in. OD × 0.060 in. thick × 7½ in. long Pyrex-glass tubing

tubing show a loss in efficiency of two to three times the loss in efficiency of steel or cold-drawn brass tubing.

This investigation thus far has been sponsored by the Babcock & Wilcox Company. It is a part of a more extended program on the study of the effect of holes in pressure vessels.

The results presented here apply to static-pressure conditions and should not be applied to conditions involving either creep or fatigue.

The results of tests so far made in this investigation, when applied to the steam drum covered in the author's paper, would indicate that 14.4 inches is the maximum diameter safely permissible for an unreinforced hole at the feed connection. Later data may modify this conclusion.

D. S. JACOBUS.[5] The conclusion by Hollister and Schoessow that an unreinforced hole 14.4 inches diameter would be safely permissible at the feed connection of the steam drum, covered in the author's paper, is consistent with the rules given in the Boiler Code, which are based on experience.

The Boiler Code contains a diagram for determining the maximum allowable size of an unreinforced opening. The method[6] of deriving the formula on which the diagram in the Code is based was published some years ago. As stated in this article, the formula gives smaller openings in the larger drums than would be sanctioned by the law of geometric proportions. The maximum allowable size of an opening obtained by the formula used in preparing the diagram in the Boiler Code is 12.2 in. The diagram in the Code was not extended to cover openings over 8 in. in diameter, as it was thought that no hardship would be involved in limiting the size to 8 in., and that it would be well not to extend the curves any further than necessary.

J. B. ROMER.[7] The author has presented the story of the cracking of the steam and water drum of the No. 5 boiler at the Edgar Station of the Boston Edison Company in an able and painstaking way, and has shown the necessity of guarding against the phenomenon known as corrosion fatigue. The generally accepted theories which are involved in a failure of this type are:

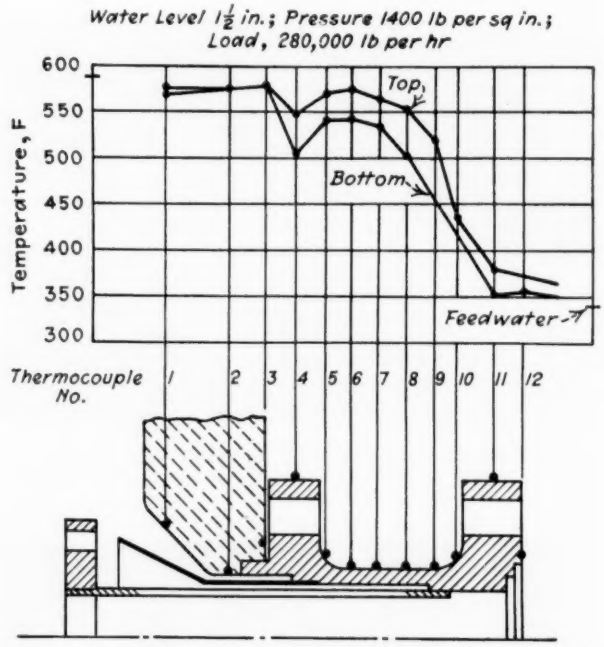

FIG. 33 TEMPERATURE AT JUNCTION OF FEED PIPE AND DRUM

(1) Carbon steel has a definite fatigue limit when tested in dry air in any one of the several types of fatigue-testing machines.

(2) The presence of a corrosive medium, such as condensate or feedwater having a hydrogen ion or pH value on the acid side, reduces the endurance limit to a value which may be below the normal stresses existing in a boiler.

(3) Sudden changes in temperature may lead to conditions favorable to the action by raising the stresses to a figure appreciably higher than the design stress.

It may happen that the above factors, especially if combined at some point in a drum, will lead to results such as described in the paper.

Cracking such as experienced at the Edgar Station emphasizes the need for careful and thorough inspections of high-pressure equipment and also the necessity of a correct design and proper operating conditions.

Reducing the corrosive conditions and the thermal stresses will slow down or stop the development of such cracking. Acid conditions in the condensate or feedwater can be partially, if not

fully, overcome by feedwater treatment, and thermal stresses may be minimized by employing special devices such as were installed at the Edgar Station.

It might be interesting to readers to learn of the temperature of the metal of the steam and water drum at the feedwater inlet after installing the inner sleeve as shown in the author's Fig. 3. The temperature was measured after the boiler was returned to service by means of a specially developed spark-plug-type thermocouple.

The temperature of the drum connection nozzle for the feedwater was measured in a similar way. Fig. 33 shows the location of twelve thermocouples.

A corresponding set of thermocouples was located at the bottom of this opening; that is, 180 deg around the nozzle. The readings from both sets of thermocouples, obtained during one set of tests, are given in the curves at the top of Fig. 33.

A review of the test data, taken at different steam flows and at different water levels, indicates that the maximum temperature variation between the saturated steam and the metal of the drum at the feed opening, thermocouples Nos. 1, 2, and 3, will be of the order of 15 F, and will be less than this under most conditions of operation. The difference is much less than that which existed before installing the sleeve. It would seem that, with proper feedwater conditions, the drum should be free from further cracking.

At thermocouple No. 6, where the highest temperature in the nozzle was noted, the maximum variation between the bottom and top of the nozzle is of the order of 70 F, whereas, the general variation at this point is of the order of 35 to 50 F. Under most conditions of operation, the variation is of the order of 10 to 40 F. Thermocouples Nos. 8 and 9 show a little higher general average possibly of the order of 25 to 30 F, but do not show as high swings as were noted in No. 6 thermocouple. At the outside end, where the feedwater enters thermocouple No. 12, a maximum range of 30 F was noted with an operating range from 5 to 10 F. From this it can be seen that sudden changes will be small and that the change from the cold feedwater at the outer end to the saturated temperature at the drum wall comes in that part of the nozzle which can best withstand this change. In general, it is a rather gradual change.

Similar measurements on the water column with its new connections indicated that its temperature was at all times close to that of the saturated steam and, hence, it is not subject to strains due to temperature differences.

The physical properties of the steel in the drum are given in Table 2 of the author's paper. Emphasis should be given the point brought out in the paper regarding the direction of the axis of the cores which were obtained in trepanning the holes for the water-column connections in the north and south ends of the drum. It has been our observation that a test coupon cut so that its longitudinal axis approaches the radius of a forged drum, or extends from face to face of a rolled plate, may give test values which are not consistent with companion coupons nor with standard coupons taken in a longitudinal direction parallel to the faces of the plate. This difference usually takes the form of low ductility but in the case of plates, particularly when the coupon is cut in a normal direction to a lamination, all the test values may be lower than they should be. In some cases the area of the lamination may be greater than the cross-sectional area of the coupon and in such a case all of the test values will fall to 0.

Apparently an inclusion of some type was present in the coupon taken from the north end of the drum and as a result the ductility was lower than it would have been for a specimen taken in the standard way. As pointed out by the author, the stress applied in testing the specimen was in a direction in which there is very little, if any, working stress. The lack of ductility shown in the test contributes in no manner to the cracks that were found.

Author's Closure

The author wishes to express his appreciation for the splendid discussions presented by M. K. Drewry, Dean S. C. Hollister, G. J. Schoessow, Dr. Jacobus, and J. B. Romer. The discussions were all pertinent and have added materially to the subject matter of the paper.

To the Question of Balancing Reciprocating Weights in Steam Locomotives

By A. I. LIPETZ,[1] SCHENECTADY, N. Y.

The Association of American Railroads has been recommending since 1933 cross-counterbalancing of revolving weights for main wheels of steam locomotives. For coupled wheels the old method of static balancing is still being considered as sufficiently accurate. For reciprocating weights the static method is also retained by the new Manual of the A.A.R. The author takes exception to this scheme. He is of the opinion that for high-speed locomotives, and for these locomotives especially, greater clearness should be introduced in this subject. The dynamic augment, which plays such an important part in all high-speed calculations, should not exceed the limit allowed for the strength of the rails and the stiffness of the roadbed. An accurate evaluation of the dynamic augment for each wheel is possible only when the revolving weights are correctly balanced for each wheel, coupled as well as main. If this is not done, some of the wheels are dynamically deficient and a uniform distribution of dynamic augments is impossible. This destroys the effectiveness of proper balancing of reciprocating weights.

The author discusses the percentage of balancing the reciprocating weights in steam locomotives and how this depends on the method of calculating counterbalancing, whether static or dynamic. He shows, on the basis of existing locomotives, that a smaller total percentage of counterbalancing reciprocating weights of a locomotive is quite adequate for modern locomotives.

The author further calls attention to the existence of the steam component on the main axle and suggests that no reciprocating balance should be placed on main wheels, even if this should somewhat reduce the total percentage of balancing. He would rather increase the dynamic augment on coupled wheels in order to spare the main wheels from excessive blows. In his opinion the disregarding of the action of the steam component is responsible for the objection of some railroads to cross-counterbalancing of locomotives. This attitude should disappear when the problem is clarified.

In conclusion the author gives an example of a correct calculation of cross-counterbalancing of all weights, revolving and reciprocating, and for all axles, main and coupled, and proves that this method involves no more work, even less, than the static method, when angling of counterbalances on wheels is attempted.

HISTORICAL REVIEW

COUNTERBALANCING of steam locomotives is not a new subject. It has been practiced since the first days of building locomotives. The first locomotive builders in England and other countries realized very early the advantages of counterbalancing. Thomas Rogers, founder of the Rogers Locomotive Works in America, patented in 1837 an application of counterbalances opposite the cranks, of sufficient weight to counterbalance the cranks and connecting rods, thus introducing counterbalancing of revolving parts.

Up to 1845 it was customary to balance only revolving weights; the balancing of reciprocating weights was not recognized until later, when investigations of the problem of balancing were started by locomotive engineers. The disturbances caused by the unbalanced inertia forces were first demonstrated by Nollau (1)[2] in Germany who made special tests with a locomotive, suspended by chains, although previously to that Fernihough in England, in October, 1845, suggested and apparently tried (2) the use of weights for counterbalancing main rods, pistons, and other reciprocating parts.

Le Chatelier in France, in 1848, made tests similar to Nollau's and enunciated a very complete theory of balancing which is now known as cross-balancing. He published his theory in 1849 (3) and shortly afterward his theory was further developed by various investigators, mostly French (4). Later the correct method of cross-balancing was popularized for the English-reading public by Daniel Kinnear Clark in his classic book "Railway Machinery" (5). This treatise had a tremendous effect on the locomotive-engineering literature of the world.

Since then, practically all locomotive textbooks (6, 7, 8, 9, 10)

[1] Chief Consulting Engineer, in charge of research, American Locomotive Company, and nonresident professor of locomotive engineering, Purdue University. Fellow A.S.M.E. Mr. Lipetz was educated at the Warsaw (Poland) Polytechnic Institute, from which he received the degree of engineer technologist (mechanical engineer) of the first grade in 1902. In 1903 he entered railway service in Russia as an apprentice on the Moscow-Kiev-Voronesh Railway, later serving as fireman, locomotive driver, inspector, and assistant master mechanic. From 1906 to 1909 he was assistant professor of thermodynamics and railway mechanical engineering at the Kiev Polytechnic Institute, also passing examinations required for the degree of adjoint of applied mechanics. For three years he held administrative positions on the Tashkent Railway, and for the three years following he was chief of the locomotive department, Ministry of Railways, Russia. From 1915 to 1920 he served the Russian Railways in the United States, first as representative of the Russian Ministry of Railways and then as assistant chief and, later, chief of the Russian Mission of Ways and Communications in the United States. Since 1920 he has been connected with the American Locomotive Company. He is the author of many papers on steam and Diesel locomotives, and was the reporter for America on locomotives of new types at the International Congress held at Madrid, Spain, in 1930. He has been awarded The Melville Medal for 1938 for his paper "The Air Resistance of Railroad Equipment," presented at the 1937 Semi-Annual Meeting of the A.S.M.E. in Detroit, Mich., May 17-21, 1937.

Contributed by the Railroad Division and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in New York, N. Y., December 5–9, 1938.

Discussion of this paper closed January 10, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

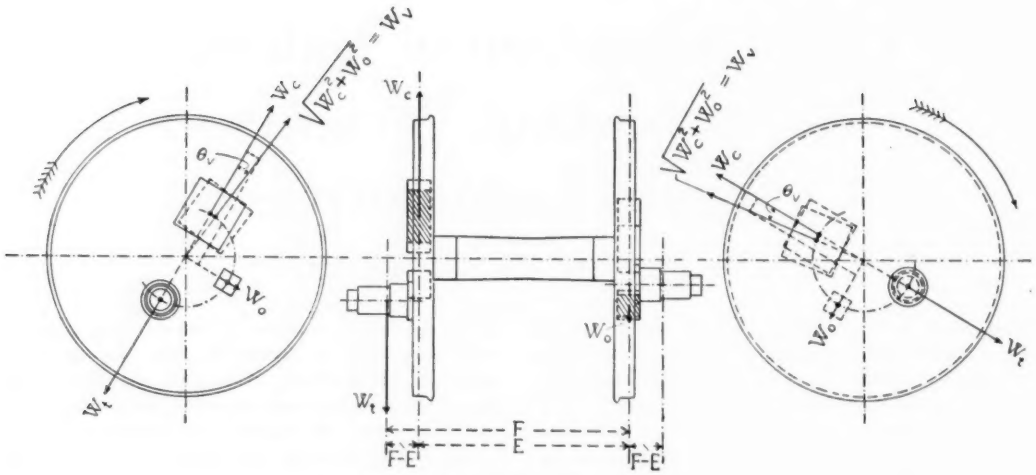

FIG. 1 MAIN DRIVING WHEEL PAIR

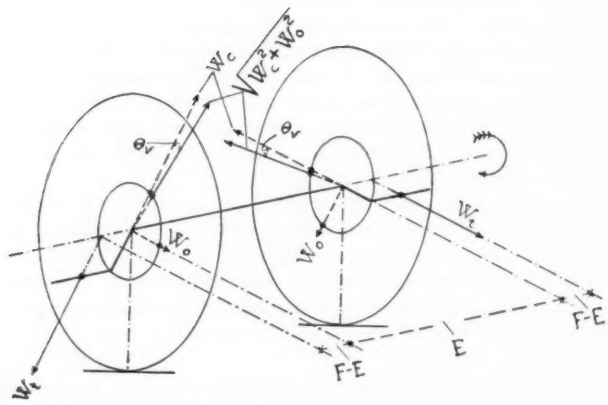

FIG. 2 PERSPECTIVE PROJECTION OF A WHEEL PAIR

have followed the Le Chatelier-Clark method as the only correct way of balancing locomotives. Locomotive builders of all countries except the United States adopted this method of counterbalancing. Some American books (11) also expounded the cross-balancing theory, although they did not recommend it for practical use. Consequently, in the United States the old method, called static balancing, in distinction from cross-balancing, sometimes called the dynamic balancing, is still in use on American railroads. In England, Professor Dalby (12) developed very convenient graphical charts for cross-balancing, which are now frequently used when cross-balancing is wanted. It is not amiss to mention here that the term "static balancing" is a misnomer and is misleading. In a moving locomotive there can be only one kind of balancing, that is, dynamic. What is meant to imply by these two terms, static and dynamic, is that the first is the balancing of forces while the other is the balancing of forces and couples. For a locomotive with forces in different planes, only balancing of forces and couples is complete. The balancing of forces alone is incomplete and, strictly speaking, cannot be considered balancing at all, although in some cases it may be sufficient and useful for locomotives. However, in this paper the old terms will be used for the sake of tradition.

The situation has been changed lately in the United States in view of the fact that the increase in size and power of steam locomotives, and especially in speed, and their effect on the maintenance of both locomotives and roadbed, called for a revision of the American practice. Several very valuable papers have been presented and discussed in various engineering societies, including those by Eksergian (13), Fry (14), and Riegel (15), the last of which recommended cross-balancing for the main wheels as the method for balancing locomotives, thus modifying A.A.R. previous recommendation (1915) for static balancing of all driving axles of locomotives. At present the recommendation of cross-balancing was incorporated in the A.A.R. Manual for 1938 (16) and has become the practice on some, not all, American railroads for high-speed locomotives.

The author believes that the reason for such a delay in adopting the universal practice of cross-balancing is probably due to the fact that for American locomotives, cross-balancing was not so important. After all, for the heavy-weight and long-base American locomotive, complete balancing was not necessary, especially for moderate speeds, and the practice which has been used for years was satisfactory. When the proper time came, the scientifically correct cross-balancing method was resorted to, after the more simple static method of balancing, requiring practically no mathematics, outlived its usefulness. Fry (14) should be complimented for using simple arithmetic instead of elaborate mathematics. If properly applied, the counterbalancing method becomes very simple. Leaving out for the present the counterbalancing of reciprocating weights and limiting ourselves to the balancing of revolving weights only, the cross-counterbalancing is fully represented in Figs. 1 and 2 and the mathematics can be easily evolved, following Fry's (14) or the A.A.R. Manual (16) formulas.

In Figs. 1 and 2 W_c, in agreement with the Manual, is the resultant of all equivalent revolving weights of one side of the wheel, actuating in different planes, and reduced to the plane of the counterbalance of the adjacent side; W_t is the total sum of the actual (not equivalent) revolving weights on one side of the wheel; $W_o = W_c - W_t$ is the component of all equivalent revolving weights on one side of the wheel, actuating in different planes and reduced to the plane of the counterbalance in the wheel of the opposite side; and θ_v is the offset angle, the tangent of which is equal to the ratio

$$\frac{W_c - W_t}{W_c} = \frac{W_0}{W_c} = \frac{F - E}{F}$$

where F and E are distances between planes of revolving weights and counterbalances as shown in Figs. 1 and 2.

The mathematics can be replaced by simple vectorial charts, such as shown in Figs. 3 and 4, which Dalby (12) so elegantly worked out. Fig. 3 is a diagram of moments of centrifugal forces

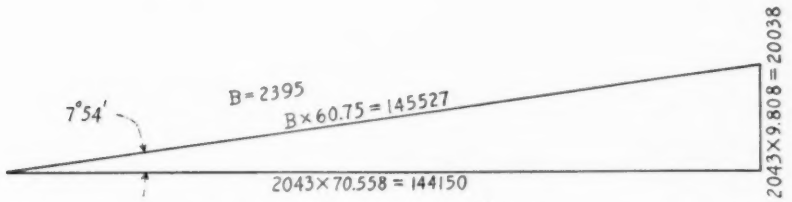

FIG. 3 DALBY'S VECTORIAL DIAGRAM OF MOMENTS

referred to the plane of one counterbalance, while Fig. 4 is a diagram of centrifugal forces themselves. In both cases the forces are, for convenience, replaced by weights, reduced to the crank radius, and the magnitudes of revolving weights so reduced, or their moments, are drawn in the direction of their centrifugal action. The reader is referred to Dalby's book (12) for particulars. Figs. 3 and 4 determine the magnitude of the counterbalances and of the offset angle.

It should be noticed that in all cases, whether with inside or outside cylinders, with the right-hand crank leading or trailing, the offset angle on one wheel is always turned to the crankpin of the wheel on the opposite side (see Fig. 12); in other words, the two wheel centers of one axle (right and left) should be cast from one pattern.

The author has no intention of going over the ground already covered by Eksergian (13), Fry (14), and Riegel (15); therefore, if the author takes the liberty of discussing this question again, it is simply for the reason that one point has been left by these authors (13, 14, 15) unanswered, namely, the balancing of the reciprocating weights.

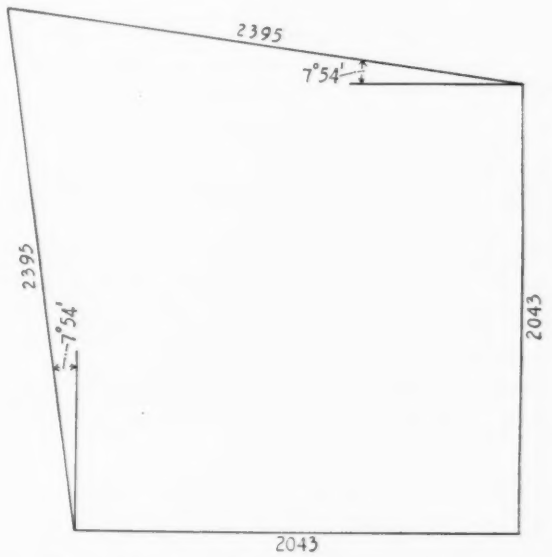

FIG. 4 DALBY'S VECTORIAL DIAGRAM OF FORCES

THE PROBLEM OF BALANCING RECIPROCATING WEIGHTS

The cross-balancing of revolving weights is an exact way of balancing; in other words, when a wheel pair is properly counterbalanced as a unit, the revolving weights (pins, crank hubs, side rods, eccentric cranks, and a part of the main and eccentric rods) are completely balanced by revolving counterbalances in accordance with the rules of dynamics. Such a wheel pair, if properly manufactured, should give no disturbing forces of any kind when rotated, even at high speed. The difficulty begins only when the reciprocating weights, consisting of pistons, crossheads, main rods, eccentric rods, also have to be considered.

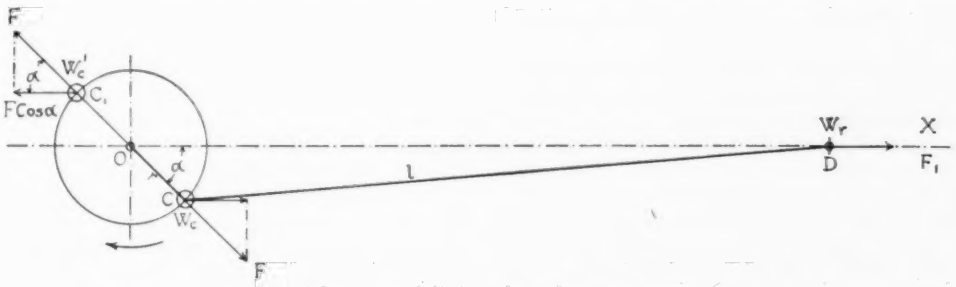

FIG. 5 INERTIA FORCES OF A ROD-CRANK MECHANISM

Propositions for balancing these weights by counterweights with oppositely directed reciprocating motion, so-called "bob weights," have been suggested at various times for reciprocating engines (17). Other suggestions, consisting of several shafts rotated at various speeds (18), have been made for automobiles and engines for cars (19), but none of these propositions have found any extended application in practice. As a result, the present universal way of balancing reciprocating weights in locomotives is by revolving weights only, built as counterbalances in driving wheels. As the reciprocating weights are producing horizontally directed forces of inertia (strictly speaking, forces in the direction of the cylinder axes), they can be balanced by horizontal components of centrifugal forces of revolving balances. These will be in addition to the counterbalances which are required for balancing the revolving weights. There will remain naturally unbalanced vertical components of the balances for reciprocating weights which act in a locomotive as disturbing forces and which cause what is known as "hammer blow" of rotating counterbalances, injurious to the track and bridges.

A few simple mathematical formulas will clarify the matter. Referring to Fig. 5, let OC be the crank of a length r, which makes an angle α with the cylinder axis X, assumed to be positive from center O to the right in the direction of the arrow. Let CD be the main rod of length l. Assume that angle α is positive in the clockwise direction of the rotation of the wheel. The centrifugal force F, in lb, of a revolving weight W_c, in lb, attached to pin C is equal to

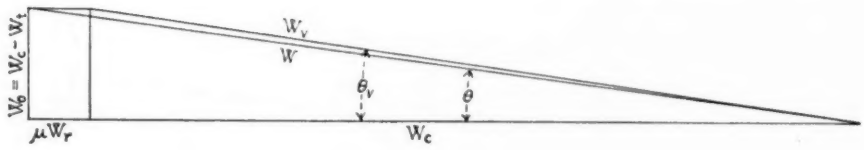

FIG. 6 DIAGRAM OF ANGLING IN LOCOMOTIVE DRIVING WHEELS

$$F = \frac{W_e}{g} r\omega^2 \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where r is the crank radius, ft; ω is the rotating speed of the wheel, radians per sec; and g is the acceleration of gravity, equal to 32.2 ft per sec per sec. It can also be expressed

$$F = 0.0000284\ W_e r n^2 \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

where n is in revolutions per minute and all other notations are the same as given previously, except r which is expressed in inches.

At diameter speed, i.e., at a speed of as many miles per hour as the driving wheels (tires) have inches in diameter (of rolling circumference), the rotating speed $\omega = 35.17$ radians per sec, and $n = 336$ rpm. The centrifugal force lies on the prolongation of the crank radius and is directed from center O.

If a reciprocating weight W_r were attached to the small end of the rod in D, its inertia force, if the rod may be considered of infinite length, or $r/l = 0$, would be

$$F_1 = \frac{W_r}{g} r\omega^2 \cos\alpha \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

In the dead center, when $\alpha = 0$, force $F_1 = F$; in all other positions, when α is different from 0, the inertia force is less than F. It may be seen, from a comparison of formulas [1] and [3], that in all cases the inertia force F_1 is the horizontal projection of the centrifugal force.

Further, it is evident that if a weight W_e' is placed in C_1 opposite to C, in the same vertical plane, and at the distance r of the radius crank from the center O, its centrifugal force will balance centrifugal force F of weight C_1 if these two weights, as the case always is in locomotives, will rotate at the same speed. On the other hand, the horizontal component of the counterweight will balance the inertia force of a reciprocating weight of the same mass, if the revolving counterweight and the reciprocating weight are connected by a crank-and-rod mechanism. This is the principle of balancing reciprocating weights in a locomotive.

It is now evident that the vertical component of the counterweight remains free. While the horizontal component can be taken up by the inertia force of the reciprocating weight, there is nothing to cancel the vertical component. This force, remaining free, exerts a vertical blow on the rail in the plane of the balance. Its maximum value is attained twice every revolution: First, when the counterweight is in its lowest position and the component is directed downward and acts as a blow on the rail, and second when the counterweight is in its highest position and the component is directed upward and has a tendency of lifting the wheel. Thus, this method of balancing reciprocating weights by a revolving balance, while very simple and effective, bears in itself an evil and, therefore, a compromise is necessary.

Shortly after the balancing of reciprocating weights was recognized, Crampton in the middle of the last century built a number of locomotives with total (100 per cent) balancing of reciprocating parts. These locomotives seemed to have very good riding qualities; consequently, they were very popular for a short while in England and on the continent of Europe. However, after several derailments with casualties, the effect of the hammer blow and the vertical disturbing force were taken notice of and, in order to diminish the effect of these forces, the partial balancing of reciprocating weights has become universal practice on locomotives, and has been so ever since. For a long time, following the Crampton mishaps, the percentage of balancing had been reduced to $66^2/_3$ per cent, meaning that two thirds of the reciprocating weights were balanced. This practice was followed in Europe in conjunction with cross-balancing of revolving weights, and also in America, with the difference that here only static balancing of revolving weights was made. Sometimes in America, following Henderson's suggestion, another figure, $^1/_{400}$ of the total weight of the locomotive, was taken as the part of reciprocating weights to be left unbalanced. This rule is now not being followed.

For European countries, in accordance with the Middle-European Technical Agreement, the following rules are being observed at the present time:

1 All revolving weights are totally balanced (i.e., cross-balanced) as much as possible.

2 From 25 to 60 per cent of reciprocating weights are balanced, depending upon the length of the wheel base and its relation to the total length of the locomotive. In modern long and heavy locomotives it is usually as low as 15 per cent.

3 Dynamic augment on each driving wheel should not exceed 15 per cent of the static weight on that wheel. This rule is strictly observed on a good many European railroads.

Moreover, the practice of figuring the counterbalance is also different from ours—the weight to be balanced is assumed to be in the plane of the cylinders and this amount is added to the corresponding revolving weight; in other words, the reciprocating weights are also cross-balanced.

In this country the opinion as to cross-balancing of all revolving weights and balancing of reciprocating weights is only now being crystallized. Eksergian seems to be in favor of cross-balancing revolving weights on all drivers, although in conclusion 2 of his paper he states: "In view that no gain is effected in cross-balancing for the reciprocating parts alone, the static balance of coupling drivers is permissible" (13). Fry is very definite in his negative attitude, when he states: "Cross-balance is therefore not necessary for the overbalance of the reciprocating parts" (14, p. 436); so is Riegel in his report (15), and the A.A.R. Manual (16) in recommending the counterbalancing of main wheels only.

As to the balancing of reciprocating weights, all three American papers (13, 14, 15) recommend the static method, which consists of adding algebraically that portion of the reciprocating weights per wheel W_r which is to be balanced (μW_r) to the revolving-balance component W_e before the component from the other side $W_0 = W_e - W_t$ is added geometrically, as shown in Fig. 6. Thus, the reciprocating balance μW_r is directed opposite the crank radius ($\theta_r = 0$) in the plane of the balance, and the resultant offset angle θ is slightly different from θ_v, the offset angle of the revolving parts alone. The reciprocating balance per wheel μW_r is now recommended by the A.A.R. Manual to be chosen so that the total for all axles is nearer 30 per cent of the reciprocating weights of one side of the locomotive when cross-balancing of revolving weights is applied, which is equivalent to 50 per cent

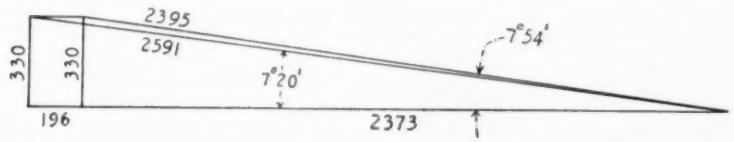

FIG. 7 DETERMINATION OF ANGLING IN A LOCOMOTIVE DRIVING WHEEL, WITH STATIC BALANCING OF RECIPROCATING WEIGHTS

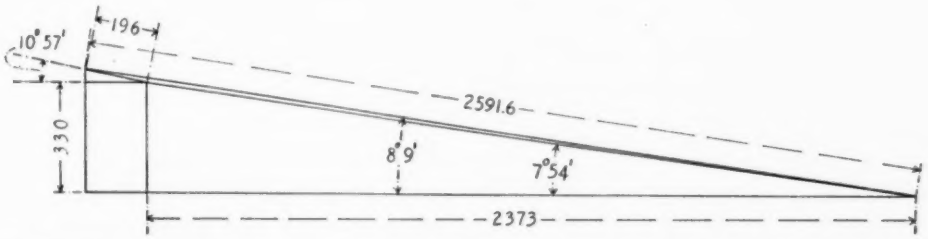

FIG. 8 DETERMINATION OF ANGLING IN A LOCOMOTIVE DRIVING WHEEL, WITH CROSS-BALANCING OF RECIPROCATING WEIGHTS

of the same weights when the 1915 A.A.R. static method of balancing was in use (20). In application to a modern locomotive, for which a Dalby diagram of revolving cross-balancing is shown in Figs. 3 and 4, the addition of the reciprocating balance would be as shown in Fig. 7. In this case the locomotive has three drivers. The weight of reciprocating parts on one side is 1681 lb, and the selected percentage for this locomotive (35 per cent) amounts to a reciprocating balance per wheel of $\mu W_r = 196$ lb. According to the A.A.R. Manual this vector should be added to component $W_c = 2373$ lb of the revolving cross-balance in the direction of the radius crank. Adding at a right angle the component of the other side $W_0 = 330$ lb, we shall get the total cross-balance $W = 2591$ lb at an offset angle of 7 deg 20 min, instead of a balance $W_v = 2395$ lb at an angle of 7 deg 54 min, for total balancing of revolving weights alone. All these balances are referred to the crank radius; in this case, $r = 15$ in.

If the reciprocating weights were also to be cross-balanced, the principle of the method remains, as shown in Figs. 1 and 2. The reciprocating balance would not be placed opposite the crank radius, since $\theta_r \neq 0$. Remembering that the reciprocating weights are in the cylinder plane, the offset angle for the reciprocating balance should be

$$\tan \theta_r = (F - E)/F \quad [4]$$

where F is the distance from the cylinder plane on one side of the locomotive to the counterbalance plane on the other side, and E is the distance between counterbalance planes.

For the modern locomotive, which we have been considering, $E = 61.5$ in., $F = 76.25$ in., and

$$\tan \theta_r = \frac{76.25 - 61.5}{76.25} = 0.1934$$

or

$$\theta_r = 10 \text{ deg } 57 \text{ min}$$

The correct cross-balance angling for the reciprocating weights for the main wheel would, therefore, be as given in Fig. 8. The offset angle of the whole balance would be slightly greater, namely, 8 deg 9 min, compared with 7 deg 20 min, as obtained in Fig. 7, but the total balance will be about the same, namely, 2591.6 lb, as against 2590.6 lb for the case of the static balancing of the reciprocating weights. The dynamic augment at diameter speed will also be the same, that is, 9408 lb, because the revolving weights are completely balanced, and only the centrifugal force of the reciprocating balance of 196 lb gives the blow in either case. The direction of the blow is slightly different in the case where the static balance is just opposite the pin; in the cross-balancing case it is 8 deg 9 min later or sooner, depending on the side—right or left. Due to the predominance of the revolving cross-balances and the smallness of the reciprocating balance, the difference in these phenomena is negligible, but in the percentage of actual balancing for the reciprocating weights the difference is considerable, as we shall presently see. In the foregoing example it is 28 per cent, instead of 35 per cent as assumed.

PERCENTAGE OF CROSS-BALANCING RECIPROCATING PARTS

This phase can be better demonstrated on the foregoing example of a 4-6-4 locomotive, which was specially studied. Curve X in Fig. 9 shows the effect of the inertia forces of all reciprocating weights (1681 lb actual weight on each side) in a counterbalance plane of one side, say A, and curve Y in the counterbalance plane of the other side, say B; in other words, referring to Fig. 10, Fig. 9 shows the horizontal reactions X and Y in the planes of counterbalances A and B as a result of two forces of inertia F_1 and F_2 on both sides. Curve A in Fig. 9 is the centrifugal force of a revolving counterbalance, in the same plane A, of a magnitude of 196 lb in order to insure the same dynamic augment as in the case of static balancing. The reciprocating balance is properly angled at 10 deg 57 min according to the rules of cross-balancing, although the total angling of the whole balance is only, as we have seen previously, 8 deg 9 min. Curve B shows the remaining unbalanced force of inertia (shaded area).

The inertia forces of reciprocating weights are usually assumed to be as determined from formula [3], which is approximately correct, and is precisely true when the ratio $r/l = 0$. In our locomotives r/l is about 1/8, and the inertia forces are about 12 per cent more in the front dead center, and 12 per cent less in the back dead center, than the centrifugal force of the same mass at the crankpin. In other words, formula [3] should be replaced, for the sake of accuracy, by

$$F_1 = \frac{W_r}{g} r\omega^2 \left(\cos \alpha_0 + \frac{r}{l} \cos 2\alpha_0 \right) \quad [4]$$

where α_0 is the angle of the right-hand crank.

Fig. 9 was drawn for the case $r/l = 1/8.6$ and to formula [4]. The forces of inertia, their distribution, and balancing by a balance of 196 lb have been accurately figured.

Fig. 11 gives similar curves for the case $r/l = 0$ and also for cross-balance of 196 lb at $\theta_r = 10$ deg 57 min. As can be seen, the difference in the curves is negligible. As practically only counter-

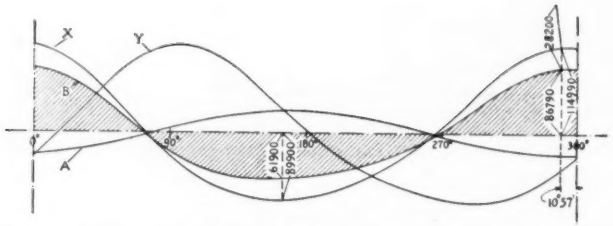

FIG. 9 INERTIA REACTIONS OF RECIPROCATING WEIGHTS, PARTIAL BALANCING; FINITE ROD

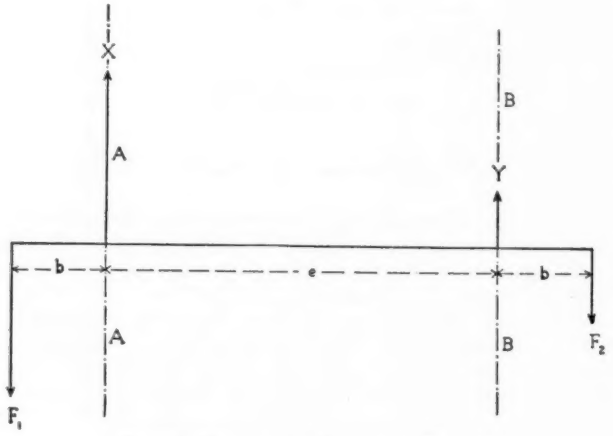

FIG. 10 DIAGRAM OF PLANES OF FORCES

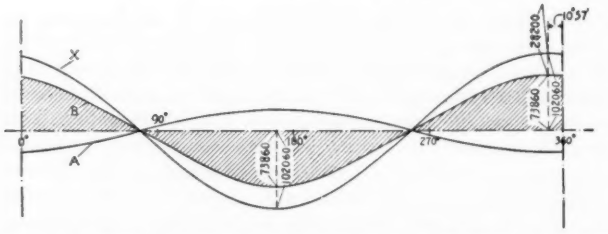

FIG. 11 INERTIA REACTIONS OF RECIPROCATING WEIGHTS, PARTIAL BALANCING; INFINITE ROD

balances for the primary forces of inertia, which result from the simple harmonic motion of the piston, assuming $r/l = 0$, can be built in a locomotive, we might, therefore, forget the more accurate formula [4]. The secondary forces of inertia, which result from the finity of the main rod cannot be balanced even in a four-cylinder locomotive. They would require counterbalances with a complicated motion and are impracticable. The study made in Fig. 9 had the object of ascertaining the error due to neglecting the finity of the main rod. It was thought that by changing the offset angle and the counterbalance some compromise could be found.

The percentage of balancing can be figured as the ratio of ordinates of curves A and X in Fig. 9. If the average of the ratios of the maximum and minimum ordinates in Figs. 9 and 11 be figured, the percentage of balancing for the locomotive taken as an example, is 27.6 for both cases. More accurately, this can be done by planimetering the areas below curves A and X and figuring their ratios. It then comes out 28.2 and 28.9 per cent for Figs. 9 and 11, respectively, indicating that it is not necessary to pay much attention to the finity of main rod for the sake of counterbalancing.

Curves have also been drawn for the same inertia reactions, but for counterbalances set at $\theta_r = 0$, opposite to the crank radius, as required by the A.A.R. Manual. The percentages for these cases were also 28.2, when $r/l = 1/8.6$, and 28.9 for $r/l = 0$, that is, for an infinite rod. This confirms the previous opinion that consideration of the length of the rod has little influence on the question of counterbalancing. In all cases the actual percentage of balancing the reciprocating forces was about 28 per cent, and in no case did we get a balancing of 35 per cent.

Thus, there is no justification for taking the percentage of balancing simply as the ratio of reciprocating balances to the reciprocating weights $(3 \times 196)/1681 = 0.35$, even after the cross-counterbalancing effect of the deficiency in balancing has been accounted for, because the actual balancing, no matter what method of figuring is used, is much lower.

This brings us to another and most important point: What percentage of balancing reciprocating weights should be used?

The object of balancing the reciprocating weights is, of course, to reduce the parasitic motions of a locomotive, of which there are as many as a free suspended body on springs may have, namely six. In a modern locomotive on good track only two need be considered, especially from the point of view of counterbalancing; these are (*a*) nosing, which is the rotation of a locomotive around a vertical axis through its center of gravity, and (*b*) the to-and-fro movement of a locomotive in the direction of its longitudinal axis. Both are caused by the unbalanced forces of inertia acting along the cylinder axes. First (nosing) is the result of a couple tending to rotate the locomotive around the vertical axis; second (to-and-fro movement), is the direct result of the application of these forces.

When a locomotive runs on a track having clearances between the rails and the flanges of the tires and, consequently, having some lateral freedom, a pure to-and-fro movement is impossible. The actual movement is a result of both nosing and the longitudinal translation of the locomotive. In any case, the inertia forces exert a couple effect which becomes apparent mainly in nosing. Therefore, to ignore the couple effect of the inertia forces, as if the locomotive were restrained laterally, is not right. When Henry, chief mechanical engineer of the French P.L.M. Railway, attempted in 1889–1890 to study the parasitic motion of a locomotive separately, he suspended a locomotive from the top and supported it by six horizontal springs laterally to restrict the movement of the locomotive sidewise (21). This, of course, is a special condition to which he was driven in order to omit the natural couple effect when he wanted to study the to-and-fro movement of the locomotive, but such a restraint does not exist in locomotives in service.

We can understand why Crampton attempted to obtain total balancing of reciprocating weights. This reduced the parasitic movements of his locomotives, but this reduction had also other effects. For practical reasons a compromise had to be made, and $66^2/_3$ per cent of balancing had been considered for a locomotive as standard for a long time. This was further reduced, until now it is much less.

We can easily see the reasons for this trend in the evolution of the steam locomotive. The power and the reciprocating weights of two-cylinder locomotives have gone up tremendously since the time of Crampton; also, the rotative speed of the wheels has increased. Consequently, the dynamic augment, notwithstanding the refinements in design of reciprocating parts, called for heavier rails, and this, in many cases, has reached the limit. Simultaneously, the locomotives have grown heavier, the rigid base longer, the moment of inertia of the locomotive has become greater, and the guiding resistance of the leading and rear trucks has become better adjusted to the service, requiring a smaller effort on the part of the guiding wheel to turn the locomotive. The riding qualities of the locomotive have improved, the importance of the unbalanced forces has decreased in value, and the percentage of balancing the reciprocating weights could

have come down without impairing the riding qualities of the locomotives. At the same time, a better understanding of the counterbalance problem, cross-counterbalancing being an example, kept pace with these developments, and permitted the industry empirically, by the method of trial and error, to achieve practical solutions.

Let us see what percentages of balancing we find in locomotives which have been running satisfactorily at high speeds on American roads, some of them for years.

A 4-6-4 locomotive with 79-in. driving wheels has been in service on one road since 1927, with maximum speeds up to 90 mph. The locomotives were originally balanced by the old static method; consequently, there was a deficiency in the balance of the main driving axle to an extent that instead of a calculated static overbalance of 271 lb per driving wheel, a dynamic overbalance of only 6 lb was attained. Likewise, on the coupled axles, overbalances of only 191 lb on the front and 190 lb on the back wheel were actually obtained, instead of 221 and 218 lb, respectively. Thus a total of

$$\left(\frac{191 \times 61\frac{1}{2}}{74\frac{3}{4}} + \frac{6 \times 61\frac{1}{2}}{75\frac{1}{4}} + \frac{190 \times 60\frac{1}{2}}{74\frac{3}{4}}\right)\frac{1}{1791} = 0.175$$

or 17.5 per cent of balancing reciprocating parts was obtained instead of expected balancing of

$$\frac{221 + 271 + 218}{1791} = 0.396 \text{ or } 39.6 \text{ per cent}$$

when using the static method of balancing of both the revolving and reciprocating weights.

The actual dynamic augments at diameter speeds are: 8550 lb on the front wheels, which is 28.2 per cent of the static weight; 269 lb on the main wheels, which is 0.9 per cent of the static weight; and 8500 lb on the back drivers, which is 28 per cent of the static weight. These values compare with a dynamic augment of 12,160 lb on the main drivers, calculated by the static method. After operating this 4-6-4 locomotive for several years, the railroad cross-balanced a great number of this type, making the actual percentage of balancing the reciprocating weights 28.6, but up to this conversion the locomotives ran with only 17.5 per cent balancing.

In a locomotive of the 4-4-2 type, which was cross-balanced, the reciprocating balance per wheel was made 173 lb and the total reciprocating weights on one side of the locomotive were 988 lb. Taking the averages for the distances of different axles, the percentage of balancing is approximately

$$\frac{173 \times 2 \times 63\frac{1}{8}}{70\frac{11}{16}} \times \frac{1}{988} = 0.312, \text{ or } 31.2 \text{ per cent}$$

The dynamic augment at diameter speed is 7750 lb per driver, or 21.5 per cent of the static weight.

This locomotive is known for its outstanding riding qualities and for its quiet running at high speeds, thus proving that 31.2 per cent of balancing reciprocating weights should not be considered excessive.

In a 4-6-4 locomotive, built about a year ago, the percentage of balancing reciprocating weights is

$$\frac{136 \times 61}{73} + \frac{101 \times 61.5}{75\frac{1}{4}} + \frac{131 \times 61}{73} \times \frac{1}{1000} = 0.307 \text{ or } 30.7 \text{ per cent}$$

The dynamic augment at diameter speed is 6300 lb, or 9.6 per cent of the static weight per wheel.

In still another 4-6-4 recently built locomotive, which was used earlier in this paper as an example, the reciprocating balance per axle is 196 lb, and the total reciprocating weight on one side is 1681 lb. Thus the percentage, as already found from Figs. 9 and 11, is

$$\frac{196 \times 3 \times 61\frac{1}{2}}{76.25} \times \frac{1}{1681} = 0.282, \text{ or } 28.2 \text{ per cent}$$

instead of 35 per cent, as it was expected.

The dynamic augment at diameter speed is 9400 lb, or 13.1 per cent of the static weight per wheel.

It should be remembered that these locomotives are supposed to run at speeds of 90 mph and higher, and that their dynamic augments may be then about 30 to 50 per cent higher than at diameter speeds.

It should also be borne in mind that some modern, especially powerful, locomotives with small weight to power ratios are liable to slip at high speed, and that then the wheels may spin at rotative speeds much in excess of diameter speeds, sometimes 40 per cent higher, which would give a dynamic augment twice as great as that calculated herein by the author. For locomotives with such tendencies, it is advisable to make the reciprocating balances (overbalances) as small as possible, even if this should reduce the total percentage of balancing of reciprocating weights. The author does not know another alternative—either less percentage of balancing, or an increased dynamic augment.

The foregoing examples would tend to show us that from 20 to 30 per cent of balancing reciprocating weights above the cross-balancing revolving weights is permissible and conducive to quiet running. Although in one of the examples the locomotive has only two driving axles, the dynamic augment in this case is not excessive, that is, only 21.5 per cent of static weight per wheel (at diameter speed). In figuring counterbalance, the dynamic augment should always be watched, and for this figure alone, it is very essential to use the correct cross-balancing method for revolving and reciprocating weights, because otherwise the dynamic augment and the percentage of balancing reciprocating weights are not accurately known. Actually the dynamic augment is the first datum necessary to start intelligently the counterbalancing calculation, and then do it by the correct, which is the cross-balancing, method. No simplifications or saving a few hours of calculation can excuse manipulating with erroneous figures in such important a matter in the design of a locomotive as counterbalancing.

As to the reciprocating weights in modern high-speed locomotives, the numerical value of the reciprocating balances per wheel is rather small, although the damage which can be done at high speed may be very large. Tests have been made on some roads which indicated that the hammer blows at high speeds, and especially when the locomotive slips, may account for rail breakages, kinking of rails, and other phenomena which take place under these circumstances. Forced vibration of a locomotive wheel on a flexible roadbed, with its own natural frequency, would call for further study (22) and experimental research (23). That counterbalances have much to do with this problem can be learned from the experience of one road which, by reducing counterbalances on main wheels of a certain locomotive by 100 lb, eliminated the kinking and breaking of rails.

The question of slipping at high speeds would also need special attention. There are indications that there is a limit to power which can be transmitted to wheels on rails through the medium of adhesion, and that this phenomenon is different at high speeds from adhesion at low. This question should be of importance to both steam- and electric-locomotive builders, and has not yet been sufficiently studied (24, 25).

Suggestions

No conclusions are offered by the author as a result of the

above study, merely the following suggestions for further study of the problem are made.

1 For high-speed locomotives the correct evaluation of the dynamic augment is essential, and this should be done not only for the main wheel, but for the coupled wheels as well. The neglect to cross-balance the coupled wheels, when main wheels are cross-balanced, and more so, when statically balanced, introduces an irregular distribution of reciprocating balances, just contrary to the object of dividing the reciprocating balance equally among drivers.

2 There always is a certain piston thrust component on the main wheel, which is nonexistent on the coupled wheels. At high speeds and short cutoffs the component is small, but not negligible, and when the full piston thrust is as high as 140,000 lb, the component may be in the neighborhood of 10,000 to 12,000 lb. It is directed downward twice every revolution; and once, when the counterbalance is in the lower quarter, the angle at which the component takes place is not far from 90 deg to the horizontal. For this reason it is advantageous to have the main wheel angled for cross-counterbalancing, because then the hammer blow takes place at $\alpha = 90$ deg $+ \theta_v$, and these two blows (of the reciprocating balance and of the steam component) are spread apart.

This may also explain why cross-counterbalancing on some railroads, when introduced for the first time, caused rail breakages and was discarded. Locomotives with static balancing had in the past an actual deficiency in the dynamic action of wheel on rail and possibly no hammer blow at all. The effect of the piston thrust component was less, because instead of two blows in rapid succession per revolution, there was only one blow. When a cross-counterbalanced locomotive is placed in service for the first time on the road, these two blows might be sufficient to break a rail. It would be still better to have no counterbalance hammer blow at all and, therefore, to eliminate the reciprocating balance from the main wheels. This will also be helpful in case of the tendency of lifting the wheel from the rail at high speed.

There should be no misgiving about running a locomotive without reciprocating balance on one axle. Many locomotives with deficiencies in dynamic action had practically no counterbalance in the main wheel, and sometimes even a negative balance. They have been running for years at high speeds without an actual reciprocating balance on main wheels. In the author's first example of the 4-6-4 high-speed locomotive, the actual reciprocating balance in the main wheel was only 6 lb.

3 Although it does not make much difference whether we add the reciprocating balance exactly opposite the crank radius or at an angle θ_r in accordance with Fig. 8, it is better for the sake of uniformity and correctness to cross-balance the reciprocating weights. Especially, it is essential for figuring the percentage of balancing of these weights by taking into account the difference in planes, which is the principle of cross-counterbalancing. Moreover, as far as calculation is concerned, it is simpler to cross-balance the reciprocating weights on the main wheel than not to. For instance, when the A.A.R. Manual rule is followed and the revolving weights have been cross-balanced, it is necessary to find, first, the offset angle for the revolving weights θ_v; second, to add a static reciprocating balance to one component, as shown in Fig. 7; and, third, to add geometrically the component W_0 from the other side, shown in Fig. 6. This will determine the final θ, which should take the place of θ_v. When the reciprocating weights are also cross-balanced, the calculation can be made either by following Fig. 8, which does not add any work to the previous procedure, or by including in the calculation of the revolving balance the reciprocating balance per axle W_r adding this to the weights in the center plane of the cylinder. The total weight of the counterbalance W and the offset angle will then be directly determined.

Another alternative for the calculator would be to add the reciprocating balance to the revolving balance vector —196 lb at 7 deg 54 min (Fig. 8) instead of 10 deg 57 min in the same example; thus, making $\theta = \theta_v$, which is approximately correct.

Examples of Cross-Balancing Computations

As an illustration, the following calculation is given for the cross-balancing of a 4-6-4 locomotive, which in this calculation has no reciprocating balance on the main wheel and about 17.8 per cent balancing of reciprocating weights in the remaining wheels:

We shall start, as it was stated previously, from the dynamic augment. According to formula [2] the centrifugal force of a weight W_r is equal to

$$F = 0.0000284 W_r r n^2 \quad \text{[2a]}$$

where F is force, lb; W_r is weight in reciprocating balance (overbalance), lb; r is radius of crank, in.; and n is the driving-wheel

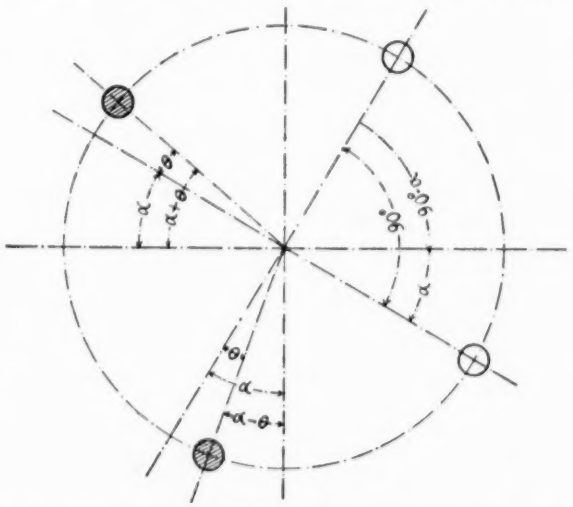

Fig. 12 Diagram of Offset Angles When Locomotive Is Cross-Balanced

speed, rpm. For this 4-6-4 locomotive, $r = 15$ in. and n, at diameter speed, is 336 rpm, thus, the formula is

$$F = 48.4\ W_r$$

Assume first that from previous experience with locomotives of this type and dimensions, or from a special study of the locomotive characteristics, we know that the locomotive will have no tendency to slip. In this case we may take the permissible dynamic augment as 25 per cent of the static weight per wheel. If the weight of this locomotive per axle is 72,000 lb, the dynamic augment for all driving wheels, except the main, i.e., the front and back wheels, can be made $36{,}000 \times 0.25 = 9000$ lb, assuming that there will be no reciprocating counterbalances on the main wheels. From the foregoing formula, we can easily find the overbalance W_r; thus, $9000 = 48.4 W_r$, or $W_r = 186$ lb.

As the locomotive is supposed to run occasionally at 100 mph, we might wish to check the dynamic augment at that speed as compared with diameter speed. The dynamic augment is $9000 \times (100/84)^2 = 12750$ lb, or $100(12750/36000) = 35.4$ per cent of the static weight, which is not excessive.

Now we can figure the percentage of balancing. From the

design of the parts of this locomotive we know that the reciprocating weights on one side of the locomotive are 1681 lb, and that the ratio of the distance F (from the center line of the cylinder to the balance plane on the other side) to the distance E (between the center planes of the balances) is 1.24. The percentage of balancing will be $100[(2 \times 186)/(1681 \times 1.24)] = 17.8$ per cent, which is sufficient.

The calculation of the main-wheel cross-counterbalance (without reciprocating balance), following the A.A.R. Manual (20) and its notations, is as follows:

W_1 = weight of the crankpin hub with included part of crankpin = 383 lb

W_2 = weight of the side rods with included part of crankpin = 750 lb

W_3 = weight of the back end of the main rod with included part of crankpin = 779 lb

W_4 = weight of part of the eccentric crank and the eccentric rod with included part of crankpin = 131 lb

W_t = actual weight of revolving parts = $W_1 + W_2 + W_3 + W_4 = 383 + 750 + 779 + 131 = 2043$ lb

$$W_c = \frac{(383 \times 61\,1/8) + (750 \times 67\,3/4) + (779 \times 75\,7/8) + (131 \times 82\,9/16)}{60\,3/4}$$

$$= \frac{144150}{60\,3/4} = 2373 \text{ lb}$$

$$W_0 = W_c - W_t = 2373 - 2043 = 330 \text{ lb}$$

The total balance will be $W_b = \sqrt{(2373^2 + 330^2)} = 2395$ lb, and the offset angle, as shown in Fig. 7, will be 7 deg 54 min.

For the front coupled axle the calculations are as follows:

W_1 = weight of the crankpin hub with included part of crankpin = 255 lb

W_2 = weight of part of the side rod with included part of crankpin = 257 lb

W_3 = part of the reciprocating weights to be balanced = 186 lb

$W_t = W_1 + W_2 + W_3 = 255 + 257 + 186 = 698$ lb

$$W_c = \frac{(255 \times 61\,1/2) + (257 \times 67\,7/8) + (186 \times 75\,7/8)}{61\,3/4}$$

$$= \frac{47239.13}{61\,3/4} = 765 \text{ lb}$$

$$W_0 = W_c - W_t = 765 - 698 = 67 \text{ lb}$$

The total balance will be $W = \sqrt{(765^2 + 67^2)} = 768$ lb, and for the offset angle, $\tan \theta_1 = 67/765 = 0.08758$, or $\theta_1 = 5$ deg 1 min.

Likewise, for the back driving axle, $W_1 = 263$ lb, $W_2 = 309$ lb, $W_3 = 186$ lb, and $W_t = 263 + 309 + 186 = 758$ lb. Also

$$W_c = \frac{(263 \times 61\,7/8) + (309 \times 68\,3/4) + (186 \times 75\,7/8)}{62\,1/4}$$

$$= \frac{51604}{62\,1/4} = 829 \text{ lb}$$

and

$$W_0 = W_c - W_t = 829 - 758 = 71 \text{ lb}$$

The total balance $W = \sqrt{(829^2 + 71^2)} = 832$ lb. For the offset angle, $\tan \theta_2 = 71/829 = 0.08565$, or $\theta_2 = 4$ deg 54 min.

However, if some precedents, or a study of tractive-effort characteristics lead to the suspicion that the locomotive might slip at high speed, it is advisable to cut the reciprocating balance. In other words, assuming that the speed of spinning may go up to 141 per cent of diameter speed, as is the case usually, the reciprocating balance should be halved, if we want to retain the same dynamic augment. In the foregoing example it should be made $186/2 = 93$ lb.

The percentage of balancing will be then reduced, but after what we have seen it would do no great harm. When larger percentage of balancing reciprocating weights is desired, greater dynamic augment must be allowed and the roadbed strengthened accordingly.

Discussion

T. V. BUCKWALTER[3] AND O. J. HORGER.[4] One of the main disadvantages of the conventional two-cylinder steam locomotive over some other forms of power is the inability to properly balance the reciprocating weights. The usual heavy weight of reciprocating parts and the use of conventional balancing methods penalize both the track and locomotive in that the dynamic stresses are increased and the riding characteristics of the locomotive leave much to be desired.

This problem becomes of such major importance because of the weight in pounds of the reciprocating parts. Since the reciprocating parts may never be completely balanced the practical solution to this problem would be the reduction of reciprocating weight. Road experience is available on about sixty high-speed passenger locomotives, where the weight of reciprocating parts is reduced, so that it is only about one half of the conventional weight. These applications have permitted both a considerable reduction in dynamic augment as well as a reduction of the shaking forces.[5] In this respect these lightweight reciprocating parts will better permit the use of much lower reciprocating overbalance than is now the practice. This is in keeping with the recommendations of the author.

The author discusses in considerable detail the beneficial influence of reducing overbalance in order to produce less dynamic augment, but little is said about the effects of the unbalanced portion of the reciprocating weights which determines the shaking forces. These shaking forces, causing (*a*) fore-and-aft motion and (*b*) turning moment of the engines on the rail, are reflected in track and locomotive maintenance and locomotive riding. The tangible dollar value of any reduction in shaking forces as it influences reduced maintenance is unknown, but tests have been made where the overbalance was reduced to such a point that the increased shaking forces produced a rough-riding engine. In some cases this roughness was reflected in the riding of the first few cars of the train. Just where the dividing line exists for the proper selection of allowable shaking forces for minimum track and locomotive maintenance has never been fully appraised. For these reasons, it is difficult to understand how the author proposes to approach zero overbalance or to bring American practice within the European limitation of dynamic augment, in order not to exceed 15 per cent of the static weight on the wheel and, at the same time have a favorable condition of shaking forces, without coming to the conclusion that a considerable reduction must be made in weight of reciprocating parts.

The existing method of balancing does not give consideration to the proper division of back- and front-end weight of the main rod as to how much should be considered as rotating and how much as reciprocating weight. Ordinarily the scale-pan weight of the back end of the main rod is considered as rotating and is so balanced. Actually the division of the main-rod weight into rotating weight and reciprocating weight cannot be properly made, unless the moment of inertia of the rod about the center line of the crosshead pin bore is known. This may be determined experimentally by swinging the rod as a pendulum. The result is that a larger overbalance exists than is calculated by the usual procedure, by an amount of about 80 to 130 lb in the counterbalance plane at the crankpin radius, as determined by pendulum tests on several designs of rods investigated. Obviously this introduces a considerable percentage of error, especially so when a low overbalance is already used. Consideration of this error at diameter speed increases the dynamic augment by 4000 to 5000 lb over what is conventionally calculated. There are, however, a few designs of main rods having heavy back ends which minimize this error over that found on conventional rod designs.

The author cites an example of a 4-6-4 locomotive with 79-in. driving wheels as having been in road service since 1927 with maximum speeds up to 90 mph. It is stated that the original static balance of 271 lb per driving wheel calculates dynamically as actually being only 6 lb overbalance. The author then gives the dynamic augment on main wheels as actually being 296 lb instead of the previous 12,160 lb obtained by static method. While the full details of this engine are not given, it is known that in cases of a similar nature the dynamic augment opposite the crankpin is considerably reduced when cross-counterbalancing methods of calculation are applied to engines balanced statically. The writer wishes to indicate, however, that the maximum dynamic augment on statically balanced drivers invariably does not occur in a position nearly opposite the crankpin because of the great effect of the unbalanced component from the opposite wheel. For this reason the question is being asked if such consideration was given in the example submitted by the author.

Forced vibrations of locomotive driving wheels on a flexible roadbed are only briefly mentioned by the author as being subjects for study and research. This phase of locomotive operation will become increasingly important as speeds are increased and will be equally as important in the future as dynamic augment and shaking forces. Even at existing operating speeds, such forced vibrations have required rebalancing and reduction in overbalance in order to prevent wheels leaving the rail in a vertical direction, which has resulted in considerable rail damage.

In order to study this subject further, tests were made where six different kinds of locomotives were slipped at high speeds. It was shown conclusively that the phenomenon of forced vibration does exist and that the main pair of driving wheels leaves the rail at a speed much lower than would be indicated only by a consideration of the inertia forces. This study was made with high-speed moving-picture cameras. The results of tests will be shown before the New York and Chicago Railway Clubs.

Here again in order to overcome this vibration phenomenon it will be found that, unless the weight of reciprocating parts is considerably reduced, while at the same time lower overbalances are used to prevent rail damage, the increased shaking forces will leave an undesirable effect on locomotive and track.

The slipping mentioned by the author may in some cases be attributed to vibrations and/or as a result of large variation in rail pressure developed by large overbalance weights. The unbalanced portion of the reciprocating weight is also believed to contribute to slipping.

The author refers to the piston-thrust component, existing on the main wheel, but does not mention a similar component which also exists as a result of the inertia of the reciprocating parts. Neither of these components varies according to a sine law but, neglecting this, their frequency is twice that of the dynamic augment, so that their effect in causing vibrations is of much less importance than that of the dynamic augment.

R. EKSERGIAN.[6] The counterbalancing of reciprocating parts is necessarily a compromise as to the permissible unbalance in the plane of reciprocation and the allowable dynamic loading at the rail. The disturbing factors causing poor riding of a locomotive are not only due to reciprocating unbalance, but very often

and to a much larger extent to torque reaction, to variation in tractive force per revolution, and to vehicle oscillations, such as self-induced lateral and nosing vibrations. For this reason the question of permissible unbalance in the plane of reciprocation is difficult to appraise. The writer some years ago recommended values around 35 per cent for the balancing of reciprocating parts. The author's observations that satisfactory riding conditions are maintained with a 30 per cent balance are very pertinent.

The disturbance due to reciprocating inertia forces may be classified into four disturbances: First, a fore-and-aft vibration; second, a nosing moment; third, an inertia torque and vertical force on the drivers, with a corresponding reaction torque and vertical reaction on the spring-borne parts; and fourth, associated with the inertia torque on the drivers, a varying tractive force, causing additional fore-and-aft vibration. The latter two cannot be eliminated by any balancing method and therefore will be dismissed in so far as the counterbalancing problem is concerned. On the other hand, in a proper appraising of the total disturbance, they augment those due to steam thrust and track disturbance.

As to balancing reciprocating parts, it is further important to differentiate between the relative importance of fore-and-aft and nosing-moment unbalance. Dynamic balancing presupposes the same percentage of balance for these two components. In static balance a greater percentage of fore-and-aft balance is obtained. However, the effects on the locomotive have an entirely different interpretation. The linear fore-and-aft displacement for the fore-and-aft unbalance depends also on the mass of the locomotive, while the angular amplitude corresponding to the moment unbalance depends upon the polar moment of inertia of the locomotive and lateral constraints. By tying in the tender through buffers spaced laterally between the engine and tender, considerable additional lateral constraint is effected. Large locomotives, in modern power, have large polar moments of inertia, which with friction and leading-truck resistances, greatly reduce the importance of nosing unbalance. Experimental data as obtained from the Indian Bridge Commission tests have indicated no correlation between nosing vibrations and reciprocating-motion frequencies. In all cases, nosing vibrations at high speeds have been correlated with track disturbances and self-induced vibrations. This condition has also been observed on some American railroads, particularly at high speeds, where the balancing problem is of greatest importance. The author also more or less concurs on this point not only in this paper but also in his discussion of the writer's paper.[7]

In the writer's paper emphasis was given to the importance of cross-balancing revolving parts, particularly for main driving wheels which are considerably out-of-plane for these weights. While the writer completely concurs with the author as to a complete balancing of revolving weights, where they only exist, it is important to note that the very feature of introducing reciprocating balance sets up a new vertical disturbance. Relief of the dynamic augment can be effected by introducing couples at quadrature, which in no way affects the balancing of the reciprocating parts fore and aft, but does increase the nosing-moment unbalance.

This method of balancing was introduced by the writer in the closure of his paper.[7] It consisted of cross-balancing only partially the revolving parts, resulting in a minimum dynamic augment at the rail. By this method the dynamic rail pressure can be reduced by roughly 30 per cent.

The essence of the method is shown in Figs. 13, 14, and 15, where W_r = any revolving weight, spaced a distance h from the wheel on the balance plane. Let a percentage k of the revolving weight be balanced statically, so that a balance weight kW_r is placed in the wheel center opposite the crank, as in the usual method of balancing the revolving weights statically. The remainder $(1 - k)W_r$ should be cross-balanced in the orthodox method of dynamic balancing, so that $(1 - k)W_r$ has no effect at the rail or at the pedestals.

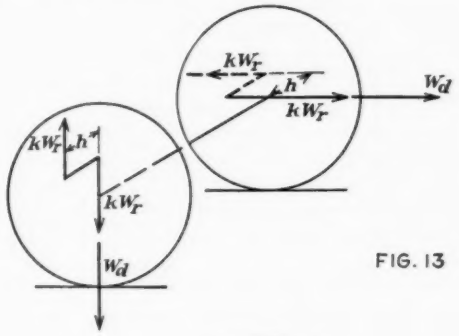

FIG. 13

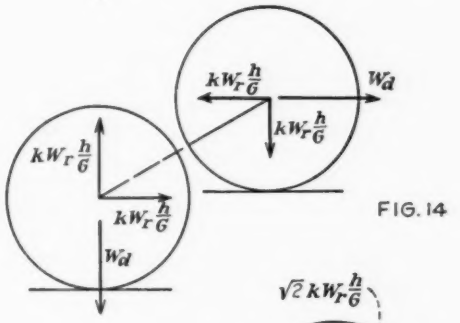

FIG. 14

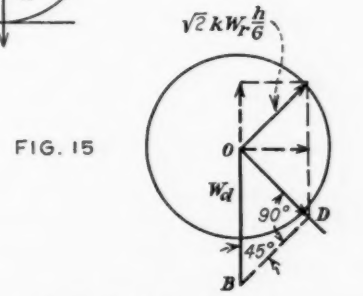

FIG. 15

FIGS. 13, 14, AND 15

From Fig. 13, obviously the couple kW_rh reduces the effect of the dynamic augment W_d, required for reciprocating balance, thus reducing the rail pressure. In Fig. 14, the couples kW_rh at either wheel are reduced to equivalent couples in the forces in the wheel (or balance) plane kW_rh/G at quadrature. These forces compound into a resultant $\sqrt{2}kW_rh/G$, making an angle of 45 deg with respect to the vertical. A little consideration will show that the minimum rail pressure occurs when OD makes a right angle with BD, Fig. 15. Therefore, since ODB is a right angle, and $OB = W_d$ and $BD = \sqrt{2}kW_rh/G$, then

$$BD = OB \cos 45 \text{ deg} = OB/\sqrt{2}$$

$$\sqrt{2}(kW_r)h/G = W_r\sqrt{2}$$

so that the percentage of revolving weight to remain statically balanced is

$$k = \frac{1}{2}\frac{W_d}{W_r}\frac{G}{h}$$

When the reciprocating parts are cross-balanced, if W_d = the required weight in the wheel center, for the reciprocating balance, and if α = the phase angle of the balance, then

[7] "The Balancing and Dynamic Rail Pressure of Locomotives," by R. Eksergian, Trans. A.S.M.E., vol. 51, part 2, 1929, paper RR-51-55.

and to a much larger extent to torque reaction, to variation in tractive force per revolution, and to vehicle oscillations, such as self-induced lateral and nosing vibrations. For this reason the question of permissible unbalance in the plane of reciprocation is difficult to appraise. The writer some years ago recommended values around 35 per cent for the balancing of reciprocating parts. The author's observations that satisfactory riding conditions are maintained with a 30 per cent balance are very pertinent.

The disturbance due to reciprocating inertia forces may be classified into four disturbances: First, a fore-and-aft vibration; second, a nosing moment; third, an inertia torque and vertical force on the drivers, with a corresponding reaction torque and vertical reaction on the spring-borne parts; and fourth, associated with the inertia torque on the drivers, a varying tractive force, causing additional fore-and-aft vibration. The latter two cannot be eliminated by any balancing method and therefore will be dismissed in so far as the counterbalancing problem is concerned. On the other hand, in a proper appraising of the total disturbance, they augment those due to steam thrust and track disturbance.

As to balancing reciprocating parts, it is further important to differentiate between the relative importance of fore-and-aft and nosing-moment unbalance. Dynamic balancing presupposes the same percentage of balance for these two components. In static balance a greater percentage of fore-and-aft balance is obtained. However, the effects on the locomotive have an entirely different interpretation. The linear fore-and-aft displacement for the fore-and-aft unbalance depends also on the mass of the locomotive, while the angular amplitude corresponding to the moment unbalance depends upon the polar moment of inertia of the locomotive and lateral constraints. By tying in the tender through buffers spaced laterally between the engine and tender, considerable additional lateral constraint is effected. Large locomotives, in modern power, have large polar moments of inertia, which with friction and leading-truck resistances, greatly reduce the importance of nosing unbalance. Experimental data as obtained from the Indian Bridge Commission tests have indicated no correlation between nosing vibrations and reciprocating-motion frequencies. In all cases, nosing vibrations at high speeds have been correlated with track disturbances and self-induced vibrations. This condition has also been observed on some American railroads, particularly at high speeds, where the balancing problem is of greatest importance. The author also more or less concurs on this point not only in this paper but also in his discussion of the writer's paper.[7]

In the writer's paper emphasis was given to the importance of cross-balancing revolving parts, particularly for main driving wheels which are considerably out-of-plane for these weights. While the writer completely concurs with the author as to a complete balancing of revolving weights, where they only exist, it is important to note that the very feature of introducing reciprocating balance sets up a new vertical disturbance. Relief of the dynamic augment can be effected by introducing couples at quadrature, which in no way affects the balancing of the reciprocating parts fore and aft, but does increase the nosing-moment unbalance.

This method of balancing was introduced by the writer in the closure of his paper.[7] It consisted of cross-balancing only partially the revolving parts, resulting in a minimum dynamic augment at the rail. By this method the dynamic rail pressure can be reduced by roughly 30 per cent.

The essence of the method is shown in Figs. 13, 14, and 15, where W_r = any revolving weight, spaced a distance h from the wheel on the balance plane. Let a percentage k of the revolving weight be balanced statically, so that a balance weight kW_r is placed in the wheel center opposite the crank, as in the usual method of balancing the revolving weights statically. The remainder $(1 - k)W_r$ should be cross-balanced in the orthodox method of dynamic balancing, so that $(1 - k)W_r$ has no effect at the rail or at the pedestals.

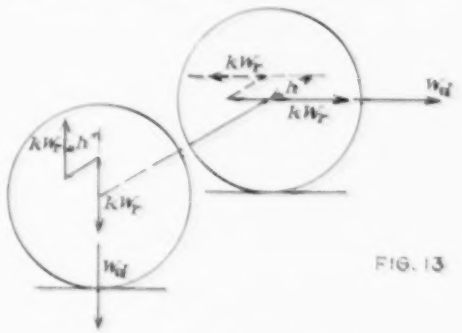

FIG. 13

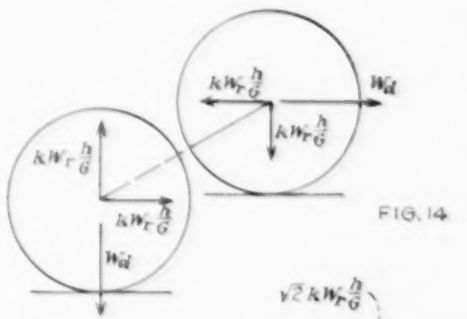

FIG. 14

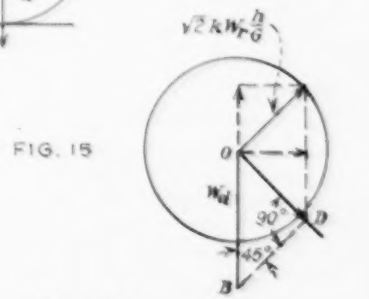

FIG. 15

FIGS. 13, 14, AND 15

From Fig. 13, obviously the couple $kW_r h$ reduces the effect of the dynamic augment W_d required for reciprocating balance, thus reducing the rail pressure. In Fig. 14, the couples $kW_r h$ at either wheel are reduced to equivalent couples in the forces in the wheel (or balance) plane $kW_r h/G$ at quadrature. These forces compound into a resultant $\sqrt{2}kW_r h/G$, making an angle of 45 deg with respect to the vertical. A little consideration will show that the minimum rail pressure occurs when OD makes a right angle with BD, Fig. 15. Therefore, since ODB is a right angle, and $OB = W_d$ and $BD = \sqrt{2}kW_r h/G$, then

$$BD = OB \cos 45 \text{ deg} = OB/\sqrt{2}$$

$$\sqrt{2}(kW_r)h/G = W_r \sqrt{2}$$

so that the percentage of revolving weight to remain statically balanced is

$$k = \frac{1}{2} \frac{W_d}{W_r} \frac{G}{h}$$

When the reciprocating parts are cross-balanced, if W_d = the required weight in the wheel center, for the reciprocating balance, and if α = the phase angle of the balance, then

[7] "The Balancing and Dynamic Rail Pressure of Locomotives," by R. Eksergian, Trans. A.S.M.E., vol. 51, part 2, 1929, paper RR-51-55.

$$P_R = \frac{W_d'}{W_r}\frac{G}{h}\cos\frac{(45-\alpha)}{\sqrt{2}}$$

Obviously the remaining part $(1-k)W_r$, of the revolving weights should be cross-balanced. Except for the main driver P_k usually considerably exceeds unity. For this reason coupled drivers should be completely statically balanced. In the case of main drivers a partial cross-balancing is necessary. With a reduction in the percentage of reciprocating balance in modern power and if the percentage of this required reciprocating balance is reduced on the main driver then the condition for full cross-balancing on the main driver is approached.

It is important to emphasize that this method of balancing is postulated on the premise that an increased nosing moment over a complete cross-balancing is permissible. On the other hand, this method results in nosing moments less than by static balance in virtue of still maintaining a considerable cross-balance for the main driver.

In the final analysis, in normal operation, the greatest concern is the rail stress and not necessarily individual rail pressures per driver. If the revolving parts are completely cross-balanced throughout and the reciprocating balance then distributed with equal dynamic augment per driver, a series of parallel vector loadings along the rail results. In this case, with equal wheel loadings, the maximum stress occurs on end drivers. Eliminating the dynamic augment on the main driver further increases these stresses. The author calls attention to steam thrust, with a downward component on the main driver. At high speeds it is questionable whether this component is sufficiently high to justify the elimination of reciprocating balance on the main drivers. The main driver can suffer greater loads due to the negative bending moments of adjacent drivers.

The advantages of the reduction in individual rail pressure by the method of partial balance (usually complete static balance for coupled drivers) more than offsets the somewhat more undesirable phase angles, even when considering rail stress.

A peculiar condition arises in locomotives running at very high speeds. Due to the elasticity of the rail, the heavy wheel-axle assemblies, and the spring-supported parts, the first approximation is that of a double-spring pendulum, consisting of an equivalent rail spring, an intermediate mass, that of the drivers, and then the driver springs connecting to the spring-borne parts.

The system has two modes of vibration with their two natural frequencies, one low and one high. The disturbing force is the unbalance in the wheel center.[8] At very high speeds the second mode can be excited, which may cause actual lifting of the driver from the rail, with consequent slipping. This phenomenon was first observed in connection with bridge vibrations. In this case the elastic rail is replaced by the elastic deformation of the bridge structure. While the actual system is more complicated with additional degrees of freedom, the cure is best obtained by a reduction of the disturbing force, particularly at the main driver; for this condition reduction in dynamic augment at the main driver may be necessary.

In conclusion the writer recommends the retaining of static balance on coupled drivers. The main driver should be partially cross-balanced on the basis of retaining at least a certain percentage of reciprocating balance with large wheels. The final design should be based on the condition of minimum rail stress. With several drivers and smaller wheels complete elimination of reciprocating balance for main drivers may be desirable, due to steam load and increased dead weight. In this case the revolving weights on main drivers are completely cross-balanced, with partial cross-balancing for the intermediate drivers with heavy revolving weights.

[8] Another disturbing force is torque reaction and vertical thrust between the main driver and spring-borne parts which may account for lifting effect on main driver and not on coupled wheels. This condition is independent of balance.

L. H. Fry.[9] Before discussing the cross-balancing of the reciprocating parts, attention is called to the fact that the author measures the amount of balance as a percentage of the weight of the reciprocating parts. If thought on the subject is to be clear, it is important that the balance should be measured in definite terms and not as a percentage of the mass of the reciprocating parts. In the case of a 350,000-lb locomotive, if the weight of the unbalanced mass of the reciprocating parts is 750 lb, the riding of the locomotive will be the same whether this is 100 per cent of lightweight reciprocating parts weighing 750 lb, 50 per cent of parts weighing 1500 lb, or 25 per cent of very heavy parts weighing 3000 lb. The longitudinal disturbance of the locomotive will depend on the mass of the locomotive and on the mass left unbalanced, not on the relation of the unbalance to the mass of the reciprocating parts. Recognition of this fact will do much to simplify the discussion of balancing problems. It is particularly desirable at the present time because of the increasing use of special lightweight reciprocating parts.

No novelty can be claimed for urging that reference to the percentage of the mass of the reciprocating parts be given up. G. R. Henderson suggested this as long ago as 1895, though the reference generally given is to his 1904 book.[10]

Henderson suggested that 1/400 of the mass of the locomotive might remain unbalanced on each side; that is, 750 lb for a 350,000-lb locomotive. However, it seems probable that satisfactory riding qualities can be obtained with a larger proportion of the mass of the locomotive left unbalanced. The author speaks of a 4-6-4 locomotive which apparently rode well with 1450 lb on a side unbalanced, which is surely more than 1/400 of the mass of the locomotive. Many supporting opinions can be quoted: Chapelon[11] refers to satisfactory results obtained in Germany with greatly reduced longitudinal balance and suggests that designers should break away from the "hypnotic influence" of the balancing of reciprocating parts; D. C. Brown[12] shows vibration diagrams taken at 76 mph, 350 rpm, from a locomotive. In one case 66 per cent of the reciprocating parts were balanced, in the other case none. It is concluded that there is little difference in fore-and-aft motion.

It is believed that existing locomotives should be studied and tests run to find out how much reciprocating balance is really needed to give good riding and how much is being put in to satisfy tradition.

Every pound of overbalance put in to balance the reciprocating parts contributes to the dynamic augment. It is, therefore, desirable to keep the overbalance down to a minimum. It is believed that this is the fundamental problem in balancing the reciprocating parts. When it is satisfactorily solved, the question of whether or not to cross-balance the reciprocating parts will prove to be of secondary importance.

Referring to Fig. 16, it is assumed desirable to balance an equivalent weight of 100 lb at the crankpin. Fig. 16 (*A*) shows the unbalanced equivalent weight with 62 in. between the planes of counterbalances and the plane of the left-hand main rod 73 in. from the plane of the right-hand counterbalance. The arrangement in Fig. 16(*B*) balances the longitudinal force, but

[9] Railway Engineer, Edgewater Steel Company, Pittsburgh, Pa. Mem. A.S.M.E.

[11] "La Locomotive à Vapeur," by André Chapelon, 1938, p. 754.

[12] "Counterbalancing and Its Effect on Locomotives and Bridges," by D. C. Brown, *Journal*, Institution of Locomotive Engineers, Jan.-Feb., 1938, p. 90.

leaves a nosing moment of 1100 in-lb. The equivalent weight producing dynamic augment is 100 lb. Fig. 16(*C*) shows the effect of cross-balancing the balance. The longitudinal force and the nosing moment are zero, but the equivalent weight producing dynamic augment has been increased to 118 lb. It seems improbable that the reduction in the nosing moment is of sufficient advantage to offset this increase in dynamic augment.

In weighing the importance of nosing moment, it should be remembered that the disturbing inertia forces, as well as the balancing components, originate in the driving wheels and

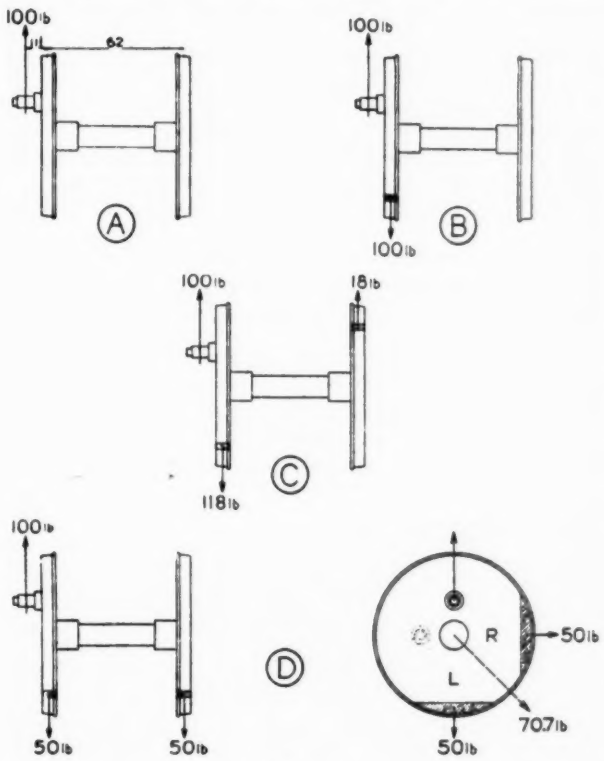

FIG. 16

attached engine parts. Until these parts move, the forces cannot reach the locomotive frame and superstructure. The group of driving wheels cannot rotate about a vertical axis until its friction on the rail is overcome. With a long locomotive the frictional moment-resisting nosing is large. Even if slippage takes place, the large mass and the length of the frame and boiler offer a high polar moment of inertia to resist nosing.

Taking advantage of this, the system of balance for reciprocating parts shown in Fig. 16(*D*) has been used with success. In this the dynamic augment is reduced at the expense of the nosing moment. To balance the equivalent weight of 100 lb at the left pin, equivalent weights of 50 lb each are added in the left- and right-hand wheels. When this is done for both sides of the engine, each wheel receives two equivalent weights of 50 lb each set 90 deg apart. The resultant, producing dynamic augment, is $50 \times 2 \times 0.707 = 70.7$ lb. Comparing the results of the three methods of balance, it is seen that in Figs. 16(*A*), 16(*B*), and 16(*C*), balance for 100 lb equivalent weight of reciprocating parts is provided on each side of the locomotive. With method (*A*), the dynamic augment is due to 100-lb equivalent weight and the nosing moment is due to an equivalent-weight moment of $100 \times 11 = 1100$ in-lb. With method (*B*), cross-balance of the reciprocating parts, the dynamic augment is produced by an equivalent weight of 118 lb, while the nosing moment is zero. With method (*C*) the equivalent weight, producing dynamic augment, is reduced to 70.7 lb with a nosing moment due to an equivalent weight moment of $50 \times 11 + 50 \times 62 = 3600$ in-lb. For any driving-wheel diameter and speed the actual value of dynamic augment and nosing moment is found by multiplying the equivalent weight or the equivalent-weight moment by

$$0.0000284\ Rn^2$$

which is derived from the author's Equation [2*a*].

Compared with direct balance, cross-balance for the reciprocating parts increases the dynamic augment by 18 per cent, while method (*D*) reduces it by 29.3 per cent. Method (*D*) was suggested in 1909 by H. H. Vaughan,[13] then superintendent of motive power of the Canadian Pacific Railway. He reported that the method was giving good results. It has also been adopted by the New Zealand Government Railways with satisfactory results, as indicated in a personal letter to the writer, dated January 10, 1935, from S. H. Jenkinson.

In conclusion attention is drawn once more to the desirability of stating the final condition of each driving wheel in simple and accurate terms. The statement that a pair of wheels is dynamically balanced is a complete and definite description. The wheels will rotate at any speed without any dynamic augment. On the other hand, the statement that a pair of wheels is statically balanced has no definite meaning. As the wheels rotate they will be subject to a varying couple, tending to rotate the axle in a vertical plane at right angles to the direction of motion. As a result each wheel is subject to a varying dynamic augment. The values of the couple and of the dynamic augment are unknown, until the equivalent weight of the rotating parts is determined and the relative positions of the vertical planes in which the rotating parts and the counterbalances revolve. If a pair of wheels is not dynamically balanced, their condition can be described in a completely satisfactory manner by saying that in each wheel there is an unbalance represented by an equivalent weight having a definite value and a definite position. Take for example the wheels in Fig. 16(*D*). Each wheel of the pair has two equivalent weights of 50 lb each in addition to the dynamic balance. The net result in each wheel is an unbalance represented by an equivalent weight of 70.7 lb acting at 145 deg from the crankpin. See also Fig. 2 in a former paper by the writer.[14]

The final condition of the wheel should be described by a single equivalent weight of definite value and position. It is immaterial whether this final unbalance arises from imperfect dynamic balancing or from the addition of an overbalance to a pair of dynamically balanced wheels, or from a combination of the two. The final net resultant unbalance should be stated as a single equivalent weight.

If this is done, a great many ambiguities will be cleared away. For example, the conditions described in L. B. Jones's discussion of this paper would be shown in their true light. In his discussion it is stated that, on one of the Pennsylvania Railroad locomotives, the balance was such that any change, either an increase or a decrease, in the amount of balance added for the reciprocating parts produced an increase in the dynamic augment. This sounds paradoxical, but is easily explained if the single resultant method is used to describe the conditions. In the main wheels in question the combination of rotating parts and of counterbalance added supposedly to produce so-called static balance and to balance the reciprocating parts is such that

[13] "Locomotive Counterbalancing," by H. H. Vaughan, Proceedings, Canadian Railway Club, vol. 8, no. 6, Sept. 26, 1909.

[14] "Locomotive Counterbalancing," by Lawford H. Fry, Trans. A.S.M.E., vol. 56, 1934, paper RR-56-2, p. 434.

the standard condition of the wheels is that shown in Fig. 17. In each wheel there is an unbalanced equivalent weight of 282 pounds acting at A in the right- and at B in the left-hand wheel. It is easily seen that if more overbalance is added at D, in the right-hand wheel, to balance a greater proportion of the reciprocating parts, the net resultant of the equivalent weights at A and D will be greater than the original 282 pounds at A and the dynamic augment will be increased. Similarly, if the overbalance at D for the reciprocating parts is reduced, the effect will be the same as an addition of overbalance at B and as before the dynamic augment will be increased.

It is also obvious that the dynamic augment could be reduced

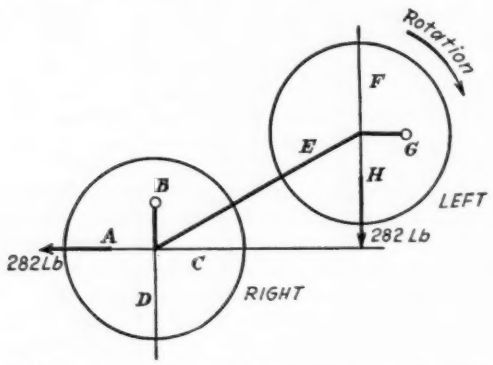

FIG. 17 NET UNBALANCE IN MAIN WHEELS OF PENNSYLVANIA RAILROAD LOCOMOTIVE

by adding overbalance at C. This would reduce the longitudinal balance opposing the inertia of the reciprocating parts because the existing unbalanced equivalent weight of 282 pounds at A in the right wheel is opposing the inertia force of the reciprocating parts acting on the left pin G.

L. B. JONES.[15] The application of the methods, suggested by the author, as well as any of the accepted counterbalancing

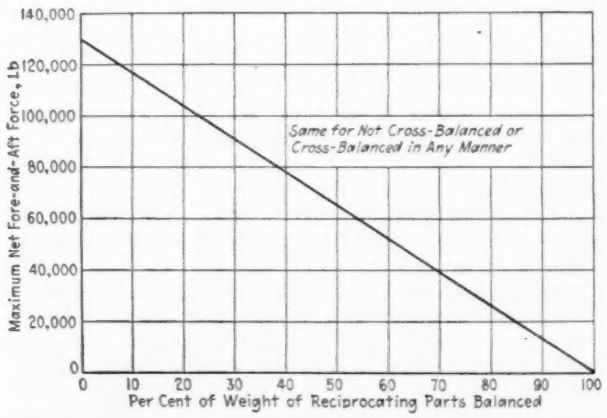

FIG. 18 GRAPHIC ANALYSIS OF FORE-AND-AFT FORCES ACTING ON PACIFIC-TYPE LOCOMOTIVE, COMPUTED AT 400 RPM

formulas, requires a large amount of calculation if the designer cares to explore carefully all the possible effects of any particular counterbalance. In operating locomotives at high speed at the locomotive testing plant, it has been found necessary to make a number of counterbalance analyses and, as a result, resort has been made to a graphic analysis by means of which it is more convenient to survey all phases of the subject.

The diagrams, Figs. 18 to 21, were computed at a speed of 400 rpm for a Pacific-type locomotive, having approximately 1500 lb of reciprocating weight per side, 28-in. piston stroke, 80-in. driving wheels, and 89-in. cylinder spread. The overbalance due to reciprocating parts is distributed equally among the three pairs of drivers. Since the percentage of reciprocating weights to be balanced is the determining factor in counterbalance behavior, all of the diagrams have this as a base, with

resulting forces as ordinates. The effect of the angularity of the main rod has been omitted, as it is relatively small, but if the designer desires to include it, he can do so after he has made his selection of the more important weights and dimensions.

Fig. 18 shows the behavior of the fore-and-aft forces, starting at 0 with 100 per cent overbalance and getting into large figures with little or no overbalance. These are the forces which tend to produce shake or vibration in the locomotive which, under certain conditions, are transmitted through the tender and couplers to the leading cars in the train. This diagram applies to any form of counterbalance—static balance, rotating cross-balance or reciprocating cross-balance.

Fig. 19 illustrates the behavior of the turning forces around the vertical axis of the locomotive. In this case, there is a difference between the effects of static balancing and cross-counterbalancing; and a further difference, as a result of cross-counterbalancing the reciprocating parts, which is illustrated by the dotted line. For high-speed counterbalancing, the effect of turning forces can probably be ignored, as the frequency is too high to produce any nosing effect of the locomotive.

Fig. 20 shows the behavior of the dynamic augment in the main wheels. The difference in behavior of the dynamic augments for static and rotating cross-counterbalance is quite marked. A peculiarity of static balancing, which is illustrated by the curve, is the fact that any decrease below or increase above the proper amount of counterbalance, will result in an increase in dynamic augment. With cross-counterbalancing, the curve is a straight line starting from 0 at 0 overbalance. A peculiarity of this curve is that it crosses the static-balancing curve at its minimum point. Above this intersection, the dynamic augment with cross-counterbalancing is greater than with static balancing and increases rapidly. It will also be noted that the static curve is relatively flat in the center and a considerable variation in overbalance produces only a small variation in dynamic augment; whereas the dynamic augment due to cross-balancing is relatively sensitive to the amount of overbalance.

In Fig. 21 the effect of cross-counterbalancing the reciprocating parts, according to the method suggested by the author, is shown by a dotted line. It is evident, for the particular locomotive under analysis, that it would be a mistake to cross-counterbalance the reciprocating parts, due to the rapid increase in dynamic augment.

Figs. 18 and 20 illustrate the necessity for a careful compromise in counterbalancing. Generally speaking, the effect of dynamic augment has been found to be greater on light rail than on heavy rail. Therefore it would appear consistent to keep the dynamic augment as low as possible in locomotives which are to operate on light rail. On the other hand, Fig. 18 shows at a glance what can be expected in the way of fore-and-aft forces, if the overbalance for reciprocating parts is kept too low.

The same form of graphic analysis can be applied to the coupled drivers, as in Fig. 21. As with the main drivers, the curves for static and cross-counterbalancing cross, but much lower down, because the plane of the counterbalance is much more nearly in the plane of the forces. For the locomotive in question, it is evident that better results will be obtained by static balancing the coupled wheels; which will also simplify the design of the wheel center.

G. F. STARBUCK.[16] It is to be regretted that the author made no reference to the paper by McCall.[17] This is the most informative paper on the subject that has appeared in many years. It includes a discussion of the steam-pressure effect and it also touches upon the cross-balancing of reciprocating weight.

It seems to be the inference that, for perfect balancing of the rotating weights, the main wheels will be just alike. That is true for the crank hubs and pins, side rods, parts of the main rods, and large ends of the eccentric cranks. It is not true for the small ends of the eccentric cranks and the back ends of the eccentric rods. These weights although small are located at considerable distances from the plane of the rail and cannot be ignored for the best counterbalancing.

While insisting that counterbalancing is a dynamic problem, the author adheres to the common practice of actually balancing the main rod statically, that is, balancing the static weight of the back end of the rod. The motion of the rod is translation combined with rotation about the crosshead wrist pin. The vertical component of the force at the crankpin, due to the inertia of the rod, is the force required for this rotation. It is, therefore, most accurately balanced by an equivalent weight of $\frac{Wk^2}{l^2}$; where W = weight of rod, k = distance from crosshead pin to center of gyration, and l = length. R. Eksergian in a recent paper[18] states: "It is difficult to see physical justification for the formula Wk^2/l^2 for an equivalent inertia mass at the pin." Justification is to be found in any treatise on the dynamics of rotating bodies. The application is not limited to the condition of a fixed crosshead. Of course there is a horizontal component, but its excess over the horizontal component of the weight determined as above, is reciprocating weight. In a typical locomotive the mistake of balancing the static weight of the back end of the rod results in a dynamic augment of about 5000 lb or, say, 15 per cent of the weight on the wheel.

There are many mathematical treatments of the subject of rotating bodies. The following illustration will help non-mathematical designers to see the mistake in the common method. If the front end of the rod moved in just such a circle as the back end, instead of moving to and fro in a straight line, the vertical effect at the main pin would be exactly as now assumed. The vertical acceleration of all points on the rod would be the same, just as in the side rods. The vertical accelerating forces for all elementary equal masses would be the same and would be resolved into forces at the two ends, according to the locations of the masses. If weights of the masses are used instead of accelerating forces the resolution of the forces between the two ends would result in the same proportions. The components would be called the static weights of the two ends. If, however, the front end of the rod moves in a horizontal line, the vertical amplitude and consequently the acceleration and accelerating force of almost every one of the equal, elementary masses will be less than in the first case and the sum of the components at each end will be less.

The unbalanced reciprocating weight will have a to-and-fro effect combined with a tendency to nose, which tendency is produced by a couple having as its arm one half the cylinder spread. Reciprocating weight simply balanced has no to-and-fro effect but has a tendency to nose, the arm of the couple being the distance between the planes of the cylinder and of the nearer counterbalance. The smallness of this tendency will be appreciated when it is realized that its arm is 13 or 14 in., compared with a locomotive length of 35 to 45 ft and a radius of gyration of 10 to 13 ft. Excepting the small amount of free lateral, there is very high frictional resistance to nosing besides the inertia resistance. To-and-fro disturbances are often transmitted to the train and can be serious if they synchronize with the draft and buffing gears.

[16] Mechanical Engineer, Waltham, Mass. Mem. A.S.M.E.

[17] "Cross or Simple Counterbalancing," by K. F. McCall, *Railway Mechanical Engineer*, August, 1936, p. 346.

[18] Discussion of: "The Design of Railway Axles and Locomotive Crank Pins," by R. Eksergian. Trans. A.S.M.E., vol. 60, Nov., 1938. See author's closure, p. 693.

Now let the reciprocating balance be angled without change in amount. The angling is equivalent to adding a 90-deg weight. Thus for each effective component opposite the crank, there will be an opposing component in the opposite wheel reducing its effectiveness as a to-and-fro balance. The resulting increase in unbalanced reciprocating weight will give rise to a nosing couple more than one half that eliminated by the angling. There has been an increase in to-and-fro rough-riding with but slight decrease in nosing, which was negligible before. If the balance weight had been increased when it was rotated, according to the customary method of cross-balancing rotating weight, the dynamic augment would have been increased.

The effect of merely angling the weight can be clearly seen by constructing diagrams similar to Fig. 9, but with these modifications—in the first diagram plot curves as follows:

(*a*) Longitudinal inertia effect of right-hand reciprocating weight.
(*b*) Longitudinal inertia effect of left-hand reciprocating weight.
(*c*) The sum of (*a*) and (*b*).
(*d*) Horizontal component of the centrifugal force of the weight opposite the crank, provided for the reciprocating weight, in the right-hand wheel.
(*e*) Same as above but for the left-hand wheel.
(*f*) The sum of (*d*) and (*e*).

Now make a similar diagram for balances angled at 10 deg 57 min. The curve *c* shows the total effect of the inertia of the reciprocating weights on both sides of the engine. The curves *f* show the effectiveness of the balances. In the first diagram the curves *d* and *e* are 90 deg apart, and 35 per cent of the reciprocating weight is found to be balanced. In the second diagram the curves are 111 deg 54 min apart. Because these curves are more nearly opposed to one another, their sum is less, as shown by less amplitude of curve *f* and the percentage is much less. This explains why so many railroads, having locomotives with main wheels only large enough for balances for the rotating weight, have found them to ride worse when the weight was angled.

In including the piston load in counterbalance calculations, it must be remembered that at slow speeds, when the load is greatest, the dynamic augment is negligible. At high speeds most of the piston pressure is used up in accelerating the reciprocating weights. The greatest axial thrust in the main rod occurs well beyond the 90-deg crank angle, after compression has begun and not far from the time when the pressures on the two sides of the piston balance. It is due of course to the inertia of the reciprocating parts. The curve of augment produced by this thrust has no resemblance to a sine curve.

When it is desired to determine the best balance for a high-speed locomotive, formulas are useful for a first approximation only. In order to minimize to-and-fro motion ("jumping," as enginemen call it) and wheel weight, while keeping within the limit of dynamic augment, nosing would best be ignored. Curves of augment, due both to inertia and steam pressure, would be plotted and weights adjusted by trial to give the best result. Accelerations are most easily found graphically. In deciding what is the best result, consideration must be given to the areas under the curves, the maximum ordinates, the elasticity of the track, and the relative crank angles of all drivers at maximum ordinates. The balances on the two sides of the engine will be different and, probably on one side, even the revolving weights will not be completely cross-balanced. It is the writer's belief that, when the main rod is dynamically balanced, nothing less than 40 or 45 per cent balancing of the reciprocating weight will be satisfactory.

It has been found that the front and rear drivers are subjected to large augments by their part in guiding the locomotive. On that account it seems inadvisable to load onto them all the reciprocating balance.

W. H. WINTERROWD.[19] In his discussion L. B. Jones mentioned the fore-and-aft or horizontal shake of the locomotive, due to the unbalanced reciprocating masses. It may be of interest to note how the effect of such horizontal shake can be effectively damped.

It is well known that much of the so-called hard riding of locomotives is due, first, to inability to eliminate entirely the slack or lost motion between engine and tender; and second, to inability to damp the horizontal unbalanced forces of the reciprocating masses.

Heretofore, the mechanism used between engine and tender has been the wedge-type radial buffer or spring-buffer type whose inadequacy became pronounced with the advent of higher speeds.

Through scientific research, embodying many tests, there has been developed and placed in service on many locomotives, an automatic buffer mechanism utilizing two principles: First, the entire elimination of slack between engine and tender; and second, the utilization of spring-operated wedges to provide high resistance to the compression forces between engine and tender, thereby enabling the tender practically to become an integral part of the locomotive.

Application of the new design of buffer has resulted, not only in greatly improved riding qualities of the locomotive, but has brought about a very material reduction in maintenance costs of such items as loose cabs, broken piping, displaced arch bricks and wear on drawbars, drawbar pins, and chafing plates.

Recently, some exceedingly interesting comparative tests between the old- and new-type buffers were made in passenger service on a prominent western railroad. The results of these tests are shown in Fig. 22.

The information contained in this comparison was obtained by the use of a highly accurate piece of scientific apparatus known as a shock-and-vibration recorder. This type of instrument is well recognized in the railroad field as an apparatus for securing accurate data in connection with the riding qualities of railroad rolling stock. As part of its development this instrument was tested for accuracy on the shake tables at Purdue University.

The comparative tests were made with the same locomotive, a 4-8-2 with 74-in. driving wheels. On these tests the shock and recording instrument was secured to the deck of the locomotive below the engineer's seat box. The tests were conducted with the same number of cars, over the same track, and on the same operating schedule. No work was done upon the locomotive between tests other than a change of buffers. Track conditions were exceptionally fine. The first test was conducted with the locomotive equipped with the old-style wedge buffer which was in excellent condition and properly adjusted.

Fig. 22 contains comparative and representative portions of the records made by the automatic recorder. The upper half shows the performance with the old-style wedge buffer. The lower half shows the performance with the improved radial buffer and clearly indicates the benefits obtained. These portions of the record were selected for comparison because the speeds over the same section of track were identical. It will be noted that there was only 0.1 mph difference in speed.

These comparative graphical records are not only interesting but highly significant. They show without question the great improvement that can be made in the riding qualities of a locomotive, particularly with reference to the smoothing out or damping effect of the new buffer on the resulting action of the unbalanced forces of the reciprocating masses.

[19] Vice-President, Franklin Railway Supply Company, Inc., Chicago, Ill. Mem. A.S.M.E.

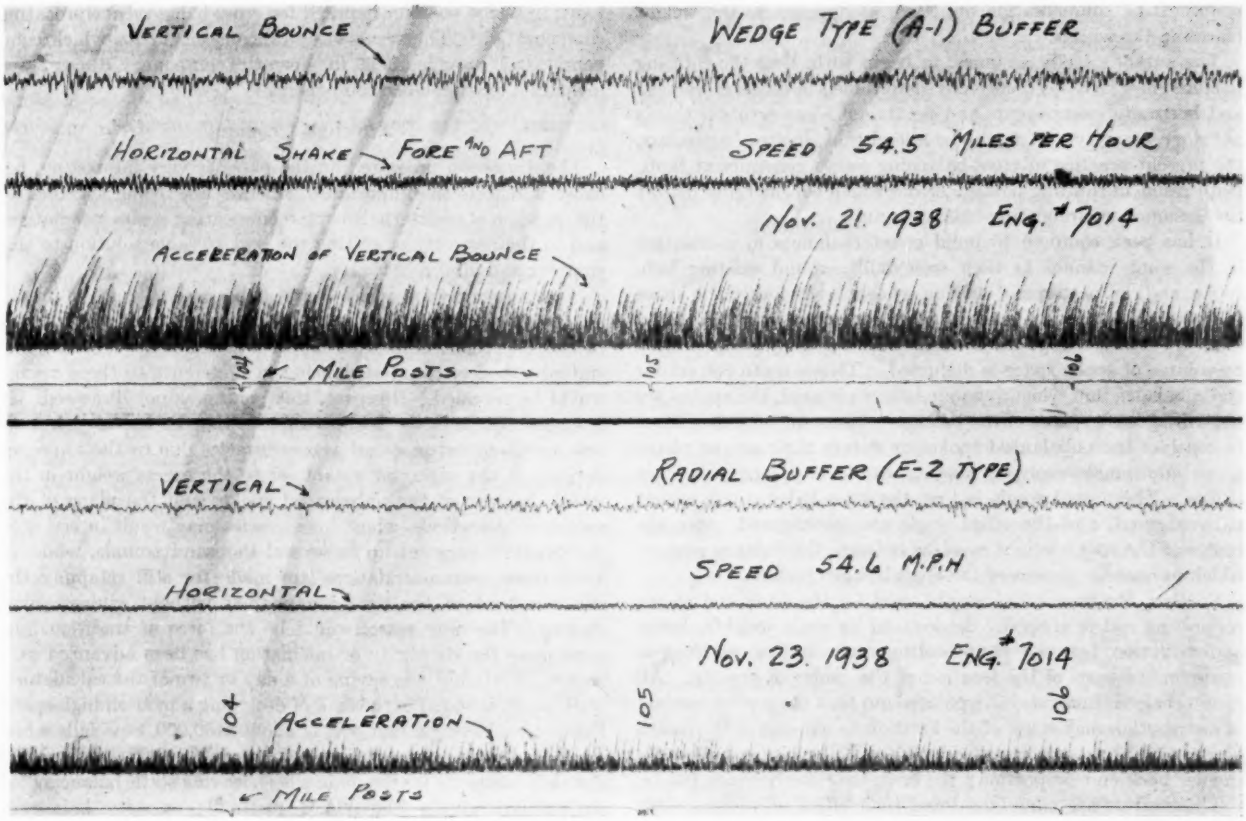

FIG. 22 RESULTS OF COMPARATIVE TESTS BETWEEN OLD- AND NEW-TYPE BUFFERS

The upper line on the record, designated "Vertical Bounce," shows one third of the actual vertical movement of the locomotive. With the old buffer a maximum vertical bounce of 0.45 in. is shown by measuring the record as compared with a maximum of 0.22 in. on the test with the new buffer. This is a reduction of 50 per cent in favor of the new buffer.

The second line on the chart represents the fore-and-aft horizontal shake due largely to the unbalanced forces of the reciprocating masses and inherent factors of steam distribution. The width of the horizontal shake line represents approximately one half of the actual fore-and-aft shake of the locomotive. A representative average width of this line on the test with the old-type buffer is approximately 0.20 in., as compared with a width of 0.06 in. with the new buffer or a reduction of approximately 66 per cent. This indicates that the damping properties of the improved design of buffer have been successful in absorbing or diminishing the horizontal shake to the point where it is less than one third of that obtained with the old buffer.

The third line on the chart, designated "Acceleration of Vertical Bounce," has a definite relation to the upper line and is really an indication of the velocity of the vertical movement or, in other words, the shock or impact obtained in conjunction with the vertical movement. A pencil movement of 1 in. represents an acceleration of G (32.2 ft per sec). A comparison of the maximum deflection of this line shows 1.40 G with the old buffer, and 0.53 G with the new buffer, a reduction of approximately 62 per cent. If it were possible to determine, it is believed the average would be still less and would probably represent only about one fourth that obtained with the old buffer.

The best possible counterbalancing of a locomotive is highly essential for the best practical and economical results from a locomotive and track-structure standpoint. Even when that is accomplished, the test data described herein indicate how a highly and scientifically developed buffer, making the tender an integral part of the locomotive, can absorb the effects of unbalanced forces, while at the same time providing increased comfort for engine crews, train passengers, and affording the means for greatly reduced maintenance costs.

In addition, it has even been suggested that the damping effect afforded by the new buffer opens up the possibility of still further reduction in the percentage of locomotive reciprocating weights to be balanced which, in turn, will decrease dynamic augment and the resulting track stresses.

E. G. YOUNG.[20] The writer particularly appreciates the clear manner in which the author has demonstrated some of the methods of counterbalancing which result in only a fraction of supposed reciprocating compensation being obtained, as well as his suggestion that, in a cross-balanced locomotive, it probably is not advisable to complicate the stresses produced under the main driving wheels by placing reciprocating balance in these wheels. With regard to the specific material of the paper, the writer would offer but a single suggestion: A formula which involves a decimal coefficient with several ciphers after the point is always treacherous. Using the same nomenclature as that in the paper, the simpler expression $3.2\,rW$, gives the centrifugal force at diameter speed, readily converted for any other speed by multiplying by the square of the speed ratio. This paper develops the need for a new technical term, representing the actual

[20] Research Professor, Railway Mechanical Engineering, University of Illinois, Urbana, Ill. Mem. A.S.M.E.

reciprocating compensation obtained, as opposed to the weight placed in the wheels.

The author's study assumes, to begin with, that the rotating balance shall have been correctly determined in terms of vertical and horizontal components and points out some errors if this is not done properly. It might be added that, in two particulars, the present practice in cross-balancing seems generally at fault. Both result in rotating-balance errors which considerably distort the assumed reciprocating-balance results.

It has been common to build counterbalances in calculation in the same manner as they were built around existing hub, spoke, and rim patterns of driving wheels. Obviously the space taken up by the spokes was not filled with counterbalance metal and, when the value of the counterbalance is estimated, the area or volume of spoke space is deducted. This is quite correct for static balance but, when dynamic balance is used, the spokes are not in the center plane of the balance. Consequently the failure to consider the unbalanced spokes or web in their proper plane, as an additional revolving weight, results in incorrect balance values. The actual result is that the cross-balance component is overfigured, and the offset angle also overfigured, since the center of the spoke weight must lie between the balance centers, which necessarily decreases the cross-balance factors.

Further, the amount of weight used for the back end of the connecting rod is generally determined by scale weights, hence a distribution between reciprocating and rotating portions is made on the basis of the location of the center of gravity. All counterbalance analysts have pointed out that the correct method of distribution makes use of the location or amount of the radius of gyration about the crosshead pin, resulting in a considerably smaller back end proportion; the error may easily reach 125 lb.

These errors are cumulative and their effect on reciprocating balance may readily be seen by the following example: Table 1 illustrates the results of these errors, the first column representing a balance calculated in the conventional way, and the second shows the refined calculation.

TABLE 1 CALCULATION OF RECIPROCATING BALANCE BY APPROXIMATE METHOD COMPARED WITH REFINED METHOD

Locomotive part	Approximate method	Refined method
Eccentric crank and part of crankpin:		
Equivalent weight, lb	90	90
Distance outside hub face to mean plane of revolution, in	14	14
Connecting rod and part of crankpin:		
Equivalent weight, lb	750	670
Distance outside hub face to mean plane of revolution, in	10	10
Side rods and part of crankpin:		
Equivalent weight, lb	620	620
Distance outside hub face to mean plane of revolution, in	3	3
Crank hub and part of pin:		
Equivalent weight, lb	350	400
Distance inside hub face to mean plane of revolution, in	3	3
Spokes or web of wheel:		
Equivalent weight, lb	...	180
Distance inside hub face to mean plane of revolution, in	...	4
Center plane of rotating weights, outside hub, in	5.29	4.03
Center of balance, inside hub face, in	3.25	3.25
Offset, balance plane to weight plane, in	8.54	7.28
Distance between balance centers, in	63	63
Offset ÷ balance centers (= cross-balance factor), per cent	13.5	11.6
Total weight of parts balanced, lb	1810	1960
Cross-balance required, vertical and horizontal, lb	244	227
Vertical component of rotating balance, lb	2254	2187
Reciprocating balance put in, opposite crank, lb	200	200
Total balance = vectorial sum of components, lb	2268	2398
Angle of offset, deg-min	6-11	5-27

In Table 1, with an offset of 6 deg 11 min, the vertical component of the balance figured by the approximate method, 2254 lb, allows but 67 lb excess over the rotating requirement figured correctly. There is an excess horizontal component available for reciprocating balance of 244 — 227 = 17 lb. The resultant overbalance is 70 lb, acting 14 deg 10 min from the vertical, and 7 deg from the position required for cross-balanced reciprocating compensation. The actual reciprocating weight for which compensation is provided is 60 lb, since the component 70 cos 7 deg includes a cross-balance component.

Author's Closure

The discussion presented on the paper is very interesting, because it reflects the importance which is now being attached to the question of counterbalancing reciprocating steam locomotives and to the necessity of getting the best possible solution to this complex and vital problem.

Since the principal object of the paper was to develop intelligent discussion of this problem, it had been hoped that the inherent, and perhaps not quite apparent, reasons for retaining the static method of counterbalancing in preference to the dynamic would be revealed. However, this point was not discussed. It is inconceivable to the author why, on the one hand, such matters are discussed in detail as inaccuracies due to the improper division of the main-rod weight, or to the excess weight in the wheels because of the unbalanced spokes and the plane of the spokes of the wheels, which inaccuracies may result in errors in the dynamic augment up to several thousand pounds, while, in some cases, recommendations are made for still retaining the static instead of the dynamic method without giving sound reasons. The only reason could be the force of tradition. In some cases the simplicity of calculation has been advanced as a reason. Certainly, the saving of a day or two of the calculator's work is not essential in the task of designing a modern high-speed locomotive, having a unit cost of about $150,000, especially when more than one locomotive is on order. Some discussers suggest dynamic balancing for the main wheel, leaving static balancing for the coupled wheels (the A.A.R. method); or static balancing for all wheels (Pennsylvania method); or a mixture of static for a part of the revolving weights and dynamic for the remainder (Eksergian's suggestion). In the author's opinion nothing better can be conceived for high-speed locomotives than the orthodox cross-balancing method for all of the revolving and part of the reciprocating weights. It is high time that an advocate of the static method of balancing come to the defense of his opinion and prove it, either theoretically, if he can, or by tests.

As the question of the distribution of the weight of the rod between revolving and reciprocating weights is the simplest one and seems to have gotten hold of the minds of some discussers, the author thinks it advisable to start by replying to discussers who touched on this matter (Starbuck, Buckwalter and Horger, Young), leaving the other questions to a later reply.

G. F. Starbuck regrets that K. F. McCall's publication[17] on cross or simple counterbalancing was not referred to by the author. This occurred simply because the author agreed fully with Mr. McCall and, finding no fault with his presentation of the question of counterbalancing, overlooked placing his article in the Bibliography. The author duly apologizes for the omission, it being understood that reference[17] compensates for the lapse.

Because of a 4000-word limitation placed on the paper, the author was obliged to confine his treatment of the subject of balancing reciprocating weights to a presentation of the principles of the methods of balancing, without devoting space to details of weight computation, i.e., what should be considered as revolving and what as reciprocating weights. This has been done by others and is presented in a number of textbooks to which references have been made. Mr. Starbuck refers to them himself when he says, "there are many mathematical treatments of the subject of rotating bodies," and gives a general explanation for the benefit of the nonmathematical designer.

Referring to the question of the division of the main-rod weight between its ends; generally speaking, this can be done only ap-

proximately. Older textbooks favored the division of the main-rod weight between reciprocating and revolving weights in accordance with the location of the center of gravity of the rod, which is known as the scale method. In this method, a rod is placed on two scales and the weights of both ends are thus registered. It also can be done by calculation, dividing the weight of the rod in inverse proportion to the distances of the center of gravity from either end.

Professor Low (26)[21] states that in many cases the practice is to consider two thirds of the weight as revolving and one third as reciprocating. Recent books (27) and as recent an author as Den Hartog (28), seem to agree to the division of the main-rod weight by the center of gravity. Professor Thurston (29) and John Perry (30) suggested establishing this ratio as half-and-half, meaning 50 per cent of the weight taken as revolving and 50 per cent as reciprocating.

Professor Dalby has analyzed the dynamics of the main rod and outlined the pendulum method for determining the two equivalent weights of a main rod. On page 247 of his book (12), he has given a formula covering the revolving part of the rod, to be assumed as attached to the crankpin

$$W_v = \frac{Wap}{l^2} = W\frac{k^2}{l^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

where W = weight of main rod

a and p = distances of center of gravity and center of percussion from center of crosshead pin, respectively

K = radius of gyration of main rod around center of crosshead pin

l = length of rod between crankpin and crosshead pin.

The remainder of the rod ($W - W_v$) is to be assumed as the crosshead pin. Thus Mr. Starbuck's formula $W_v = \frac{Wk^2}{l^2}$ is correct, provided k is radius of gyration referred to the crosshead pin.

The $p = \frac{K^2}{a}$ may be determined by calculation, or by swinging a rod as a pendulum which gave the name to the method. If T is the time in seconds of one double oscillation of the pendulum, the distance p in feet is determined from the known pendulum formula $T = 2\pi\sqrt{p/g}$ where g is the acceleration of gravity 32.2 ft per sec^2.

Professor Dalby's formula is not exact for all positions of the main rod. On pages 242 to 247 of the 1902 edition (12), he gives the inertia forces of the equivalent parts of the main rod, and on page 247, Fig. 169, he indicates the discrepancy between the actual curve and that obtained from the above formula. The discrepancy is very slight.

G. R. Henderson, on page 57 of his treatise (11), gives a more complicated formula

$$W_v = W\frac{k^2 - (a/l)r^2}{l^2 - r^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

where the notations are the same as above, the r is the crankpin radius. However, this has been derived for one position only of the crank—at 90 deg from the horizontal—and is coincident with the 90-deg point on the Dalby curve. The author, therefore, accepts Dalby's formula as the more general for all positions of the crankpin circle.

Professor Lanza (32) also gives a formula which actually is identical with Professor Dalby's, as a simple mathematical manipulation would show. Thus, both seem to have agreed that the division of the main rod between revolving and reciprocating weights should be made in accordance with Equation [5].

Henderson's Equation [6] should be considered as an approximate formula, if it is applied to the whole circle. Kenneth Cartwright[22] made tests with wooden models of full-size rods and, from these tests, found that Henderson's formula for the main-pin revolving weight is in very close coincidence with the scale-weight figure, if it is multiplied by a coefficient $^7/_8$; in other words, he suggests that

$$W_v = \frac{7}{8}W\frac{a}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

Before these tests, K. F. McCall[17] and, still earlier, Dr. R. Eksergian in his paper (13), page 79, made the same suggestion.

Of course, these formulas give different results, depending upon the relative weights of the crankpin and crosshead ends of the rod and, therefore, depend upon the design. In order to check the foregoing formulas for modern rods, a pendulum test of a full-size steel rod was recently made in the Schenectady shops of the American Locomotive Company. A rod of modern design although not very light in weight, was suspended on knife-edges located in the center line of the crosshead eye. From these tests, values were established which are summarized as follows:

	Total weight main rod with bushings, lb	W_v, lb	Per cent
Dalby-Lanza Equation [5]	834	461	55.2
Henderson Equation [6]	834	461	55.2
McCall-Cartwright Equation [7]	834	463	55.5
Schenectady swing test	834	461	55.2

These figures demonstrate the fact that all the recent formulas namely, Equations [5], [6], and [7], at least for the rod which was tested, give practically identical results. For calculation purposes while designing, before the rod is finished in the shop, Equation [7] can be used as the simplest.

It is interesting to note that for modern rods it more closely approximates the 50–50 percentage distribution, as suggested by Professors Thurston and Perry years ago, than does the more recent center-of-gravity method.

Having finished with this important matter of the influence of the main rod on the question of counterbalancing and wholeheartedly subscribing to Dalby's Equation [5] for general use, as a result of a very elaborate scientific investigation and determination of W_v, and to Equation [7] as the most accurate and so far the best empirical formula for modern locomotive rods, the author now turns to the discussion as such.

T. V. Buckwalter and Dr. O. J. Horger first raise the question of reducing reciprocating weights. Nothing can be said against this, as the reduction of reciprocating weights has always been the aim of locomotive designers, both in this country and abroad as evidenced by channeling-out rods, making them of alloy (vanadium, chrome-nickel, high-tensile steel), using lightweight forged pistons, etc. With the increase in speed, the recent adoption of more refined methods in counterbalancing and, what is more important, with the progress in metallurgy which made available high-tensile steels, the lightening of reciprocating parts became quite natural. Again, since the paper was only to discuss the methods of counterbalancing on the basis of actual weights, without considering what those weights might be, the author did not state that the reduction in weight of reciprocating parts is an aim for counterbalancing, although throughout his paper he stressed the point that the overbalance, which is in direct proportion to the reciprocating weights, should be kept as low as possible. A statement that the reciprocating parts should be

[21] Numbers in parentheses (26 to 33 inclusive) refer to the Bibliography at the end of this closure; all previously numbered references are to the Bibliography at the end of the paper.

[22] Mechanical Engineer, New York, New Haven & Hartford Railroad, New Haven, Conn.

made light was to him a self-evident, long-known truth and, therefore, no emphasis on his part was necessary. The author, therefore, cannot understand the discussers' remark in the third paragraph of their discussion regarding the author's neglect to mention the necessity of reducing the reciprocating weights for the sake of the shaking forces. This is the more surprising as earlier, the discussers, speaking on the same question, remarked that their views are in keeping with the author's recommendations.

The aforementioned writers take exception to the author's suggestion of leaving out the overbalance on the main wheel. The author did not suggest leaving out the overbalances entirely on all wheels; he is conscious of the necessity of some balancing of the fore-and-aft movements in a locomotive, but he is not at all convinced that American locomotives require as much reciprocating balancing as they actually have. Therefore, he would like to see a test with a locomotive properly cross-balanced, having as little overbalance as possible, and maybe leaving it out entirely, so that conditions of balancing would be accurately known. American locomotives are subjected to all kinds of disturbing forces, when the influence of the opposite side is taken into consideration. This condition is mainly due to static balancing. A test similar to that made by the Madras & Southern Mahratta Railway in India (33) is suggested. Possibly zero is not attainable, but reducing this percentage to a very small figure would be found quite sufficient for American locomotives, which are long and heavy.

On the Madras & Southern Mahratta Railway two cross-balanced locomotives, XB/1 and XB/1/RO, were tested. The first locomotive was cross-balanced with 66 per cent balancing of reciprocating weights, while the second had no balance for reciprocating weights. According to a statement made by Mr. Lean, chief mechanical engineer, in a private letter to the author, no difference could be found between these two locomotives, either in the wear between the driving boxes and pedestals, or between their riding qualities, at three inspections for the second locomotive, during a mileage of 232,000 miles. In an unpublished interdepartmental typewritten report (35), it was recommended that "a deduction of 33 per cent should be made in the formula laid down in the Bridge Rules of 1935" and that "the beneficial effects of rebalancing locomotives should at once be brought to the notice of all Indian railways." In view of this, it is natural that a test with "nil balancing" should have been recommended by the author for American railroads, as he has always advocated as little balancing of reciprocating parts as possible (13).[23]

It is also stated by Mr. Lean that on some 4-8-0 meter-gage locomotives, converted to superheat, no overbalance could be placed in the small wheels on the drivers when the converted engine became heavier. These were, therefore, omitted and the reciprocating balances were redistributed over the coupled wheels. That permitted placing the locomotives in successful operation—as the author suggested in the paper.

The beneficial effect of reducing the reciprocating balance by 100 lb on each side of a high-speed locomotive has been proved by Kenneth Cartwright (36).

One point must be remembered: Messrs. Buckwalter and Horger talk about the necessity of neutralizing the shaking forces up to the point where maintenance of the locomotive and of the track becomes excessive. This is probably about 25 to 30 per cent. In this case, 70 to 75 per cent of the unbalance still remains. Why is it possible for a locomotive to stand 75 per cent of the shaking forces and why would it not be possible to stand 95 per cent—an increase of only 28 per cent? Without a test to the contrary, it is not logical by pure reasoning to decide one way or another, in view of the prevailing evidence. The author only suggested that such a test be made to determine this very question for American locomotives. Of course, the locomotives to be tested should have as light reciprocating weights as possible and practically no reciprocating balances. His reference to the 4-6-4 locomotive, which actually had only 6-lb overbalance on the main wheel, was cited as an indication that many locomotives were riding with very slight balancing of reciprocating parts. His point was that, in a great many American locomotives, the old figures of overbalancing, which were necessary for shorter and lighter locomotives, do not obtain now and, therefore, there is no reason to insist on 30 or 40 per cent balancing as is practiced in many cases. After the dynamic balancing of rotating parts has been carried out and referred to the plane of the cylinders, 12 to 18 per cent balancing of reciprocating weights may prove quite sufficient.

For the information of the discussers who inquired whether or not the influence of reciprocating weights from the other side of the locomotive was taken into account for the 6-lb overbalance, the author states that it was not. If it had been, the numerical value might have been larger, but the angular direction of the augment would be such that its value would be of very little use. This statement will be clearer from the author's reply to the remarks of L. B. Jones.

The tests on slipping, as reported by Messrs. Buckwalter and Horger before the New York and Chicago Railway Clubs, are of great value. This difficulty has been recognized by the author in the paper. It must be remembered, however, that the problem is in its infancy and before drawing conclusions, more experimental work will be needed.

While the piston-thrust-component effect may not be important in some cases, this fact does not lessen the necessity of giving it attention. This is especially true from the standpoint of demonstrating why the main wheel should be made without an overbalance, provided the dynamic augments on the remaining wheels can be kept within reasonable limits. The effect of the steam component is not less than several thousand pounds, in some cases greater than the effect of improper division of the main rod.

Dr. Eksergian in his discussion refers again to a suggestion which he made several years ago in his paper (13) concerning a mixed method of balancing. A portion of the revolving weight should be statically balanced and the remainder of the revolving weight should be cross-balanced by the dynamic method. He tries to prove that ultimately, if the reciprocating balance is also added, it would result in a smaller dynamic augment of the main wheel. This may be true, in so far as dynamic augments are concerned, but the balancing of reciprocating weights would be thus disturbed by the effect of revolving parts of the other side.

It is easy to prove by pure reasoning that Dr. Eksergian's proposition is a fallacy because no smaller dynamic augment, due to the counterbalance of revolving weights of both sides, can be obtained than by complete dynamic balancing of these weights. Then the dynamic augments on both wheels are equal to zero, if the counterbalances are properly angled. The dynamic augment due to the reciprocating balance, when properly angled, is as large as necessary for the balancing of these parts and the sum of zero and the dynamic augment will be minimum for maximum effective balancing. As stated at the beginning of this closure, no better system than the orthodox cross-balancing method of all revolving weights and part of the reciprocating weights has yet been devised for two-cylinder locomotives. Any change in this system will lead to greater dynamic augments or a lesser balancing of reciprocating weights, or both. This fact will be clearer after studying the statement in reply to Messrs. L. H. Fry and L. B. Jones.

In conclusion, Dr. Eksergian recommends retaining the static balance of revolving weights on coupled drivers, the mixed cross-balancing of revolving weights, with static balancing of the rest

[23] Bibliography (13) of paper; discussion, pp. 84–85.

of the revolving weights on the main drivers, and static balancing of a certain percentage of the reciprocating weights. The mixed balancing of the main drivers will involve just as much work as the total cross-balancing of the same drivers. The static balancing of the coupled drivers would probably reduce the work of the calculator 1 or 2 hr for a new locomotive design, but would also introduce new disturbing forces in the locomotive and a confusion in the mind of the operator. No advantage can result from this mixed procedure.

In substance, Mr. Fry's discussion calls for very littly reply. Referring the unbalanced force rather than the balancing force to the weight of the locomotive is a logical thing to do, if it can be done conveniently and practically. With the rapid changes in the design of steam locomotives, this coefficient varies. It will be different if a friction-damping coupler, such as the Franklin Railway Supply E-2 coupler, is used. This eliminates the propagation of shaking forces to the cars of the train and makes them unnoticeable (see the reply to Dr. Winterrowd's discussion later); also with the improvements in the guiding of locomotives; with increase in length and moment of inertia of the locomotives, this percentage will be continually dropping. Nevertheless, it will always be necessary to watch the dynamic augment; in other words, double work, always properly done, would be required. Therefore, if there is any objection to the use of dynamic balancing because of the complication introduced, more objection may be leveled at the proposition of referring the unbalanced force to the weight of the locomotive. However, the author does not see any objection to doing this or why balancing of locomotives from this angle should not be investigated.

However, as to Mr. Vaughan's proposition of substituting for overbalances in one wheel, two half-size balances in each wheel, no advantage can be gained toward balancing the locomotive.

Referring to Fig. 16 of Mr. Fry's discussion, scheme (*B*) represents static balancing of a reciprocating weight of 100 lb with a static balance of 100 lb. The shaking force is zero, the nosing moment, when the left-hand crank is at its dead center, is $100 \times 73 - 100 \times 62 = 1100$ in-lb. Scheme (*C*) represents dynamic balancing. Under the same conditions as above, the shaking force is $100 + 18 - 118$, or zero, and the nosing moment $100 \times 73 - 118 \times 62$, which is also zero. Scheme (*D*) represents the Vaughan method. It is true the shaking force is then $100 - 50 - 50$, or zero, but the nosing moment is $100 \times 73 - 50 \times 62 = 4200$ in-lb, or 3.82 times greater than in (*B*), and the dynamic augment, as given by Mr. Fry, is 70.7 lb, multiplied by the coefficient as in the paper. In other words, better results can be accomplished by balancing *statically* 29.3 per cent of the 100-lb reciprocating weights. In this case the nosing moment would have been $100 \times 73 - 70.7 \times 62 = 7300 - 4383 = 2917$ in-lb, or only 2.65 times greater than in (*B*), instead of 3.82 times greater as in Vaughan's method of counterbalancing. The dynamic augment would be 70.7 lb, as in Vaughan's method. In other words, by ordinary static balancing, with the same dynamic augment, a smaller nosing moment would result. Of course, as good balancing would not be derived as in (*C*) dynamic, when both shaking and nosing are zero. Next in quality of balance is (*B*) orthodox static balancing. This proves the contention of the author that for a two-cylinder locomotive, nothing better as yet has been devised than cross-counterbalancing of 100 per cent of the revolving weights plus partial cross-balancing of reciprocating weights to the limit of dynamic augment the track can stand.

Mr. L. B. Jones introduces his discussion with a statement to the effect that the author's application of the cross-balancing method requires a great amount of calculation, if the designer wishes to explore carefully all the effects of counterbalancing. The author is satisfied that by the numerical example given in the paper, he has demonstrated how simple the correct cross-balancing of any locomotive actually is. Such a calculation is certainly worth carrying out, because the subsequent corrections, after the locomotive has been built, namely, changing counterbalances, replacing kinked or broken rails, and the less visible maintenance of locomotive and track, result in much greater costs than the original calculation. Mr. Jones has not advanced a reasonable argument; a complete exposition of the matter would be necessary to establish proof that his suggestion gives better results.

Mr. Jones introduces, in his discussion, curves which represent an analysis of a theoretical study made of a K4s Pennsylvania locomotive before it was tested at the locomotive-testing plant in Altoona. The most interesting curve is Fig. 20, which gives the component in the plane of one wheel, say, right, of centrifugal forces of all revolving weights, including the revolving balances in both wheels, as a function of the percentage of balancing of reciprocating parts. While the locomotive is statically balanced, the analysis is made on the basis of the theory of dynamic balancing; i.e., taking into account the various planes, studying both couples and forces. In other words, the analysis is more complex than the counterbalancing itself, as any one who tries to make such an analysis will discover. If certain rules, previously familiarized, are followed, cross-balancing is much simpler.

Referring again to Fig. 20, when the percentage is zero and there is no reciprocating balance, the action of the revolving weights of the locomotive on both sides is 24,314 lb. In Fig. 23 of this

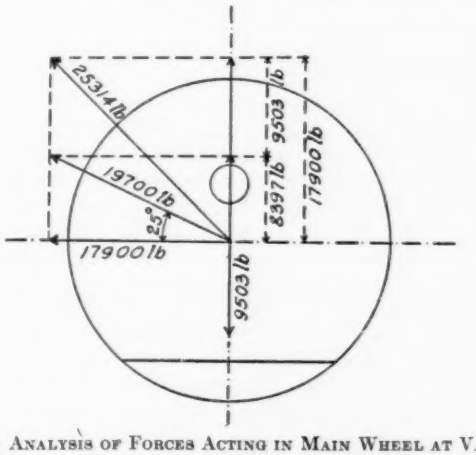

FIG. 23 ANALYSIS OF FORCES ACTING IN MAIN WHEEL AT VARIOUS PERCENTAGES OF RECIPROCATING BALANCE, COMPUTED AT 400 RPM

closure, the small circle on the vertical radius represents the upward position of the right-hand crankpin. The static balancing of the right side will result in a deficiency of 282 lb, a figure to which Mr. Fry also refers in his discussion. The centrifugal force of the right-hand revolving weights is 17,900 lb at 400 rpm, as a result of the deficiency. At the same time, the left-hand revolving weights also give a component at the right-hand wheel directed horizontally backward (the left-hand pin leading) of 17,900 lb, which, together combine into a centrifugal force of 25,314 lb at an angle of 45 deg as shown in Fig. 23. So far it has been assumed that there is no balancing of reciprocating parts whatever (zero per cent of balancing). Now suppose that we have 30 per cent static balancing of the reciprocating parts. As the total reciprocating weights on one side of the locomotive are 1500 lb, 30 per cent balancing for one wheel (150 lb) represents, at 400 rpm, a force directed downward of 9503 lb. Consequently, we still have in the right wheel a force directed upward equal to the difference of the two, which is 8397 lb, as shown in Fig. 23. As the action of the revolving weights from the left side results in 17,900 lb directed horizontally, the compound action gives 19,700 lb at an

angle of 25 deg. The magnitude of this deficiency of 19,700 lb is correctly given by Mr. Jones in his Fig. 20; only he calls it dynamic augment, although it is not directed downward and will have the tendency to lift the wheel.

At 56.4 per cent balancing, a centrifugal force of the balance in the right wheel is again directed downward and is greater than before. It is equal to 17,900 lb, which cancels the centrifugal force of the revolving-weight component directed upward. At the same time, from the left side the action of revolving weights gives a horizontal, backwardly directed component of 17,900 lb and thus the total resultant of all revolving weights and the counterbalance in right wheel is 17,900 lb directed horizontally.

It is easy to see that, when the pin on the right side is in the highest position, the reciprocating weights on the right side are in the middle position and the inertia force is, therefore, equal to zero. Consequently, when the horizontal force is 17,900 lb, there is no reciprocating force on the right side to be balanced. There is only a shaking force of 17,900 lb at the maximum percentage of balancing (56.4 per cent). At the same time, the left pin is in its extreme forward position. The combined effect of the left-hand-revolving weights, left-wheel balance, and the action of the right-hand side on the left wheel results likewise in a force, which is now a vertical force of 17,900 lb—a real dynamic augment. The left-hand inertia force of 56.4 per cent of the reciprocating weights of one wheel (500 lb) has at that time its maximum, also 17,900 lb directed forward, with no horizontal balance to take care of the force, because the balance has been used up, so to speak, for the action from the other side.

Thus, combining the two sides, for one axle two horizontal and oppositely directed forces result, which, true enough, will be balanced in so far as shaking is concerned. However, taking place simultaneously on the right and left sides of the locomotive, they will give an additional couple to the unbalanced couple around the vertical axis through the center of gravity, or a total nosing couple with a moment of $31{,}700 \times 44.5 + 17{,}900 \times 31 = 1{,}965{,}000$ in-lb. In this instance 31,700 lb is the inertia force of 500-lb reciprocating weights on the left side, and 17,900 lb is the above component of all centrifugal forces in the right wheel. The dynamic augment on either wheel will be 17,900 lb.

If the Pennsylvania locomotive were cross-balanced with the same maximum dynamic augment of 17,900 lb and the reciprocating weights, as in the example just given, were 500 lb per wheel, the total percentage of balancing reciprocating weights referred to the cylinder center planes, would be 46.0 and the unbalanced moment around the vertical axis through the center of gravity of this cross-balanced locomotive would be only 755,620 in-lb. The high figure of 56.4 per cent, which is necessary for these locomotives on the Pennsylvania Railroad, is probably due to the peculiar system of balancing which results in forces directed opposite to what they should be, causing more disturbance than balancing. If the locomotive were cross-balanced, probably not more than 30 per cent balancing of reciprocating weights would be required. Then a dynamic augment of 11,590 lb would not be exceeded and a moment around the vertical axis through the center of gravity of only 987,190 in-lb would be obtained.

The foregoing results in reference to the Pennsylvania K4s locomotive are summarized as follows:

Method of balancing both revolving and reciprocating weights	Reciprocating balance, per cent	Dynamic augment, lb	Unbalanced nosing moment, in-lb
Static	56.4	17900	1965000
Dynamic	46.0	17900	755620
Dynamic	30.0	11590	987190

The most astonishing and probably most unexpected result of the above static balancing is the following:

The inertia forces of the reciprocating weights on one side of the locomotive are not balanced by the reciprocating balance over the revolving weights, placed in the adjacent wheel on the same side of the locomotive, but by the resulting dynamic reactions in the wheel of the other side. The arms of the balancing moments are, therefore, very large; they reach almost the entire width of the locomotive.

The foregoing applies to 56.4 per cent balancing of reciprocating weights, where the straight line intersects the curve in Mr. Jones's Fig. 20. For zero per cent balancing, the right-wheel reaction is greater, namely, 25,314 lb, Fig. 23, with the same horizontal component, but 45 deg out-of-phase with the inertia forces of the reciprocating weights. At 30 per cent balancing, it will be 19,700 lb with 25 deg out-of-phase.

It is quite different in the case of dynamic balancing when the angling of reciprocating counterbalances in each wheel places the balancing force in a position exactly opposite the crankpin in each side. By this method, the best possible balance of the reciprocating weights on each side of the locomotive is obtained, at an arm from the wheel plane to the plane of the cylinders. This results in smaller arms for balancing moments, and smaller stresses being transferred from one side of the locomotive to the other through the driving axles. Consequently, the axle stresses will be lower than in statically balanced locomotives. It also reduces the unbalanced nosing moments, as can be seen from the table summarizing the Pennsylvania K4s results, without any increase in dynamic augments.

Dr. Winterrowd's contribution is very interesting as it shows how the mass of the tender can be made to take part in the total mass of the locomotive and thus reduce the shaking effect of reciprocating weights. If this can be conveniently done and the horizontal and vertical vibration reduced as shown on his charts by the application of the E-2 spring-controlled-friction radial buffer, the percentage of balancing reciprocating weights can be reduced, with resulting decrease in the dynamic augment and the consequent track stresses.

Prof. E. G. Young's discussion is very pertinent. His suggestion regarding the calculation of revolving weights in so far as wheels are concerned, is much to the point and has been for years taken care of by locomotive builders. His complaint about the miscalculation of the distribution of weight of the main rod is well taken, and already has been discussed in this closure.

The Resistance to Relaxation of Materials at High Temperature[1]

By ERNEST L. ROBINSON,[2] SCHENECTADY, N. Y.

Relaxation tests at high temperature give direct information on the permanent tightness of bolted joints and shrinkage assemblies. They also give direct measurements of the effectiveness of strain-relief anneals. Indirectly they give, in relatively short time and small furnace space, reliable information on long-time constant-stress behavior although direct computation of either type of performance from the other is uncertain. In relaxation tests, total strain is definitely limited, whereas, creep rates based on constant-stress tests may, but do not necessarily, correspond to excessive amounts of strain, thus giving too optimistic indications of strength. Although advantageous, relaxation tests do not take the place of constant-stress tests. A simple formulation for relaxation is given which holds good for considerable periods although rather sudden changes of trend suggest the possibility of physical changes in the material which are not easily predictable in advance. Test results are given on six materials at various temperatures.

THE CONDUCT of relaxation tests under the sponsorship of the "Joint Committee"[1] was authorized in December, 1936, and the Subcommittee[3] for Project 16 was organized early in 1937. Relaxation tests relate directly to the applicability of materials for service involving elastic action at high temperature. Such service includes all types of bolted joints and all sorts of assembly depending on a shrink fit or a pressed fit for tightness. Such tests also contribute information of a less specific nature as to the general metallurgical behavior of materials at high temperature.

This project formed a part of the larger program of the Joint Committee at a time when its activities were being expanded to include, in addition to the accumulation of results on creep strength in simple tension, information on performance in pure shear and on the important case of compound stress existing in pipes and boiler drums where the hoop stress is twice the axial stress.

Therefore in order to facilitate useful comparisons as to the performance of a material under different types of service, the Subcommittee on Relaxation has scheduled tests on each of the various materials being sponsored by the Joint Committee regardless of its special suitability for bolting or other elastic service. However, certain other tests have been included on their own merits.

Table 1 gives a complete schedule of relaxation tests so far completed as a part of Project 16.

Table 2 summarizes the chemical compositions, heat-treatments, and physical properties of the six materials tested. Of these Nos. 1, 4, and 5 were regular Joint Committee materials more completely described in the references accompanying Table 2.

No. 2 was a wrought carbon steel tested by the General Electric Company. This was included because the original program of the Joint Committee drawn up in 1936 had contemplated testing carbon steel at 750 F. However, the need of keeping the program within the resources of the committee led to the abandonment of such tests. Although material No. 2 is not identical with any other material tested by the Joint Committee it represents a composition about which information is desired and hence is included for comparison with the other materials.

No. 3 was S.A.E. 4140 steel furnished by the Westinghouse Electric and Manufacturing Company and No. 6 was a steel of similar composition furnished by the General Electric Company. These were the only materials tested by Project 16 which were especially adapted for bolting material and only a stress-relief-anneal test is given for No. 6.

Thus the subcommittee would like to reiterate that the materials on which results are presented were not chosen for their high creep strength in elastic service. It is possible that the relaxation-test program may be extended in the future to include materials more especially intended to maintain elastic tightness at high temperature.

General Characteristics of Relaxation Tests

Several methods of running relaxation tests are represented by the results presented in this report. However all of them have functional significance and, although this method of testing lends itself to the rapid accumulation of a bulk of results at various stresses, the tests reported herewith were not intended solely to shorten the time of testing. Extrapolation, under any guise, requires caution.

There are a number of good reasons for the conduct of relaxation tests regardless of their direct applicability to machine performance. In the early stages of creep some form of progressive strengthening appears always to take place so that, even without relaxation of stress, the rate of flow decreases with time. This is frequently called "the first stage" of creep as distinguished from the "second stage" where the rate stays constant for a relatively long time. Relaxation tests with direct applicability to machines are usually of necessity completed within the range of total deformation where progressive strengthening is still taking place. There is thus no danger of basing results on specimens which have been subjected to strains which never would be allowed in service.

Of course, constant-stress tests may be extrapolated by plotting the stress against time to attain a specified total extension on log-log paper. Such an interpretation of constant-stress data avoids the objection just raised of basing conclusions on tests in which the material has been overstrained. Relaxation tests have the definite virtue of automatically limiting total extension while in their later stages they approach more and more closely

3 Values for modulus of elasticity assumed.
4 Stress-relief-anneal test.

Initial Strain and Initial Stress. When both quantities have been measured directly, the modulus of elasticity is found by dividing the stress by the strain. Where only one of the two has been measured, the other is computed from an assumed modulus of elasticity.

The elasticity factor b is the ratio of the total elastic deformation of the system to that of the bar subjected to creep. Thus, an elasticity factor of 1.0 represents the performance of a bolt in an unyielding flange, while an elasticity factor of 5.0 represents the performance of a bolt in a flange possessed of four times the elastic deformation of the bolt so that the entire system has five times the elastic deformation of the bolt alone. See Fig. 1.

The rate-stress index n is the slope of the line resulting on log-log paper when the stress is plotted against the rate of creep. See Figs. 16, 17, 18. The slope of the stress-time lines given in the log-log plots of Figs. 2 to 14 is $(n-1)$.

The residual stress for a certain number of hours is a measure of the bolt performance of the material. At the lower temperatures the residual stress corresponding to 10,000 hr has been given. At the higher temperatures where the tests approach the conditions of stress-relief anneal rather than bolt performance shorter comparative times have been selected. While this makes direct comparison difficult, it was felt that there was no particular object in comparing the performance of the high-temperature materials with those used at lower temperatures. The residual stresses given in the table, in all cases, refer to performance with an elasticity factor of 1.0. In cases where the test was run with elastic follow-up the actual residual stresses would be higher and may be determined by reference to the several diagrams.

The nominal creep strength is expressed in pounds per square inch for a creep rate of one millionth of the length per hour, that is, a rate of 1 per cent per 10,000 hr. For comparison with similar values determined from constant-stress tests, see Table 3.

to constant-stress conditions. Less caution is required in drawing conclusions from such tests than from well-made high-strain tests which are prone to show the material better than it actually is as used.

Step-Down Tests at Constant Extension

At the laboratory of the General Electric Company relaxation tests are run by what is ordinarily referred to as the "flow-rate" method, because individual rates are measured during each of the several steps. A similar procedure was used at the Massachusetts Institute of Technology in running the test for The Babcock and Wilcox Company except that the load was reduced in very small decrements. This more nearly approaches continuous relaxation although direct measurements of rate are not so easy.

These tests are run in the same furnaces ordinarily used for constant-stress work in which the load is applied by weights on a lever. After the furnace is brought up to temperature the stress is applied by adding weights and the elastic extension is noted as each weight is applied. The modulus line is plotted as elastic extension occurs and any deviation indicating the appearance of plastic flow is immediately evident.

As soon as the predetermined total extension corresponding to the initial stress in the bolt has been reached, the stress is reduced and the relaxation test begins. Creep occurs at constant stress to the predetermined limit after which the stress is again reduced and so on in successive steps. Each step suffices to give a rate corresponding to the applied load, and the entire process approximates the performance of a bolt in an unyielding flange, with the entire elasticity of the system being included within the member in which the plastic action occurs.

When large steps are taken, there is usually a period of a day or two during which a certain amount of recovery or shortening of length occurs. If credit is taken for this recovery in analyzing the results of the test the corresponding computed bolt strength is likely to be somewhat higher than if no credit is taken for such recovery.

Bolt Tests in Test-Block Assembly

At the South Philadelphia Works of the Westinghouse Electric and Manufacturing Company, some relaxation tests are made by assembling an actual bolt in a test block having approximately 30 times the cross section of the bolt.[4] The assembly is placed in the test furnace and the actual change of length measured after an elapsed period of time. While this method does

[4] At the Westinghouse Research Laboratories, East Pittsburgh, Pa., an automatic relaxation machine has been used. See "Relaxation of Steels at Elevated Temperatures—A New Automatic Relaxation Machine," by A. Nádai and J. Boyd, *Journal of Applied Mechanics*, Trans. A.S.M.E., vol. 60, September, 1938, p. A-118.

DIAGRAMMATIC SKETCHES OF ELASTIC BOLTS

not facilitate readings of extension at intermediate intervals, equivalent information is secured by starting a series of identical assemblies in test together and withdrawing them after successively longer periods of time. This test has the merit of reproducing actual conditions with fidelity. The total elasticity of the system is practically identical with that of the bolt subject to plastic action although other arrangements are possible.

TESTS WITH EXTRA ELASTIC FOLLOW-UP

At Crane Company laboratory tests have been run in a machine which simulates the action of a bolt in a flange possessed of considerable elasticity such that the stretching of the bolt only partially results in relaxation of the initial stress.[5] In the Crane machine the total elasticity of the system is five times that of the specimen in which the plastic action occurs. Continuous readings on a "weigh bar" at room temperature indicate the elastic stress effective at any time. Fig. 1 illustrates this type of test diagrammatically. At (*a*) and (*b*) are shown bolts without and with extra elastic follow-up.

Tests with extra elastic follow-up are also practicable using the methods employed by the General Electric Company, by The Babcock and Wilcox Company at Massachusetts Institute of Technology, and by the Westinghouse Electric and Manufacturing Company. Of the two tests on No. 5 material, 4-6-Cr–Mo tubing, by the General Electric Company, one was run with a system elasticity factor of 1.0 and the other with a factor of 3.0. This result is approximated in the step-down method by noting the elastic recovery after each stress reduction and requiring three times as much plastic extension before the next stress reduction.

FORMULATION OF RELAXATION BEHAVIOR

In order to facilitate application, the results of ordinary relaxation tests can usually be interpreted satisfactorily by the following fairly simple formulas which relate elapsed time with residual stress or elastic extension.

$$t = \frac{b}{(n-1)\,r_0}\left(\frac{S_0}{E}\right)^n\left[\left(\frac{E}{S}\right)^{n-1} - \left(\frac{E}{S_1}\right)^{n-1}\right] \quad \ldots\ldots [1]$$

$$t = \frac{b}{(n-1)\,r_0}\,x_0^{\,n}\left[\frac{1}{x^{n-1}} - \frac{1}{x_1^{\,n-1}}\right] \quad \ldots\ldots [2]$$

NOMENCLATURE

t = elapsed time, hr
b = ratio, total system elasticity to that of creep bar
n = per cent increase in creep rate per per cent increase in stress
E = modulus of elasticity, psi
r_0 = nominal rate of creep; 1 millionth of length per hr
S_0 = nominal strength, psi to cause r_0
S_1 = initial stress, psi
S = residual stress, psi after time t
x_0 = elastic extension corresponding to nominal strength S_0
x_1 = elastic extension corresponding to initial stress S_1
x = residual elastic extension after time t

These formulas simply represent the usual test results in which a stress-time plot on log-log paper, shown in the lower half of Figs. 2 to 14, is a straight line of slope $(n-1)$. This behavior is consistent with the usual straight line for the rate-stress plot on log-log paper of slope n but the value of n is not the same as given by a series of constant-stress tests. It is likely to be larger, corresponding to a flatter log-log line than the constant-stress test although the results given in Figs. 17 and 18 do not show this trend.

Examination of these formulas shows that they represent the difference of two time quantities. For an initial elastic extension which is large in comparison with the residual extension, the second term may be omitted. Hence, for year-long bolt performance the following expressions are satisfactory

$$t = \frac{b\,S_0^{\,n}}{(n-1)\,r_0\,E S^{n-1}} \quad \ldots\ldots [3]$$

$$S = \sqrt[n-1]{\left[\frac{b\,S_0^{\,n}}{(n-1)\,r_0\,E\,t}\right]} \quad \ldots\ldots [4]$$

[5] "Interpretation and Use of Creep Results," by J. J. Kanter, Trans. American Society for Metals, vol. 24, Dec., 1936, pp. 901–903.

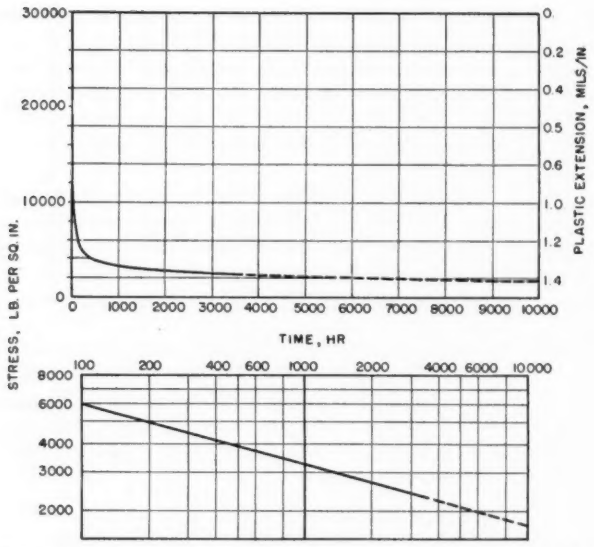

FIG. 2 GENERAL ELECTRIC STEP-DOWN TEST. MATERIAL 1, BAR 14A5, ANNEALED 0.35 PER CENT CARBON STEEL K20, 850 F

Measured elastic modulus E = 20,000,000 psi.
Constant elastic-plus-plastic extension = 1.5 mils per in.
Elasticity factor b = 1. Stress-rate index n = 4.7.
Computed 10,000-hr residual stress = 1700 psi.
Creep strength for rate of 1 millionth per hr = 6200 psi.

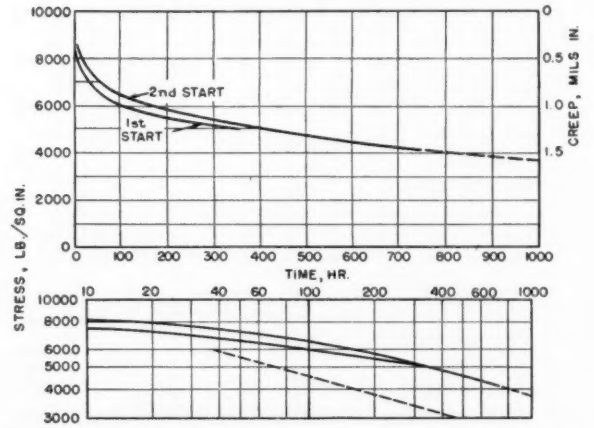

FIG. 3 CRANE CONTINUOUS RELAXATION TEST. MATERIAL 1, BAR 342, ANNEALED 0.35 PER CENT CARBON STEEL K20, 850 F

Measured elastic modulus E = 20,000,000 psi.
Constant elastic-plus-plastic extension = 2.5 mils per in.
Elasticity factor b = 5. Stress-rate index n = 4.5.
Computed 10,000-hr residual stress, (b = 1) = 1260 psi.
Creep strength for rate of 1 millionth per hr = 5130 psi.

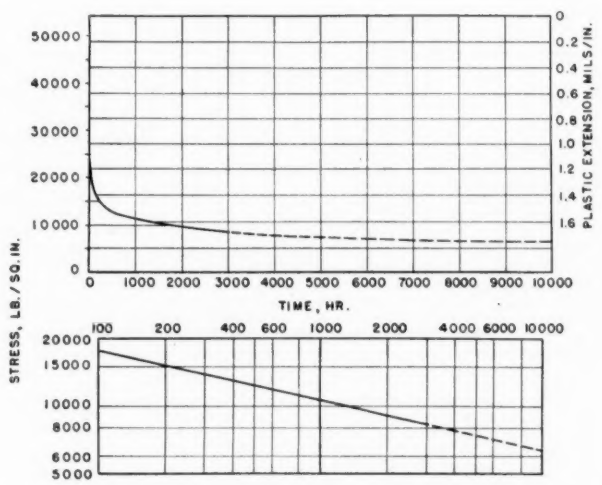

FIG. 4 GENERAL ELECTRIC STEP-DOWN TEST. MATERIAL 2, BAR 462, WROUGHT 0.58 PER CENT CARBON STEEL, 750 F

Measured elastic modulus E = 27,200,000 psi.
Constant elastic-plus-plastic extension = 2.0 mils per in.
Elasticity factor b = 1. Stress-rate index n = 5.6.
Computed 10,000-hr residual stress = 6400 psi.
Creep strength for rate of 1 millionth per hr = 16,400 psi.

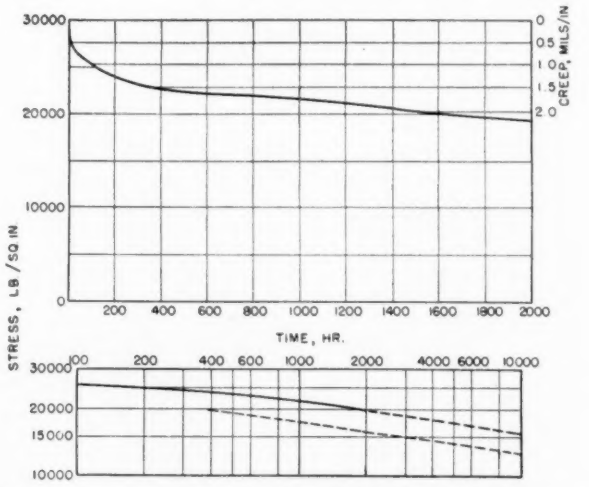

FIG. 5 CRANE CONTINUOUS RELAXATION TEST. MATERIAL 3, BAR 368, S.A.E. 4140, 850 F

Assumed elastic modulus E = 24,000,000 psi.
Constant elastic-plus-plastic extension = 6.25 mils per in.
Elasticity factor b = 5. Stress-rate index n = 8.5.
Computed 10,000-hr residual stress, (b = 1) = 12,800 psi.
Creep strength for rate of 1 millionth per hr = 23,000 psi.

Formula [3] is also satisfactory to give the time required for an annealing cycle in order to assure elimination of all stresses above a prescribed value.

Relaxation tests in various forms have been used to determine a nominal creep strength for comparative purposes. One of the objects of Project 16 is the comparison of such values with values determined in other ways. For this purpose formula [3] may be rearranged thus:

$$S_0^n = (n-1)\, r_0 E t S^{n-1}/b \quad \ldots\ldots [5]$$

TEST RESULTS

In presenting the results of the various tests sponsored, it has not seemed desirable to give elaborate records showing every test point in detail. Such a procedure would have emphasized the differences of method; whereas it seemed better to show the derived performance given by all tests according to some uniform scheme which would facilitate comparison and eliminate differences in so far as possible except such as characterize the actual behavior of the test bars.

In each case the stress-time relaxation curve is given using ordinary scales with uniform divisions. At the right of the diagram the plastic extension or creep is shown, increasing as relaxation of stress occurs. In all cases the bottom of the diagram is the zero for stress and in all except Figs. 12 and 13, the top of the diagram is the zero for creep.

Immediately below the relaxation curve, the stress-time relation is plotted on log-log coordinates in order to show the agreement with or departure from the rules represented by the formulas.

Where the elasticity factor is greater than 1, a dotted line has been drawn on the log-log plot to represent the corresponding behavior with unit elasticity. According to the formulation,

when the system elasticity is b times that of the part subject to creep, it takes just b times as long to relax to any particular stress level. The corresponding lines are parallel and separated by a distance equal to the logarithm of the ratio b.

The test results not only illustrate the characteristic behavior of materials when called upon to maintain elastic tightness at high temperature but also show a number of characteristic vagaries. The formulation corresponding to the straight line on the log-log plot is amply justified over extended periods of time but it cannot be extrapolated indefinitely in either direction. The direction of the line is likely to change. Material may appear to strengthen or to weaken as time goes on. Both the rules and the deviations from them are evidenced by the results presented on different materials. Furthermore different laboratories working in quite different ways agree both as to general trends and as to the deviations that may be expected.

Strengthening. Both material 3, S.A.E. 4140 at 850 F tested in a series of test blocks (Fig. 6), and material 4, carbon-molybdenum tubing at 800 F tested in continuous relaxation (Fig. 8), show apparent "creep limits" below which further relaxation fails to occur. It is possible that more precise methods of testing would show some relaxation still going on but the evidence as it stands points to a definite strengthening after several weeks.

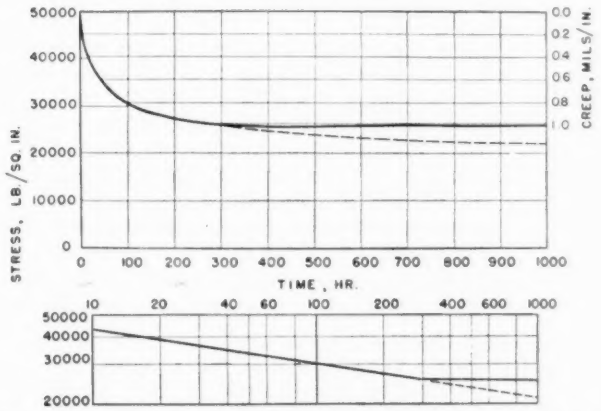

FIG. 6 SERIES OF TESTS IN WESTINGHOUSE TEST-BLOCK ASSEMBLY. MATERIAL 3, S.A.E. 4140, 850 F

Assumed elastic modulus E = 24,000,000 psi.
Constant elastic-plus-plastic extension = 2.15 mils per in.
Elasticity factor b = 1.03. Stress-rate index n = 7.8.
Computed 10,000-hr residual stress = 15,350 psi (dotted line).
Creep strength for rate of 1 millionth per hr = 27,860 psi.
Apparent creep limit = 25,800 psi.

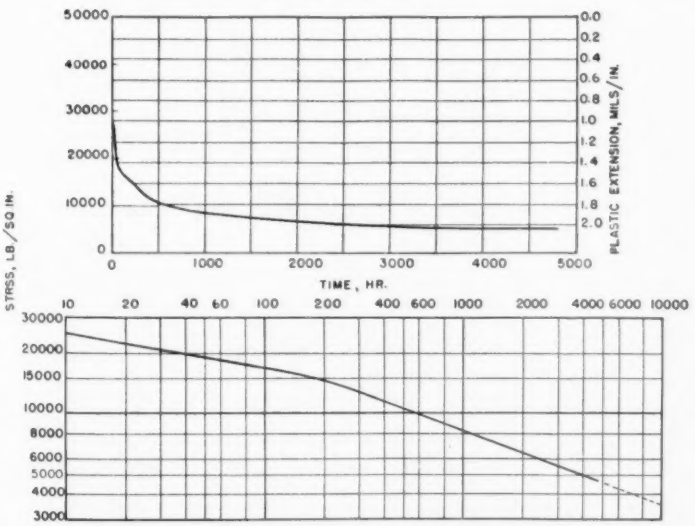

FIG. 7 SERIES OF TESTS IN WESTINGHOUSE TEST-BLOCK ASSEMBLY. MATERIAL 3, S.A.E. 4140, 930 F

Assumed elastic modulus E = 22,000,000 psi.
Constant elastic-plus-plastic extension = 2.15 mils per in.
Elasticity factor b = 1.03.
Stress-rate index n = 7 above 15,000 psi and 3.75 below.
Computed 10,000-hr residual stress = 3550 psi.
Creep strength for rate of 1 millionth per hr = 13,970 psi.

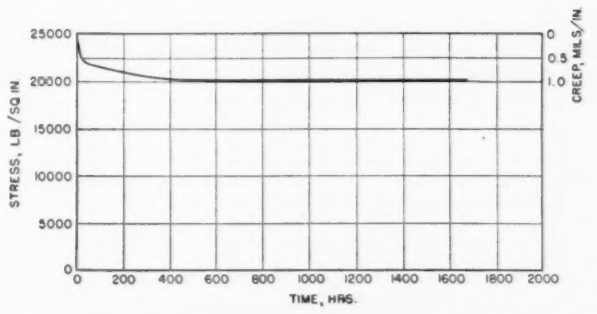

FIG. 8 CRANE CONTINUOUS RELAXATION TEST. MATERIAL 4, BAR 370–2, CARBON-MOLYBDENUM TUBING, 800 F

Assumed elastic modulus E = 25,000,000 psi.
Constant elastic-plus-plastic extension = 5.0 mils per in.
Elasticity factor b = 5.
Apparent creep limit = 20,000 psi.

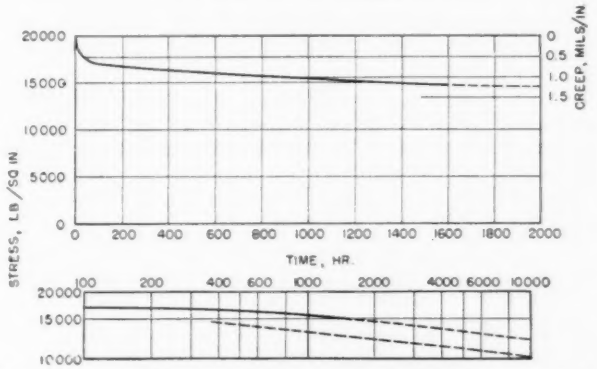

FIG. 9 CRANE CONTINUOUS RELAXATION TEST. MATERIAL 4, BAR 370–3, CARBON-MOLYBDENUM TUBING, 950 F

Assumed elastic modulus E = 22,000,000 psi.
Constant elastic-plus-plastic extension = 4.55 mils per in.
Elasticity factor b = 5. Stress-rate index n = 10.5.
Computed 10,000-hr residual stress, (b = 1) = 10,200 psi.
Creep strength for rate of 1 millionth per hr = 16,900 psi.

Another important type of strengthening appears in connection with successive tightening. A bolt is almost always more creep-resistant on its second tightening than at first. This effect is illustrated in Fig. 3 by the higher residual stresses after the second start.

Probably for similar reasons, higher initial stresses generally result in higher subsequent residual stresses. Another way of saying this is that tests run with larger values of specified constant elastic-plus-plastic extension give higher residual stresses after a certain stated time interval and indicate higher nominal creep strengths corresponding to a specified rate of extension. These effects certainly represent some form of progressive strengthening associated with the greater amounts of strain involved.

While the complete formulation [1] includes the initial stress and therefore appears to take account of various initial stresses, examination of the various test results is convincing that this formula cannot be used over a wide range without great discretion. Thus, with a test made with a certain total elastic-plus-plastic

extension, formula [1] may be used to compute behavior between any two stress levels covered by the test. But for service with a different total elastic-plus-plastic extension it is preferable to have a different test.

The only series of tests enumerated in the report that were run on the same material at the same temperature and the same elasticity factor but with several different initial stresses, that is, total elastic-plus-plastic extensions, are those indicated in the first three lines of Table 1, on 0.35 per cent carbon steel at 850 F. The effects mentioned were noted by the Westinghouse Company in the references cited with Table 1.

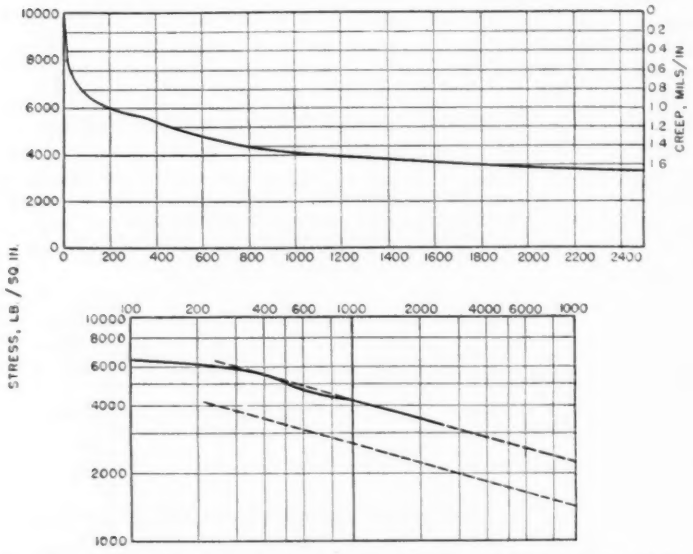

FIG. 10 CRANE CONTINUOUS RELAXATION TEST. MATERIAL 4, BAR 370–1, CARBON-MOLYBDENUM TUBING, 1050 F

Assumed elastic modulus E = 20,000,000 psi.
Constant elastic-plus-plastic extension = 2.5 mils per in.
Elasticity factor b = 5.
Stress-rate index n = 4.55 below 5500 psi.
Computed 10,000-hr residual stress. (b = 1) = 1400 psi.
Creep strength for rate of 1 millionth per hr = 5500 psi.

Weakening. Material 1, annealed 0.35 per cent carbon steel K20 tested in continuous relaxation (Fig. 3) shows an almost continuously curving line on the log-log plot. If all the results were like this, it would have to be considered typical and a different formulation sought. However, since the straight line is more typical, this curving over may be thought of as a progressive weakening tendency relative to a straight line at a former slope. Eventually the line in the lower half of Fig. 3 attains pretty nearly the same slope as in Fig. 2 and, if the elasticity factor had been somewhat smaller in Fig. 3 the two tests would have agreed even more closely.

More typical tendencies to shift to a new and weaker trend are shown by material 3, S.A.E. 4140 at 930 F tested in a series of test blocks (Fig. 7); material 4, carbon-molybdenum tubing at 1050 F tested in continuous relaxation (Fig. 10); and in the step-down test with many small steps (Fig. 11); and material 5, 4-6 Cr–Mo tubing at 1200 F tested in the step-down test with unit elasticity (Fig. 12) and with an elasticity factor of 3 (Fig. 13). In all these cases a fairly definite trend maintained for a period of some days, then shifts to a new trend with something of a knee in the log-

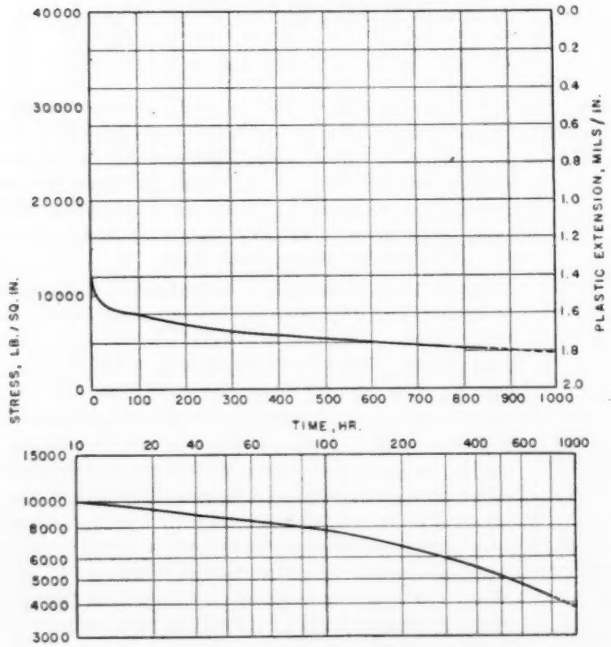

FIG. 11 BABCOCK & WILCOX STEP-DOWN TEST. (MANY SMALL STEPS.) MATERIAL 4, CARBON-MOLYBDENUM TUBING, 1050 F

Assumed elastic modulus E = 20,000,000 psi.
Constant elastic-plus-plastic extension = 2.0 mils per in.
Elasticity factor b = 1.
Stress rate index n = 9.2 above 6800 psi and 3.5 below.
Computed 10,000-hr residual stress = 1530 psi.
Creep strength for rate of 1 millionth per hr = 8000 psi. (Based on trend at lower stresses.) This test is being continued beyond the 850 hr shown here and future results may require revision. (See Fig. 26.)

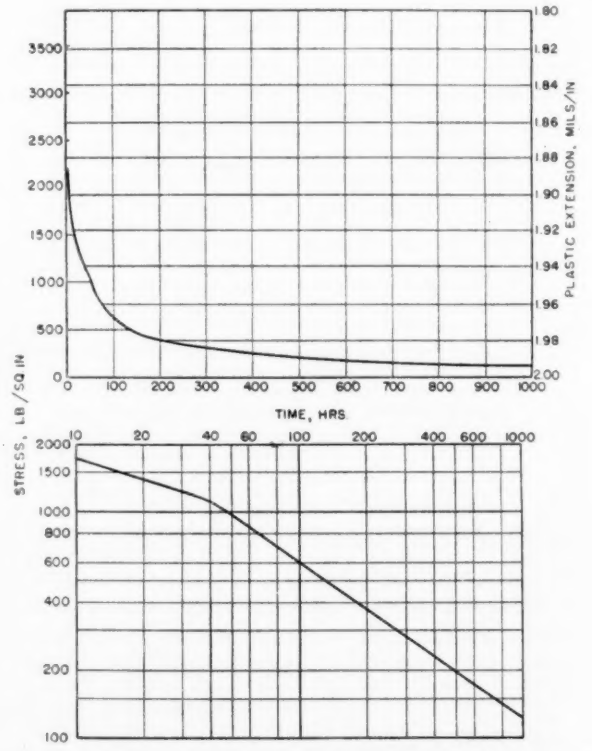

FIG. 12 GENERAL ELECTRIC STEP-DOWN TEST. MATERIAL 5, BAR 3–1, 4–6 CR–MO TUBING, 1200 F

Measured elastic modulus E = 19,400,000 psi.
Constant elastic-plus-plastic extension = 2.0 mils per in.
Elasticity factor b = 1.
Stress rate index n = 4.2 above 1120 psi and 2.5 below
Residual stress after 1000 hr = 125 psi.
Creep strength for rate of 1 millionth per hr = 1110 psi.

log plot. This change may appear in the ordinary relaxation plot in the upper halves of the diagrams as a sort of flattening when one hyperbolic curve gives way to another or it may appear as an actual dent as in Fig. 13.

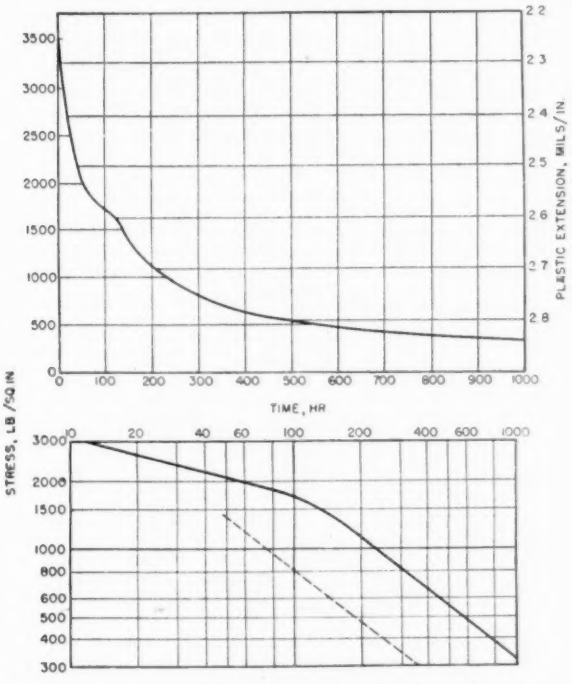

FIG. 13 GENERAL ELECTRIC STEP-DOWN TEST. MATERIAL 5, BAR 3-7, 4-6 CR-MO TUBING, 1200 F

Measured elastic modulus E = 16,200,000 psi.
Constant elastic-plus-plastic extension = 2.9 mils per in.
Elasticity factor b = 3.
Stress rate index n = 5.0 above 1670 psi and 2.25 below.
Computed 1000-hr residual stress, (b = 1) = 135 psi.
Creep strength for rate of 1 millionth per hr = 1240 psi.

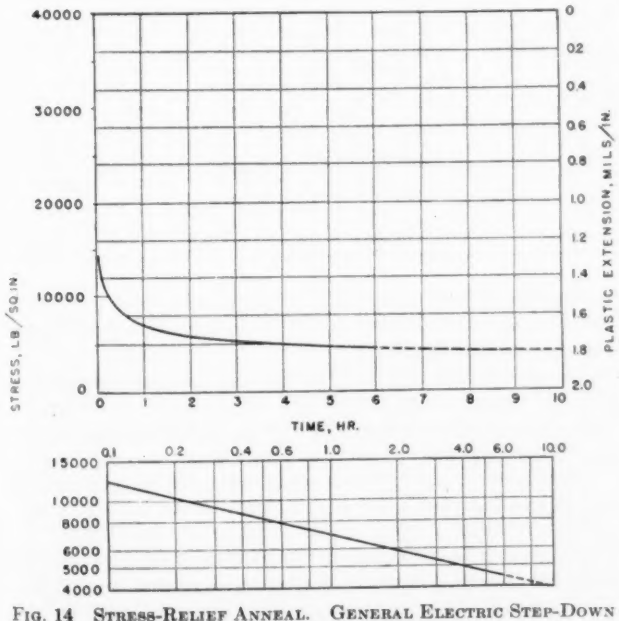

FIG. 14 STRESS-RELIEF ANNEAL. GENERAL ELECTRIC STEP-DOWN TEST. MATERIAL 6, BAR 550, S.A.E. 4140, 1112 F, 600 C

Measured elastic modulus E = 20,000,000 psi.
Constant elastic-plus-plastic extension = 2.0 mils per in.
Elasticity factor b = 1. Stress-rate index n = 5.3.
Residual stress after 10 hr = 4000 psi.
Creep strength for rate of 1 millionth per hr = 3000 psi.

It is a fair question whether this alteration represents some metallurgical transformation or physical change within the material or whether the analytical relations chosen are too simple and some more complicated relationship would be better.

STRESS-RELIEF ANNEAL

The process of developing materials to resist creep at high temperature results actually in the development of materials which are difficult to anneal and hence require higher temperatures or longer periods of time or both to accomplish the same degree of stress relief. Thus if a modern creep-resisting material is good for 200 deg higher temperature, it will require just that much hotter anneal to accomplish stress relief in the same period of time. If there are good reasons why the annealing temperature should not be raised in accordance with the strength, then greater time periods are necessary.

Relaxation tests are, in fact, quantitative measurements of stress relief and, in their early stages if run at annealing temperatures, are no more nor less than direct measurements of the effectiveness of the anneal.

The test on material 6, S.A.E. 4140 at 1112 F, 600 C, shows the early stages of relaxation or, in other words, the effectiveness of the annealing action. This test was not run long enough to see if the trend which characterizes the first few hours of behavior would continue unchanged. It is just as important to use a short-time test to predict short-time performance as to use a long-time test to predict long-time performance.

COMPARISON WITH CONSTANT-STRESS TESTS

A few comparisons are possible at this time between relaxation tests and constant-stress tests. (It is to be hoped that some time in the future more complete comparisons will be prepared for the several materials sponsored by the Joint Committee showing how they behave under different conditions of loading and different methods of test.) The prediction of bolt tightness or the determination of adequate time for stress relief is difficult from constant-stress tests. Similarly it is difficult to predict long-time constant-stress behavior from a relaxation test.

In its final stages a relaxation test is likely to approach constant-stress conditions but long-time behavior at the higher stresses is not so well indicated because of the short periods at which such stresses are sustained.

It should also be pointed out that a relaxation test with an elastic follow-up is intermediate between a relaxation test with constant elastic-plus-plastic strain and a constant-stress test.

Fig. 15 shows the relations between constant-stress tests and relaxation tests for material 1, annealed 0.35 per cent carbon steel K20 at 850 F. Specimen 10A1 was tested at Battelle Memorial Institute under a constant stress of 10,000 psi. Specimen 342 was tested in continuous relaxation at Crane Company with an initial stress of 10,000 psi and an elasticity factor of 5. This test duplicates Fig. 3. Specimens 3 and 4 were tested in test-block assembly by the Westinghouse Electric and Manufacturing Company with an initial stress of 10,000 psi and an elasticity factor of 1.03.

Fig. 15 illustrates the manner in which the relaxation method of running creep tests protects the specimen from excessive strain. It is plain that the constant-stress specimen has stretched in the brief period of test as much as would be allowable in many applications and much more than would be allowable in some. All of the curvature of this line is due to progressive strengthening usually attributed to strain and hence the indicated strength is greater than is likely to be experienced in service. On the other hand, the curving over of the relaxation tests is caused for the most part by the automatic decrease of stress.

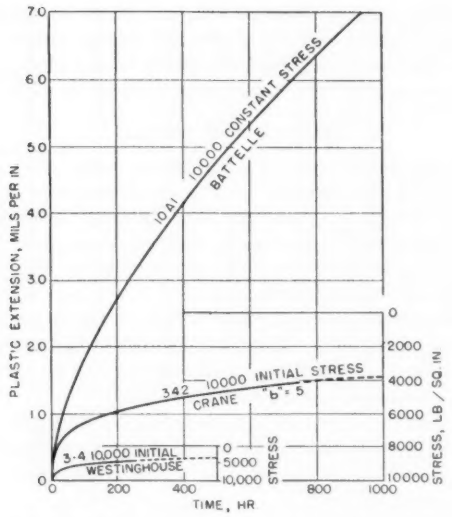

FIG. 15 COMPARISON OF CONSTANT-STRESS TEST WITH RELAXATION TESTS HAVING ELASTICITY FACTORS OF 5 AND 1. MATERIAL 1, ANNEALED 0.35 PER CENT CARBON STEEL K20, 850 F

For constant-stress test see "Long-Time Creep Tests of 18 Cr 8 Ni Steel and 0.35 per cent Carbon Steel," by H. C. Cross and F. B. Dahle, Trans. A.S.M.E., vol. 58, February, 1936, RP-58-3, pp. 91–96.

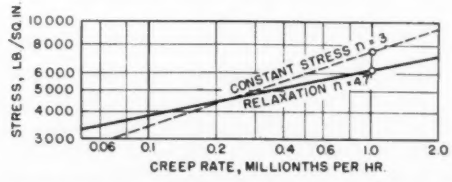

FIG. 16 COMPARISON OF CONSTANT-STRESS AND RELAXATION-TEST RESULTS. MATERIAL 1, ANNEALED 0.35 PER CENT CARBON STEEL K20, 850 F

Run by General Electric Company in same furnace at same time under identical conditions except loading.

A relaxation test comes to an end when the true allowable strain has been reached. Consequently creep rates measured during relaxation are not "inflated" estimates.

Fig. 16 for this same material shows how, at the higher stresses, the constant-stress test gives lower creep rates than the relaxation test. On the other hand, when tested at low stresses, constant-stress tests are likely to give results more nearly in line with the results of relaxation tests.

On three of the materials included in Table 1, results of constant-stress tests are available and these are listed for comparison in Table 3. Examination of this table shows that the nominal creep strength for a rate of one millionth of the length per hour is likely to be appreciably smaller when determined by the relaxation test. However, this is not necessarily always true. When the value of n is larger there is the possibility of equal values for a lower rate of creep. Thus in the case of material 1, Fig. 16 shows that the constant-stress and relaxation tests would agree for a rate of 0.22 millionths per hr. Furthermore, for the rate of 0.1 millionths per hr the relaxation test shows a higher nominal strength of 3800 psi as compared to 3500 for the constant-stress loading. Figs. 17 and 18 give similar comparisons for materials 4 and 5, respectively.

A Possible Acceptance Test?

It is a noticeable characteristic of relaxation tests that their most important stages of creep occur in the early periods of the test. After a few hours or days, a "knee" is passed after which further relaxation occurs very slowly. The rapid initial creep is what occurs in the well-known annealing process. On the other hand, after a brief period, a stress level is reached at which

TABLE 3 COMPARISON OF CONSTANT-STRESS AND RELAXATION-TEST RESULTS

	MATERIAL	TEMP °F	SPECIMEN	TIME HR.	PLASTIC EXT. MILS/IN.	RATE-STRESS INDEX τ_L	NOMINAL CREEP STRENGTH LB/IN² FOR RATE OF 10^{-6}	TYPE OF TEST
1	ANNEALED .35C STEEL "K20"	850	14A5	100	1.2	4.7	6200	RELAX.
			14A1-2-4	1000	2.1	3	7500	CONST. S.
4	C. MO. TUBING	1050	370-1	400	1.15	4.55	5500	RELAX.
			B. & W.	100	1.6	3.5	8000	RELAX.
			C-MO-3-2	2000	1.2	5.6	8000	CONST. S.
5	4-6 CR. MO. TUBING	1200	3-1	40	1.94	2.5	1110	RELAX.
			3-7	175	2.68	2.25	1240	RELAX.
			4-6CR-1-2	1800	2.5	2.5	2200	CONST. S.

creep proceeds very slowly indeed. This stress level is different for different materials and a bolt will stay tight if higher stresses than this are not required.

A test of from 2000 to 3000 hr can usually be extrapolated to give a 10,000-hr residual stress with a high degree of confidence. Often a much shorter test suffices if no sudden changes in the log-log representation of results occur. Such changes occurred as early as 40 hr and 1.95 mils per in. extension on specimen 3-1 of material 5 at 1200 F and after as much as 800 hr and 1.6 mils per in. extension on specimen 368 of material 3 at 850 F.

It must still be concluded that no short-time creep test can be regarded as very trustworthy for long-time predictions. A material which is of superior strength for one day or for 100 hr may alter its trend of relaxation so as to have an inferior residual strength after 1000 or 10,000 hr.

Discussion

JOHN BOYD.[6] Inasmuch as the committee's report is essentially a collection and a comparison of various relaxation tests on several materials it may not be out of place to offer some additional test data on one or two of the same materials and to make a few comments in connection with an interpretation of the results.

The data presented herewith have been obtained from automatic relaxation tests. This method has been described previously[4] but since it has been published only in abstract form it might be well to say briefly that it consists of keeping the gage length of the test specimen at a constant extension by automatically decreasing the load. A diagrammatic sketch of the apparatus is shown in Fig. 19. Fig. 20 shows a typical set of relaxation curves obtained by this method.

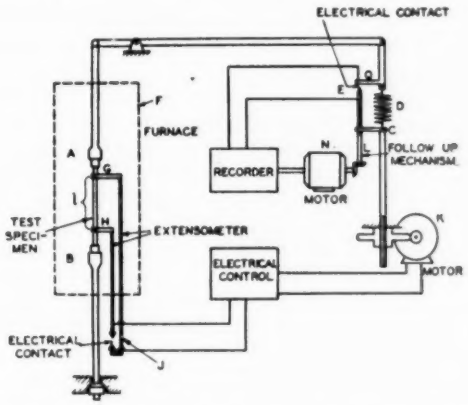

FIG. 19 DIAGRAMMATIC SKETCH OF AUTOMATIC RELAXATION TESTING MACHINES

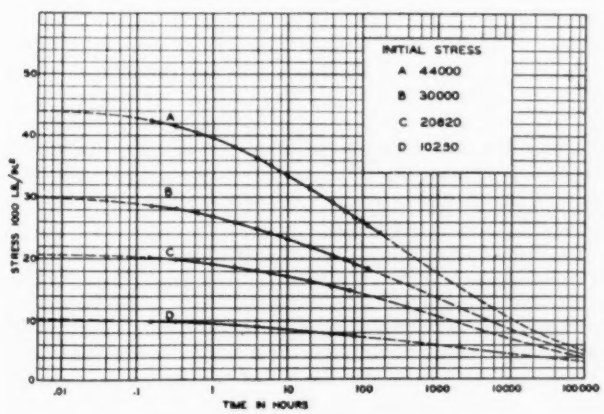

FIG. 20 AUTOMATIC RELAXATION TESTS
(On four samples of Cr–Mo–W steel at 850 F.)

TABLE 4 COMPARISON OF AUTOMATIC TESTS

Material		Laboratory	Initial stress, psi	Remanent stress, 10000 hr, psi: From Table 1	Remanent stress, 10000 hr, psi: Automatic tests
1 K20	14A5	G.E. Co.	30000	1700	...
	342	Crane Co.	10000	1260	1000
3 S.A.E. 4140	368	Crane Co.	30000	12800	11300
	.....	W.E.&M. Co.	50000	15350	14500

In Table 4 a portion of Table 1 has been reproduced for comparison and the last column shows the results of automatic relaxation tests on K20 carbon steel and S.A.E 4140 Cr–Mo steel at 850 F.

In comparing the various results it is well to remember that all of the remanent stresses shown in Table 4 have been obtained by extrapolation but it may be seen that in each case the results of the automatic tests are the lower. It may be said that the values for the Cr–Mo steel agree as well as might be expected considering all the factors which are involved. More should be said however about the case of the carbon steel K20.

Previously, the remanent stress in K20 steel after 10,000 hr had been estimated at about 800 psi on the basis of automatic tests. However more recent work has led to revising this figure upward to about 1000 psi. This value is still less than that of 1260 shown for the Crane Company tests. This is readily understandable. As a matter of fact the two figures should not be compared because the value shown is for a test piece which has been loaded twice (see Fig. 3) and experiment has shown that relaxation is less pronounced if a specimen is reloaded after having previously relaxed. Fig. 21 shows the results of a test on K20 steel in which the load was raised several times to approximately its initial value. An increase in resistance to relaxation is apparent.

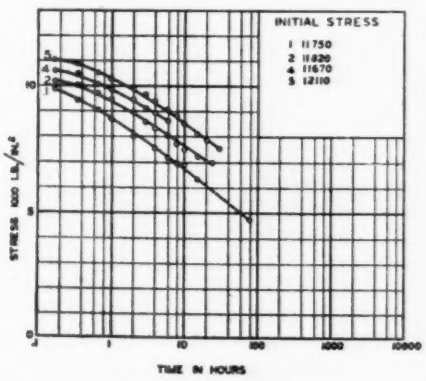

FIG. 21 EFFECT OF RELOADING ON THE RELAXATION OF STEEL K20 at 850 F

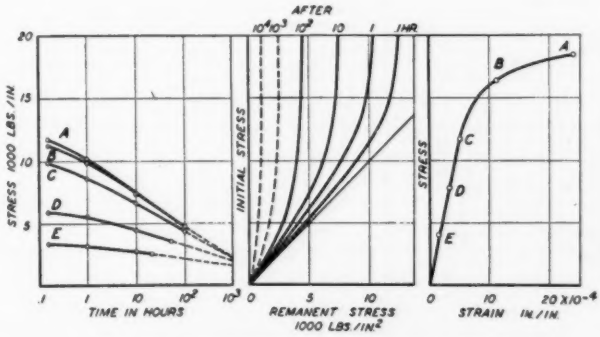

FIG. 22 RELAXATION OF K20 STEEL AT 850 F
(*a*) Relaxation tests
(*b*) Initial stress versus remanent stress
(*c*) Stress versus strain during loading period

In the case of the test at 30,000 psi initial stress no direct comparison with automatic tests could be made. In attempting to secure higher initial stresses for K20 than those shown, difficulties were encountered. In attempting to apply the load at a uniform rate, as is usually done in bolting applications, it was found impossible to increase it fast enough to keep the strain within the measuring capacity of the machine. In fact the initial extension of 0.0015 shown in Table 1 was reached before a stress of 20,000 psi was applied. That this is what might be

expected may be seen if reference be made to the Progress Report of Subgroup D on the short-time tensile tests on K20.[7] Here it will be found that the 0.2 per cent yield point occurs at a stress of about 20,000 psi when tested under these conditions. It would seem therefore that a serious practical difficulty would be encountered in running any kind of relaxation test (except the type used by Mochel where the load is applied cold) in which an initial stress of 30,000 psi was used. These experimental troubles may have been avoided in the case of the published data by the scheme which seems to have been used in the reference mentioned as note 2 of Table 1. This appears to consist of using a smaller initial stress of say 10,000 psi and allowing the extension to increase until a strain of 0.0015 has been obtained before the load is stepped down in a manner which is calculated to keep the extension constant. Inasmuch as a true relaxation test in which the initial stress was actually 30,000 psi would undoubtedly be a test in which an extension of many times 0.0015 would be held constant, it seems that it would be necessary to show that such an experimental procedure gives results that are the same as those of the true case just mentioned. This does not follow a priori.

Several relaxation tests on K20 are shown in Fig. 22(*a*). Fig. 22(*c*) shows the stress-strain relations for these tests during the loading period and Fig. 22(*b*) shows the remanent stress plotted as a function of the initial stress. These curves bring out the fact that as the initial stress is raised above about 12,000 psi the relaxation curves tend to fall on top of one another so that the remanent stress is not greatly affected by changes in the initial stress. This fact seems to be the basis for the statement sometimes made that the remanent stress is independent of the initial stress. That this statement is misleading can easily be seen by consulting Figs. 22(*b*) and 20.

Relaxation Equations

The equations developed in the report follow directly from certain fundamental assumptions. The first of these is that the creep rate is a power function of the stress, and the second expresses the fact that the creep rate is exactly equal to the rate of decrease of the elastic strain. The general expression, Equation [4], is of course obtained by neglecting the term S_1 which is the initial stress. If any one flow-rate test, corresponding to any one particular initial stress, be extrapolated by the use of this equation it is the same as drawing a straight line on the log-stress–log-time plot. This appears to be a reasonable procedure although it naturally will not take account of any hardening or softening that may occur.

When any one such flow rate or other test is used to predict the remanent stress for a different initial stress from that already used it immediately raises the question as to whether or not the value of S_0 corresponding to the rate r_0 is constant. In general, experiment does not show this to be true as will be seen immediately from Fig. 24. That this should be expected may be made clear from Fig. 23. Let the heavy line through point B in the stress–creep-rate plot be obtained by maintaining the extension corresponding to B in the plot of extension against time. If instead, the extension C were held constant it is clear that the creep speed found for the stress S_1 would be higher and conversely if extension D were held constant the speed would be lower. This indicates that in general a unique value of S_0 should not be expected and that the creep rate is a function of the strain as well as the stress.

F. H. NORTON.[8] At the time this report was presented in December, 1938, the test on material No. 4 at 1050 F, being conducted at the Massachusetts Institute of Technology, was only about 1000 hr old. Before it was stopped this test had been run for approximately 5000 hr and the rate of relaxation had increased noticeably over what was indicated in the results available at the time as presented in Fig. 11.

Fig. 26 presents the test results for the entire 5000 hr. Since

[7] "Short-Time Tensile Tests at 850 F of the 0.35 Per Cent Carbon Steel Material K20," Trans. A.S.M.E., vol. 58, 1936, pp. 97–101.

[8] Department of Metallurgy, Massachusetts Institute of Technology.

it was necessary to use a counterweight, the loading system was not particularly sensitive to such low loads, and therefore it was thought to be impractical to carry the test on at stresses below 1000 psi. It is noteworthy that at the time the test was stopped the log-log plot of the time-stress relationship had attained a slope of 45 deg corresponding to a value of $n = 2$ for the relation between stress and creep rate. While at the time of the December report the 10,000-hr residual stress appeared to be approximately 1500 psi, the load had relaxed to 1000 psi in half that time with every indication that there would be not more than 500 psi remaining at the end of 10,000 hr.

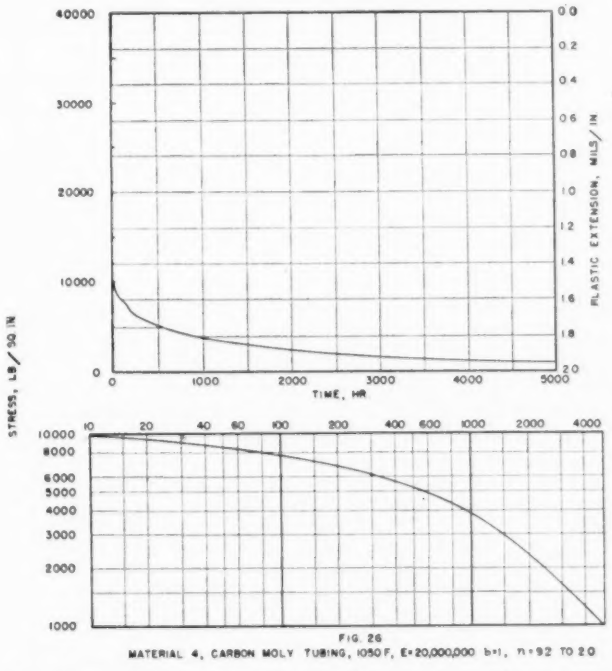

FIG. 26 BABCOCK & WILCOX STEP-DOWN TEST. (MANY SMALL STEPS.) MATERIAL 4, CARBON-MOLYBDENUM TUBING, 1050 F. (CONCLUSION OF TEST SHOWN IN FIG. 11.)

Assumed elastic modulus E = 20,000,000 psi.
Constant elastic-plus-plastic extension = 2.0 mils per in.
Elasticity factor b = 1
Stress rate index n = 9.2 above 6800 psi decreasing to n = 2.0 below 2000 psi and after 2500 hr.
Based on 5000-hr test, computed 10,000-hr residual stress = 500 psi.
Based on trend during last 2000 hr of test, creep strength for rate of 0.1 millionth per hr = 3200 psi. The actual creep rate at the conclusion of the test under a load of 1000 psi was 0.01 millionth per hr.

Whereas the nominal creep strength for a rate of one millionth per hour is shown in Table 1 as 8000 psi, and during the first week the stress to cause a rate of 1 per cent per 100,000 hr was 6400 psi, at the conclusion of the test this value had been reduced to 3200 psi and the specimen with a load of 1000 psi was actually creeping at a rate of 0.1 per cent per 100,000 hr.

The report of the Committee points out that relaxation tests are subject to changes of trend. However, such a marked alteration of strength as shown here constitutes more than an ordinary alteration of trend and makes it necessary to raise the question as to whether or not other materials may not suffer similar loss of strength after a period of time at high temperature.

The thought occurs to the writer that a relaxation test might actually come down to a zero stress or even a negative stress provided the specimen itself showed a gradual permanent expansion. Such an expansion may possibly have taken place in this particular test due to structural changes in the steel. It would be interesting to run a specimen with no load and measure any length changes which might occur. Thus, it is quite possible that relaxation is a combination of creep and structural expansion.

Creep as ordinarily measured may be a combination of extension due to stress and a permanent expansion which would occur anyway without stress. If so, it may be important in the future to measure expansion under stress-free conditions as well as extension due to a number of definite stresses.

AUTHOR'S CLOSURE

Mr. Boyd discusses the differences between the relaxation tests as run with a prescribed constant extension and a "true relaxation test" in which care is exercised really to secure a prescribed initial stress. His doubts of similarity are entirely justified and the Committee fully agrees that such a test would be quite different from one obtained by the experimental procedure used in the tests presented by the Committee.

The relaxation tests sponsored by Project 16 might well be called "tests at constant strain," that is, tests run with a total elastic-plus-plastic extension held constant, since that is a more precise way of describing the conditions obtaining during relaxation than by reference to an initial stress.

The initial stresses given in the report should, in every case, be interpreted as referring to equivalent calculated values, actually present only at the lower temperatures where the elastic limit is not exceeded.

The reason why the Committee has used this procedure is because the constant quantity in a bolted flange, a press fit, or a shrunk-on bushing, is the total strain, that is, the elastic-plus-plastic extension. The actual presence of the equivalent initial stress depends on the conditions at the start of service, and in any event, these conditions are highly transitory. On the other hand, it is important to note that in any actual machine, as in the Project 16 tests, the total extension is what is definitely known and limited rather than the stress.

Furthermore, an important consideration is the likelihood that the permanent strain, which the Committee carefully limits, is of greater metallurgical significance than the transient presence or absence of a high stress for a brief period.

The Committee fully agrees with Mr. Boyd's concluding remarks. In fact, even though not universally true, a preference has, on several occasions, been expressed for assuming that for a given temperature the nominal strength, S_6, is uniquely determined by the strain and the stress.[9]

The final results of the test on carbon-molybdenum tubing at 1050 F given by Professor Norton in Fig. 26 show a falling off in strength after several months at temperature which is very unusual although worse cases have been known. This is a widely used material tested about 100 F hotter than the maximum temperature commonly used. Even if only occasional samples are subject to any such loss of strength, it is a matter of importance to operators and worthy of investigation by metallurgists.

Professor Norton's suggestion that structural expansion might be taking place irrespective of creep due to stress, is an interesting possibility. If so, the constant-extension tests sponsored by the Committee represent not only constant elastic-plus-plastic extension, but rather a condition in which the sum of three quantities is constant; (1) elastic extension, (2) plastic extension due to stress which is commonly called creep, and (3) structural expansion due to temperature regardless of stress. While an ordinary bolt would never pass beyond a condition of zero stress, a bushing shrunk on a shaft and confined within a wheel, experiencing such

growth might well pass beyond the zero condition, and find itself in compression due to its external constraint, in case the latter were not subject to similar growth.

In the ordinary tests as run by the Committee such behavior would lead to zero stress after which expansion beyond the prescribed limit would occur. No results of this nature have so far come to the attention of the Committee, although of course, no special investigation has been directed at this question.

Discussion

Operating Methods and Problems of a Combined Hydro- and Steam-Electric System[1]

ALBION DAVIS.[2] The authors have presented a paper that is constructive in every respect. It covers a wide field, yet is accurate in its statements. It shows the complexity of the problems that arise in the operation of a large interconnected system and how futile it is for anyone to attempt to give simple answers to economic questions involving the balance between hydro and steam. The writer's comments are intended to supplement their paper and bring out angles of operation which are of importance on combined steam and hydro systems that have a considerable amount of seasonal storage available.

FORECASTING

The first point to be emphasized is the value of forecasting. The contribution of forecasting to smooth operation and system economy is often overlooked, but it is basic. If someone will predict specifically what the flow and the load are going to be, planning economic operation becomes a matter of curves, loading tables, computations, and personnel. Good forecasting, anticipating load conditions—foresight rather than hindsight—and timely reports are essential parts of good operation.

In many cases it is nearly as serious to overestimate runoff from a given rain as it is to underestimate. In the first case too much low-cost energy will be dropped from the steam plants and in the second case the reservoir may fill and actual waste of water occur which otherwise could have been used for generation. There are systems where a 5-hour gain in a forecast of spill may mean as much as $1000.

NEED OF A SYSTEM PLAN

The second point is the need of a well-grounded system plan for allocation of plant loadings. This would include not only a daily and weekly plan but, where storage is available, a seasonal plan. These general load-allocation plans should be sufficiently flexible so that there is an opportunity for each person concerned in actual operation to contribute the best of his experience. Where several plants of both hydro and steam are involved, the economic balance between hydro and steam is continually changing and it takes the combined intelligence of a lot of individuals to get the finest results. Automatic devices can be considered as aids but hardly as substitutes for engineering in operation. Too often elaborate schedules of operating are devised and gradually forgotten. Rigid schedules and too specific regulations do not secure the best results.

Good forecasting, a flexible system plan that will give the widest possible opportunity for intelligence to be applied all along the line, plus a follow-up are the essential elements for securing the best results.

CAPACITY USE OF HYDRO

Hydro has two values to a system, a capacity value and an energy value. Its capacity value depends on how many kilowatts of the annual system peak it can carry with minimum river conditions. Its energy value depends on the steam-plant operating costs it can replace with the average river conditions that will occur over a period of years. Distinction between these two values is more pronounced where a system has a large amount of seasonal storage available, making peak value the dominant one.

Hydro will be used for maximum capacity when all plants of the system are taxed to their utmost to supply the system load, as will be the case just before the bringing in of a new major unit of system capacity. When used for maximum capacity, storage reservoirs will seldom be drawn appreciably until the steam plants are operating at or close to their maximum output. By using reserve steam capacity when it is available, additional water can be held in storage for use during the period of actual outage of the largest unit, thereby supplying an additional amount of system capacity during the period of greatest need.

In providing reserve capacity for short system outages, the leaning will be toward hydro on account of its quick availability as compared to steam. For rolling reserve capacity also the leaning will be toward hydro because it is usually far cheaper than steam. On the other hand, for the long-continued outages where quantity production is required, the emphasis will be on steam capacity.

ENERGY USE OF HYDRO

Hydro will be used to yield its maximum energy value when there is an ample margin of capacity elsewhere on the system. Securing a maximum energy value from the hydro plants is a long and detailed story, most elements of which have been covered by the authors. There is, however, one point which the writer would like to stress, namely, the necessity of hour-by-hour analysis of the use of hydro in the load curve.

System conditions are continually changing during the day. A plant may be operating at perfect efficiency as a unit by itself yet be considerably out of balance with the best system plan. At one hour of the day the system object may be to obtain the maximum amount of capacity regardless of efficiency; at another hour of the same day the objective may be to save all possible kilowatthours, even sacrificing some efficiency to build up a reserve against more expensive steam generation a month or two later; at still another hour of the day efficiency of generation may be the rule. And there are all shades of operation between these limits. For such a day the average efficiency of any one plant, as the term is ordinarily defined, may be poor, yet as a unit of the system, its operation may be perfect. Rather than its being a simple undertaking, operation is one of the most complicated.

The exact proportion of hydro used in the top of the system load curve during low-water periods will depend largely on the difference between on-peak and off-peak steam increment costs. When hydro is flush and it is operated on base load, the steam plants may be operating at minimum loadings particularly during nights and Sundays. Under such conditions, increment steam costs are low and the value of the last few kilowatthours squeezed from hydro may be small.

INCREMENT COSTS

Since the value that can be attached to kilowatthours generated by hydro is measured by the steam-plant production costs they save, a clear knowledge of what these steam increment costs are

[1] Paper by H. L. Harrington and E. B. Strowger, published in the February, 1939, issue of Transactions of the A.S.M.E., p. 89.

[2] Chief Hydraulic Engineer, Union Electric Company of Missouri, St. Louis, Mo.

for all types of loadings and for all hours of the day is essential to all determinations of the balance between hydro and steam.

Fig. 1 of this discussion shows increment costs of steam generation for a hypothetical system supplied in part by hydro plants that have seasonal storage available. The curves show how increment costs might increase with the steam-plant loadings. It will be noted from the drawing that each unit coming on the load adds a block of constant losses which are a function of time only. Once the machine is on the load and carrying its minimum permissible load, from there on up, increment costs are nearly constant until the unit is pushed up close to its maximum output.

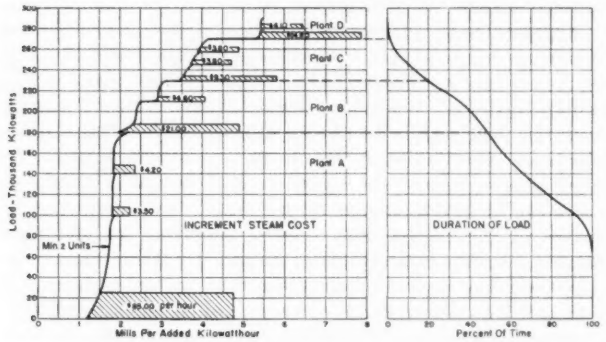

FIG. 1 INCREMENT COSTS OF STEAM GENERATION ON A HYPOTHETICAL SYSTEM SUPPLIED IN PART BY HYDRO
(A typical load-duration curve for such a system is shown at the right.)

When a plant is brought on load there is a lump-sum cost to get the plant ready for service. Then to operate the plant there is the fixed minimum hourly cost for operating labor plus the fixed cost of starting each unit.

At the right of the drawing there is shown an annual duration curve of load that might be typical for the same section of the hypothetical system. It will be noted from the increment-cost curve that if all the load is to be carried on steam some high-cost generation will result, as the top increment costs run perhaps three times the lowest. At the same time, the duration of such generation would be quite limited. The periods of low-cost steam generation are extended. If the available hydro generation can all be used in the top of the load curve the value of the water power will be large. If it all must be used in the base, its value will be small.

The object of any system operating plan would be to so fit hydro generation into the daily and weekly plan that a maximum amount of the high-cost steam generation could be saved. These steam-plant costs saved may include the shutdown of an entire plant. Where sufficient storage is available on a hydro system this use of hydro to avoid starting up inefficient steam plants is one of the main objectives to strive for in the system plan.

DIVIDING LOAD FLUCTUATIONS

The thesis that hydro is most useful in the top of the load curve operating at low load factor is true only up to a certain point. Fluctuation of hydro loads and low-load-factor operation reduces the amount of generation which can be obtained from a given use of water. This effect is exaggerated in the low-head plants where the reductions in head caused by rising tail water are a larger proportion of the total head. Increased fluctuation of load means less generation at the higher heads during the night hours and more generation at the lower heads during the day period. The combination means less total generation from a given river flow than would be secured by uniform operation throughout the day. Such losses increase very nearly as the square of the kilowatthours transferred from the night to the day period. When there is added to these losses those due to the additional turbine starts and stops that are required and the losses due to the load passing through more inefficient part-gate zones of operation, the total losses may easily run up to 8 or 10 per cent.

Fluctuation of the load carried by a steam plant likewise increases unit production costs. Fluctuation may mean additional boiler starts and machine starts or it may mean carrying excess rolling or stand-by capacity during the light-load periods, all of which increase unit costs. And yet there is a practical limit to the gains to be made in steam-plant operation by improved load factor. Few steam plants are designed for operation at load factors above 80 per cent. The last few increments of load-factor increase may yield insignificant gains.

Disregarding some minor practical considerations, the broad statement may be made that all plants should share the load swings. Just how much of a share each plant should take, however, will vary from plant to plant. The proportion of the daily swings of load which each plant should take may be determined by evaluating the losses each plant would be subject to by reason of typical fluctuations. The results may be summarized in tabular form for each plant. The best division of the load swing will be that in which the total loss due to fluctuation of load on all plants is a minimum.

SOME LONG-RANGE USES OF STORAGE

First in importance on systems where seasonal storage is available would be the planning of reservoir levels for the different periods of the year, both to yield the most energy during low water for use in the top of the load curve, and to catch excess flood waters for building up the total generation.

The many factors involved in such planning make it desirable to develop "rule curves" which will sum up experience equivalent to operating the system through all the river conditions of the past. These rule curves will show the economic drawdown of the reservoir prior to any regular spring or fall rains that may be characteristic of the drainage. The rule curves serve merely as a summary of much detailed engineering analysis. They should be looked on not as rigid schedules but merely as guides.

Usually it will be necessary to develop two rule curves; the first for energy operation where maximum economy is the guiding aim, the second for capacity operation when ability to carry peak is the first and economy the second consideration. The first rule curve will utilize greater reservoir drawdown to catch more flood waters and generate the most energy, while the second rule curve will be less concerned with catching flood waters and will aim to conserve storage primarily to yield maximum output during the extreme low-water periods. Reservoir drawdowns in the second case will be considerably less than in the first.

With these two rule curves available it is possible to judge fairly closely the proper position of the reservoir for any type of operation at any season of the year. A new plant coming on the system or a new transmission facility, or changes in the seasonal characteristics of the system load curve, will alter these curves for system use of storage.

A second use of seasonal storage is in reducing the fluctuations of top average steam loads from week to week, thus in effect substituting more low-cost generation for that of high cost. Such use may often avoid the high cost of starting up another stand-by steam plant.

Seasonal storage may also be used in anticipating fuel shortages at the steam plants, and in connection with planned outages of major equipment. Many times by planning ahead, sufficient storage may be conserved to handle such outages without loss. When the outage comes it may be handled from storage without making it necessary to use inefficient generating capacity.

Judicious use of storage sometimes makes it possible and eco-

nomical to shut down a plant entirely for extended periods and transfer the operating force to maintenance work on other parts of the system.

Scheduling Plant Maintenance

Outages of steam turbines for inspection and maintenance are often a serious tax on economic operation, particularly where the units are large and efficient. When they come down, their load must be supplied by other units which usually will carry higher top-increment costs. With large units this may represent quite a spread in generating costs. Such outages can be very expensive. Outages for maintenance of efficient steam units during periods of low hydro may require generation on other steam units at double the cost.

On a system where this is the case, it may be quite advantageous to take steam-turbine outages ahead of their regular schedule if hydro conditions at the time are favorable. If these conditions are not favorable and continue unfavorable it may be feasible to postpone the outages until there is improvement. It may be desirable to postpone the outage six months beyond the due date as, usually, water conditions will get better within a one-year period.

By scheduling steam maintenance in this manner, the steam turbines may be serviced on the average oftener and the direct cost for maintenance will be increased, but the energy cost of the outage will be reduced far more and the total cost resulting from maintenance will be substantially reduced.

System Governing

Considerable attention was given in the paper to the important problem of frequency control and its relation to tie-line loadings. The writer would like to add a further word suggesting that many of the difficulties in connection with this part of the problem can be eliminated by improving the performance of governors. On an isolated system these irregularities of governor action show up as short-period swings of system frequency. On an interconnected system, irregularities of governor action show up as swings of tie-line loadings. It is believed that proper system coordination of governor action can do much toward smoothing out the short-period swings of system speed and make it much easier to maintain frequency by either manual or automatic control.

J. H. Harlow.[3] The authors of this paper have undertaken a broad subject and have admirably succeeded in pointing their finger at a great number of system operating problems. In attacking a subject of this type, one is forced to decide whether the approach should be from the broad and inclusive point of view, or whether it would be better to confine the discussion to a few selected aspects of the problem and thereby be able to go into greater detail. From either point of view, the subject is timely and worthy of presentation. However, it is to be regretted that time did not permit them to go into a more extensive discussion of the load-allocation problem for both steam and hydro; of the manner by which transmission-line losses and capacities are considered in these allocations; and of the type of data supplied to the load dispatchers as tools for the efficient and safe operation of the system.

Of these problems, the one of steam-station load allocation is probably the most widely encountered. It would seem well, therefore, to discuss this phase of the system operating problem briefly.

In this connection, it is not necessary to go into a comparison of methods or a theoretical discussion of the proper fundamental basis for solving the load-allocation problem. Suffice it to say that it is now generally recognized that the base-loading scheme, which was frequently used a few years ago, was erroneous and that the true economical scheme of load allocation among steam stations is on the basis of incremental costs. Under this scheme, the load is allocated in such a manner that the incremental costs of energy, within the limits imposed by the system, are the same for all sources. With this premise established, the problem of economical load allocation among steam stations reduces to one of discovering a ready and accurate means by which the incremental costs can be determined and of being sure that all pertinent factors are considered.

In determining the true incremental cost of energy from any given source, there are at least three items of cost which must be considered, namely, fuel, maintenance, and transmission loss. The first two items are involved because they each have components which are functions of the station load. The third item is important because it enters into the determination of the effective value of the others. In some cases, it may be found that labor and expense costs have components which are functions of the load, but, in general, these items of cost do not enter into the problem because they are essentially constant regardless of the magnitude of the plant load and, therefore, do not enter into the plant increment cost.

By far the largest single item which is included in the total incremental cost is the incremental cost of the fuel. This item, therefore, must be determined with great care, and can be expressed most readily in units of fuel consumption per net kwhr, this, in the preponderance of cases, being a determinable ratio which is not influenced by the fuel price.

The incremental fuel rate at any given load may be defined as the change in the rate of fuel input resulting from a unit change in the load. Or, in the terms of the input-output curve of the plant, it is measured by the slope of the curve at the load for which the increment rate is to be determined expressed in units of fuel per unit of net output. Thus, in order to establish the incremental-fuel-rate curve of a plant, the most reasonable procedure is to begin by preparing a curve showing the relationship between net load and rate of fuel input. The basic data for such a curve should be obtained from actual performance tests on the various units of plant equipment such as boilers, turbogenerators, condensers, pumps, fans, and the like, because no curve of this type can be any more accurate than the groundwork upon which it is built. Where several similar units are installed, the testing of one unit, which may be selected as being typical of all, is permissible, but separate tests should be conducted to determine the performance of all units of dissimilar type. Over-all plant tests are not acceptable, due to the fact that, during such tests, it is impossible to be sure that all plant conditions are properly controlled and the effects of operating various numbers of units will not be determined. Also, small items, which enter into the proper operation of the equipment will be missed completely. It is much better to design the plant operation by building up from tests on the individual units.

The input-output curve can be simplified to a great extent by separating the total fuel into three components, namely, (1) the so-called generating fuel, which includes the total input less the banking or no-load boiler fuel with all of the boilers in service; (2) the so-called adjustment fuel, which comprises adjustments to the generating fuel resulting from the operation of fewer boilers, but does not include the banking fuel; and (3) the banking fuel, which is a constant dependent upon the number of boilers in service. The effect of circulating-water temperature can be shown best by means of a family of generating-fuel curves.

Parenthetically, it may be noted that the usefulness of a curve, such as has been described, is not limited to a study of load allocation. It is extremely valuable for use in checking up on the

[3] Assistant Superintendent, Station Economy Section, Philadelphia Electric Company.

quality of the plant performance, when converted into a daily input-output curve by coupling it with data covering typical load shapes for various daily outputs. In fact, an operating factor indicating the departure from standard performance which will be obtained through checks of this type is a desirable refinement to the determination of the load-allocation data, and is a necessity if incremental-cost data are to be used in pricing economy power transferred under pooled-power agreements.

An increment-fuel-rate curve can be developed from the input-output curve by plotting the slope of tangents to the input-output curve at various loads against their respective loads. Such a curve provides an accurate basis for load-allocation work, and is simple in its application. Similar curves are required for each steam station. The development of such a curve will reveal several facts, to which attention should be called. First, in most cases, the generating-fuel-increment rate shows a sudden increase of from 15 to 20 per cent at about 80 per cent load because at this point the overload valves on the units open. This is indicated on the input-output curve by a slight break and change in slope. Because of the increase at this point, it is not usually desirable to generate in the overload-valve region, but rather to hold this capacity for reserve. Second, there is a family of generating-fuel-increment curves resulting from various circulating-water temperatures. Third, the adjustment-increment rate, which is obtained from the adjustment input-output curves in a manner similar to that used for obtaining the generating-increment rate, must be added, as conditions require, to the generating-fuel rate. Fourth, constant components of the input, such as banking fuel, plant no-load fuel, and machine no-load fuel, do not appear in the increment rate.

As noted, the incremental fuel-rate data are expressed in terms of units of fuel per net kwhr. These fuel units multiplied by the fuel price per unit will give the desired increment-fuel cost.

The second item to be considered in determining the total incremental cost is the increment cost of maintenance. This may be determined from an analysis of the actual maintenance costs which have been experienced over a number of years of operation. A study of this subject leads to the conclusion that the total maintenance cost (and incidentally all costs of station operation other than fuel) can be expressed by a general formula in the following form

$$\text{Cost} = C_1 + C_2 \times \text{kw capacity} + C_3 \times \text{kw peak prepared for} + C_4 \text{ kwhr generated} \quad [1]$$

The constant C_4 in this formula is the desired incremental cost.

If the capacity and the peak which a station has been prepared to carry have not changed materially over a period of years, this formula can be reduced to

$$\text{Cost} = K + C_4 \times \text{kwhr generated} \quad [2]$$

In such a case C_4 can be determined simply by establishing the relationship between cost and generation. However, if the capacity or the peak prepared for have varied from year to year, it is necessary to make a more exhaustive study of the costs and to divide them into the various components. This can be done by setting up in advance certain conditions of plant operation to be covered by the various components and allocating to each component its proper share of the costs actually charged to each accounting subdivision. Although this requires the exercise of judgment to a considerable extent, it is not particularly difficult to establish the proper formula if the conditions are properly defined.

The increment fuel cost and the increment maintenance cost, which have been discussed, when combined give the total increment cost at the station bus. For load-allocation work, however, the true basis is the incremental cost at some selected point on the system, with the incremental costs of power from all sources adjusted to this common point. This cost may be greater, less, or equal to the incremental cost at the station bus depending upon the effect of transmission-line loss. For instance, if power is being fed out of the station over a transmission line and the load is increased on the station, the load and resultant loss on the line will be increased and the effective increment cost at the end of the line will be greater than the increment cost at the station bus. Conversely, if power is being fed into a station and the station load is increased with a resultant reduction in line loss, the effective increment cost at the end of the line will be less than that at the station bus. The increment line-loss factor, therefore, can be expressed best as a percentage to be added to, or subtracted from, the station increment cost and, for this purpose, may be defined as the change in line loss corresponding to a change in line load expressed as a percentage of the change in the line load. It is, therefore, the first differential of the curve of line loss against line load. On a three-phase line, this results in the following

$$\text{Per cent increment line loss} = 0.2r \frac{kva}{kv^2} \quad [3]$$

Where r = the single-phase resistance of the line in ohms; kva = line load at which the per cent increment loss is to be determined; kv = operating voltage of line.

Knowledge of the incremental line loss, being dependent upon line load, must be supported by a knowledge of the line loading which, in turn, is a function of the station load and the manner in which the system load is divided among the various distribution centers.

It is not necessary to illustrate the procedure to be followed in applying the data, the determination of which has been discussed. Suffice it to say that, from this point on, the load-allocation problem is a cut-and-try one necessitating increasing or decreasing station loads here and there until the desired result of balanced incremental costs is obtained.

A permanent allocation chart of the type described based on normal system conditions should be developed, but it should also be realized that such a chart is subject to error in its application due to the variations which occur from time to time on the system. Such variations may be caused by outages of units, outages of transmission lines, operation of more or fewer boilers than were used in the computation of the chart, changes in fuel-price differentials among stations, and the like. In order to make the most effective use of the increment-cost data in load-allocation work, therefore, the employee who is responsible for distributing the load should be thoroughly educated in the method of proper economical load allocation and should be supplied with all of the basic increment-cost data on fuel, maintenance, and transmission loss. This is important, for only in this way can load be correctly allocated under the many variations which occur from day to day. That such a procedure is entirely practical has been demonstrated by several years of experience.

The Kaplan Turbines at Bonneville[1]

C. I. GRIMM.[2] It occurs to the writer, who prepared the general designs for the Bonneville dam and power plant which were used as a basis for the project adopted by Congress, that further data relating to factors governing the selection of type and size of turbines may be of interest.

[1] By Paul L. Heslop and George A. Jessop, published in the February, 1939, issue of the A.S.M.E. Transactions, p. 97.

[2] Head Engineer, U.S.E.D., North Pacific Division, Portland, Ore.

Variation in head at the Bonneville plant is extreme. It is of primary importance that the plant have the best attainable capacity at heads around 30 ft, which are of infrequent occurrence and short duration. It is also important that the plant operate efficiently under the usual head of about 60 ft. For these conditions the adjustable-blade, propeller-type turbine was found to constitute the most economical and practical power plant. Even with this type of turbine, a material loss of capacity during high floods cannot be avoided. The two turbines installed have sufficient capacity to run the generators under full load (60,000 hp each) at a head of 44 ft. This corresponds to a river flow of 650,000 cfs. During 60 years of record, the river has been above this stage an average of $9^1/_2$ days per year, or 2.6 per cent of the time. During 43 of the 60 years, it has remained below this stage. Since the high flows occur in the summer and the peak load in this area occurs in the winter, some loss in peaking capacity during floods, even after the plant is fully loaded, is of no consequence. Six floods of about 750,000 cfs have occurred, which flow reduces the head to 40.8 ft and the turbine capacity to 54,000 hp. Three floods of about 800,000 cfs have occurred, which flow reduces the head to 39.6 ft and the turbine capacity to 52,000 hp. The effect of reductions up to this extent causes no concern. Three floods of about 900,000 cfs have occurred, which flow reduces the head to 31.6 ft and the turbine capacity to 37,800 hp or 63 per cent of the generator capacity.

As stated by the authors, the capacity of a turbine would be reduced to 27,400 hp during a flood of 1,170,000 cfs, which has occurred once during the period of record, in the year 1894.

High floods on the Columbia River are caused by melting snow and always occur about June 15. Their magnitude can be estimated by March 15. It is therefore practicable, when there is danger of plant capacity being reduced below demand, to arrange either for curtailing the load for a brief period or obtaining surplus power from other plants.

The Bonneville plant was designed with the expectation that it would be interconnected with the power network, as is now being done. Under this condition small units are not necessary for flexibility. Large units have been found to result in minimum costs per unit of capacity. The turbines and generators were therefore made about as large as available manufacturing plant and practice would permit.

Based on costs to date, the cost per kilowatt of installed capacity of the Bonneville power plant with six main units will be as follows:

Substructure	$22.80 per kw
Superstructure	3.40 per kw
Turbines	17.20 per kw
Generators	17.60 per kw
Transformers and switching	10.00 per kw
Total	$71.00 per kw

The cost per kilowatt of installing four additional units will be about the same.

J. F. Roberts.[3] The writer has watched with interest the development of welded construction for turbines of this type and feels that the statements submitted by the authors of the paper are in fact rather conservative. The use of welded-steel construction instead of steel castings offers many attractive advantages over and above those mentioned by the authors. They do bring out one of the important points, however, and that is the reliability such welded structures offer, as compared with the doubtful quality of some steel castings. Furthermore, the lack of distortion in such welded structures as compared with cast-steel members might also be mentioned. Frequently, cast-steel members will change their shape some months after being machined, with the result that, when reassembling the parts in the field, or even after being placed in operation, the turbine parts may be thrown out of line, requiring a great deal of trouble and considerable expense to correct.

One point which seems inconsistent is that the manufacturer of the Bonneville turbines uses a riveted draft-tube liner, while at the same time using welded-steel structures throughout for such important items as the speed ring, the head cover, the gate-shifting ring, and other parts which are subject to heavy strains and carry the most important loads during operation. Even granting the desirability of riveted connections in the draft-tube liner for the field joints, where they cannot be stress relieved, the writer would like to ask why the shop joints in the draft-tube liner could not have been welded in a manner similar to the other welded parts of the turbine? This would result in a smoother surface of the interior of the draft-tube liner and should be stronger than the riveted joints.

The method of checking the turbine and generator shafts on a vertical table in the manufacturer's shops certainly was an ingenious development. However, it is noted that, on account of lack of head room, it was impossible to test the entire generator and turbine shafts together. The turbine shaft was first checked with the intermediate shaft, then the turbine shaft was removed and the intermediate shaft was checked with the generator shaft. This procedure, the writer feels, might offer possibilities for future trouble, since with the expense involved in preparing the equipment, it would have been well worth while to make a complete check on the entire assembly of turbine, intermediate, and generator shafts combined.

It is noted that the engineers responsible for the design of the Bonneville structures made preliminary tests with models on which they based the design of the intake, the scroll case, and the draft tube. It seems to the writer that the design of the scroll case and the draft tube is a matter which should be left primarily to the designer of the water wheel. This is particularly true in the case of the Kaplan type turbine, since the action of the scroll case and the draft tube is so closely related to the operation of the turbine itself that only the manufacturer can determine adequately what form these parts should have to offer the best coordination with the turbine. While there are many structural designers who feel they are competent to design draft tubes and scroll cases, there is serious doubt if they should be allowed such freedom. Several cases are known where draft tubes, designed by structural designers and upon which the manufacturers were required to put their water wheels into operation, have caused serious disturbances and even vibration at certain outputs of the hydraulic turbine.

The outline of the method used in erecting the Bonneville turbines, especially the stiffening of the members to be embedded in concrete, should be very interesting to the engineer who is doing any work of this kind. It will be of great assistance to engineers planning the installation of similar or even smaller equipment, as such information has to the writer's knowledge never been published heretofore. One point that might be added to this discussion is the advisability of attaching the head cover in order to stiffen the upper flange of the speed ring during the pouring of concrete. If the head cover is available, it should be bolted into the upper flange of the speed ring and wedged solidly with steel shims in the clearance space around it. To the writer's knowledge, this was done with very beneficial results in at least two cases. While it did not materially improve the level condition of the upper flange of the speed ring, it held that upper flange to a true circle much more closely than the result given by the authors for the Bonneville turbines.

[3] Mechanical Engineer, Knoxville, Tenn. Mem. A.S.M.E.

The method used for supporting the turbine runner and shaft in the turbine pit, until the weight of those parts could be carried by the generator thrust bearing, was ingenious. In the writer's opinion, however, it certainly resulted in some rather heavy work in removing the large I-beams from between the guide vanes and speed-ring ribs after the load of the runner and shaft was taken by the thrust bearing. The high cones of the Moody spreading draft tube had one advantage during erection in that the runner and shaft could be set on the high cone until coupled up to the generator. Another system that is now being used extensively is to provide a small flange on the turbine shaft and to arrange the head cover of the turbine so that it can carry the load of the turbine runner and shaft until the load can be taken by the generator. In this case the runner, shaft, and head covers are assembled on the erection floor. Then the combination is lowered into the turbine pit in one piece.

The results of the efficiency tests and cavitation tests as given by the authors are interesting and will be helpful to many engineers, as they give much more information than is usually found in published data.

Authors' Closure

Paul L. Heslop. Extensive index tests on the units have been made since publication of the original article. Such tests do not reveal absolute efficiency but they do measure actual output, which was found to exceed predictions. An examination of the shape of the index-test curves demonstrates that model tests are a reliable means of predicting turbine performance in advance.

The net-head gate limiter described in the article was found to be unnecessary and will not be furnished on additional units. The inherent strength of the machines plus other devices present furnish ample protection.

George A. Jessop. Mr. Roberts suggests that a draft-tube liner wholly or partially welded is preferable to one entirely riveted. There is no practical advantage to a welded tube from the hydraulic standpoint when the riveted tube is made with butt straps and the plates are flush at the joints. There are small spaces between the plates forming the riveted tube, whereas with the welded construction these spaces are eliminated. The spaces between the sheets are so small that disturbances to the flow are not set up.

It is considered undesirable to have some joints welded and some riveted in the same structure. The shop assembly of such a large tube with its formed plates is a difficult and expensive process if the plates are to be joined by welding because of the necessity of having close and exact fits to enable the welding to be done according to the best methods.

The writer agrees with Mr. Roberts that it is highly desirable to allow the turbine manufacturer to design the scroll case and draft tube for the turbine. Even where model tests are made by the power-plant engineers, it is seldom that a runner and gate case of the proper characteristics are available. The turbine manufacturer has access to more previous tests and has had experience with more plants than the engineers. The manufacturer can be depended upon to submit designs which will assure the best results and not require unjustifiable dimensions or construction. The manufacturer's designs, in any event, are subject to review by the engineer.

Mr. Roberts mentions the desirability of attaching the head cover to the speed ring to afford additional rigidity during the pouring of the concrete. For turbines as large as those at Bonneville the head cover is divided in such a way that there is an outer and inner cover, the former of which contains the two sets of bearings supporting the upper gate stems. It is seldom, if ever, that the entire head cover is available on such large turbines at the point in the construction schedule when the concrete is poured around the speed ring. There have been instances where the outer head cover was used. It is pointed out that when this is done it is not safe to eliminate bracing inside this structure as the forces set up by the concrete are so great that this part itself may be distorted. The outer head cover must remain perfectly true because if it does not the wicket gates will not be in proper alignment.

Mr. Grimm offers valuable data in regard to stream flow and turbine output. The figures on costs per kilowatt are interesting as would be similar figures for the dam and the fishways.

Modern Boiler Furnaces

By E. G. BAILEY,[1] NEW YORK, N. Y.

The paper considers the fusing temperatures of various kinds of coal ash and slag, and their significance with respect to furnace temperatures, operation, and design.

A method of comparing furnace operating results is suggested consisting of (1) taking accurate gas temperatures throughout a furnace, (2) then calculating from them the rates of heat absorption in different zones, (3) calculating an "equivalent heat-receiving-surface temperature" for each zone, (4) taking samples of ash and slag from different portions of the furnace and determining the fusing-temperature range from such samples, (5) plotting these data as a "gas-ash temperature graph" against heat-absorbing surface, (6) comparing the data as shown on such graph with observed behavior of ash and slag in the furnace, and (7) comparing different furnaces, different coals, and methods of operation through the use of such graphs. Examples of the use of the method are given.

There is also included a comparison of methods for measuring furnace temperatures. Colored motion pictures illustrating some phenomena relating to slag in furnaces were shown at the time of presentation of the paper.

ASH AND SLAG from the burning of coal have long been recognized as important factors in boiler-furnace operation. Hand-fired boilers were often limited in output by clinkers in the fuel bed, with resulting excess burden on the firemen. Certain kinds of stokers were ill-adapted to handling clinkering coals, while others were developed to cope with the same coal much better. Forced-draft stokers extended the clinker trouble, formerly restricted largely to the fuel bed, to the furnace walls and boiler tube banks, where "bird nesting" of slag was a serious trouble. Pulverized-coal firing, as first applied to slightly modified furnaces, did the same, but to a greater degree, as a higher percentage of ash was in suspension.

Water-cooled furnaces have overcome the erosion of the walls, and aided in lowering the temperature of the gases before entering the boiler tube bank. The spacing of the boiler tubes has been increased to minimize the tendency of ash and slag to accumulate. Turbulent pulverized-coal burners, resulting in more complete combustion with shorter gas travels and low excess air, have also been developed.

It seems that as soon as there are solutions for one set of conditions, new problems of economic importance arise which can only be solved by further study of the factors which enter the problem.

Some of the new problems of today are found in the design of steam-generating equipment for higher capacities which will produce steam at high pressures and at temperatures of from 900 to 950 F under close control, and which can be erected within restricted building spaces available. In fact, the steam temperature must be under accurate control because of the requirements of the turbine and the approach toward safe limits of tube temperatures at the high pressures. Superheaters must absorb more than 25 per cent of the total heat produced in the furnace, and to do this with any reasonable amount of surface they must receive gases at fairly high and dependable temperatures. Furthermore, the economics of superheater size and construction calls for high steam velocities within the superheater elements, hence relatively small and closely spaced tubes for high gas-mass flow through the tube bank. The distribution of steam inside and of gas velocity and temperature outside to the different portions of the superheater should be quite uniform, to prevent localized overheating.

The greatest single difficulty to be overcome in accomplishing all of this is the ash in the coal being burned. Not so much ash as such, but ash converted into slag through high-temperature combustion; slag that is inevitable, even from the lowest possible combustion temperature when using many of the low-fusing-ash coals, which are available today. Ash constitutes the main problem; ash in the form of molten slag, plastic slag, sticky slag, sponge ash, and fly ash.

Dry ash removal from pulverized-coal-fired furnaces is satisfactorily accomplished with a wide range of ash-fusing temperatures, using turbulent burners, water-cooled furnaces, and rates of combustion from 25,000 to 35,000 Btu per cu ft per hr. Such units are suitable for steam outputs up to about 200,000 lb per hr, and for moderate steam temperatures. For larger units, the ash and slag limitations call for lower rates of liberation and/or higher fusing temperature of ash, and perhaps less turbulent burners. In many localities there is available only a limited amount of coal of high ash-fusion temperature and therefore large furnaces for dry ash removal are being used less extensively.

The nature of the ash in the coal is of greatest importance in designing a furnace for dry ash removal. The intense heat resulting from turbulent burners causes temperatures sufficiently high to fuse almost any ash locally within the active-combustion zone. For satisfactory operation with dry ash removal, the places where the ash discharges to the ashpit, and the gases to the tube bank, must be far enough away from the burner zone to permit the necessary cooling of the ash before leaving the furnace, or else it will adhere to the hopper or other cooling means at the bottom, and to the boiler tubes at the top. In any event, some ash will adhere to waterwalls of any known construction, around the middle of the furnace within the burner zone, as shown diagrammatically in Fig. 1.

If mechanical cleaning is applied to this area, and it is kept reasonably clean, the furnace may be too cold for stable ignition and efficient combustion, especially at lower rates. The rate of radiant-heat absorption may also be too high for the safety of the tubes, if the water conditions are not perfect. Experiences with gas- and oil-fired boilers bear out these points, and some protection of bare water-cooled walls is necessary to obtain complete combustion and protect the walls against tube losses.

With coal firing, the ash or slag accumulation in this zone is uncertain, and troublesome because of its uncertainty. With a combination of ash characteristics and rate of combustion which produce a sticky but not liquid ash formation on the walls, the thickness of sponge ash may increase and spread both up and down to greater areas, insulating the heat-absorptive surface so

[1] Vice-President, Babcock & Wilcox Company. Mem. A.S.M.E.

Contributed by the Fuels and Power divisions, and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

that gas temperatures rise. Higher gas temperatures further accentuate the spreading and thickening until unduly high temperatures reach the boiler tube bank and the bottom of the ash discharge and cause slagging troubles in one or both of these locations. Thick accumulations of slag, sometimes quite bulky, may fall intermittently from the upper part of the furnace, causing damage to the furnace structure.

If the ash characteristics and temperature to which it is subjected are such that the slag is of a molten plastic nature,

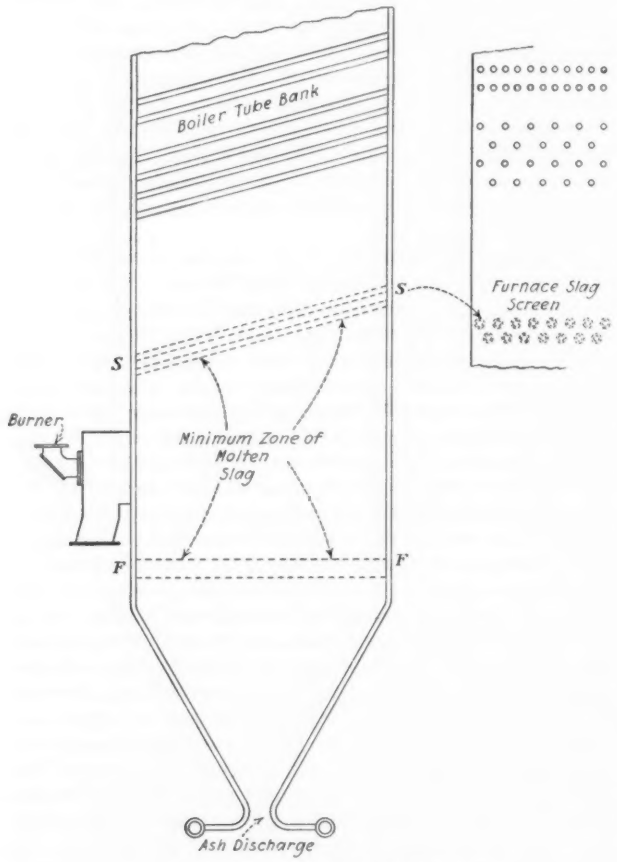

FIG. 1 DIAGRAMMATIC FURNACE

the covered area will also spread downward and upward, necessitating some cleaning to keep the coated area within bounds and also cleaning of the tube bank and ash discharge openings.

Another approach to the problem is to make the furnace of Fig. 1 with a floor at *FF*, which will accumulate molten slag, and to tap it out continuously or intermittently. This raises the furnace temperature in this zone so that the ash on the walls melts and thins down to an equilibrium thickness, with the net result that a higher rate of heat absorption per square foot of the lessened area takes place than existed in this zone before the floor was installed. The temperature in the slag zone is high enough to cause extending of the slag coating upward toward the boiler tube bank. This may call for cleaning of the walls in the upper part of the furnace, as the tube bank would otherwise have to be at an unreasonable height to prevent a gradual extension of slag, which would further insulate the wall and increase the gas temperature as the slag coating extended upward into the tube bank.

As radiant heat from the hot burner zone reaching the upper part of the furnace and boiler tube bank contributes to keeping the slag particles hotter than they would be if shielded, it is obvious that the placing of a screen *SS*, shown as consisting of water tubes coated with a slag-resisting refractory held on to the tubes by a suitable means, across the upper part of the furnace, making a two-stage furnace, serves a useful purpose. (1) The arch effect further increases the temperature of the combustion zone in the primary furnace, which increases the rate of heat absorption per square foot of remaining wall area and makes tapping of slag possible for higher-fusing-temperature ash, and for lower rates of combustion with a given ash. (2) The temperatures of ash and slag above the screen are reduced. (3) Any cleaning of the walls or boiler tube bank in the upper or secondary furnace is more effectively done in this cooler zone, and there is a more definite zone within which cleaning is possible. The screen cleans itself by the melting of the ash, which drips back into the primary furnace. (4) A larger percentage of the ash of the coal is collected than is recovered in a furnace for dry ash removal.

In actually building such furnaces the general scheme of Fig. 1 was carried out on the first installation at State Line Generating Co.[2] in 1929, except that the burners were changed to vertical firing, in order to utilize the furnace volume to better advantage and to collect a larger percentage of ash, especially the coarser particles.

There is full realization of the great importance of going into this problem thoroughly and obtaining sufficient data to make possible the most economical designs of boiler furnaces; designs that permit the operators to cope with the conditions of combustion and the removal of ash in the most satisfactory manner. Some of the results already obtained from these studies are so interesting and instructive that it seems best to present them now in a brief preliminary form.

TEST RESULTS

Table 1 gives, for comparison, certain data pertinent to the operating conditions and results from three different designs of boiler furnaces as shown in Figs. 2, 5, and 8, and plotted in Figs. 3, 6, 7, 9, and 10. As this work was undertaken primarily for gas-temperature studies and the comparison of different temperature-measuring devices rather than to check performance results and efficiency, complete test data were not taken. The heat input has been determined from the steam output, and the heat losses include heat returned in preheated air for combustion.

The nature and behavior of the ash and slag have also been observed during operation, samples have been taken of ash from the coal being burned, and samples of slag and the different kinds of ash from various parts of the furnace, slag screens, and tube banks. The fusing-temperature ranges of these samples have been determined with a view to learning whether or not the ash and slag samples, and their behavior at known temperatures in the Laboratory would add to the knowledge of actual temperatures in different zones of a furnace.

The gas temperatures were determined by a high-velocity thermocouple described by Dr. Mullikin,[3] and these readings were used to calculate the rate of heat absorption in the primary furnace, secondary furnace, and the boiler generating tubes. In the primary furnace the heat absorbed is the difference in sensible heat in the gases between the adiabatic temperature,

[2] Prime Movers Committee Report on Combustion, 1936, Publication D-7, Edison Electric Institute.

[3] "The Accurate Measurement of High Gas Temperatures," by H. F. Mullikin, *Power*, vol. 78, 1934, p. 565. This high-velocity thermocouple is inserted into the gas stream at any desired point in the furnace, and by an aspirator, gas is drawn across a shielded thermocouple at a sufficiently high velocity to bring the couple close to the true gas temperature, free from surrounding radiating influences.

[1] Includes heat in preheated air, less heat required to evaporate moisture and less heat in unburned fuel.

[2] The equivalent temperature of heat-receiving surfaces within a zone is calculated according to the Stefan-Boltzmann law, using the mean of observed gas temperatures and the rate of heat absorption within the zone, assuming black-body radiation. This may not represent the true average temperature of the tube with its coating of mill scale, dust film, sponge ash, or slag, due to undetermined values of such factors as emissivity and the like, but it is suggested as a method of comparing results which undoubtedly will lead to further knowledge regarding heat absorption in boiler furnaces.

[3] Adiabatic.

[5] Bottom second open pass.

as given in Table 1, and the observed temperature of gases leaving the primary furnace. The latter temperature was taken as the average of gas temperatures just before and after passing through the slag screen between the primary and secondary furnaces. A Leeds & Northrup optical pyrometer was also used in the primary furnace only, as it checks the high-velocity thermocouple (HVT) closely near 3000 F. The rate of heat absorption in a zone divided by the total absorption surface of the zone gives the heat absorbed, Btu per sq ft per hr, for that zone. See Table 1, item 25.

Item 26, found in Table 1, is the "equivalent heat-receiving-surface temperature" and is shown on the gas-ash temperature graphs as a straight line for each furnace zone. It is calculated according to the Stefan-Boltzmann law, using the mean of observed gas temperatures and the rate of heat absorption within a zone, assuming black-body radiation with both the radiating and receiving emissivities as 1.0 and the angle factor as 1.0. For the heat absorbed per sq ft per hr in each zone, determined from gas temperatures in and out, there is a black-body equivalent temperature of heat-receiving surfaces, given in Fig. 4.

With the mean gas temperature in the cavity as the radiating body, and the rate of heat absorbed per sq ft per hr by the projected surface of the water-cooled walls and the tube banks, determined by the HVT temperature readings entering and leaving the cavity, it is simple to calculate the equivalent black-body-surface temperature of the receiving-wall boundary areas of the cavity. It is, of course, known that the emissivity is not constant and may be much less than 1.0. This temperature, which may not be a real temperature of any physical body, is then compared with the determined fusing-temperature range of the slag, and some useful conclusions can be drawn about ash deposits on walls and tubes, as shown later. The latter temperatures are determined from actual samples of slag taken from the walls, tap spout, and tube banks throughout the unit and tested in the laboratory according to the A.S.T.M. method.

It is noted in Table 1, items 21, 22, 25, and 26, that the primary-furnace adiabatic temperature in Fig. 3 is 3740 F, the gas temperature leaving is 3100 F, the rate of heat absorption is 78,000 Btu per sq ft per hr, and the equivalent heat-receiving-surface temperature is 2820 F. The slag on the walls, and that being tapped from the primary furnace is about 2600 F and observation showed the water-cooled walls to be covered with a relatively thin film of molten ash that flowed down to the floor continuously and was readily tapped intermittently. The ash-softening and initial-deformation temperatures have little significance in the primary furnace.

FIG. 6 (RIGHT) GAS-ASH TEMPERATURE GRAPH FOR UNIT SIMILAR TO FIG. 5

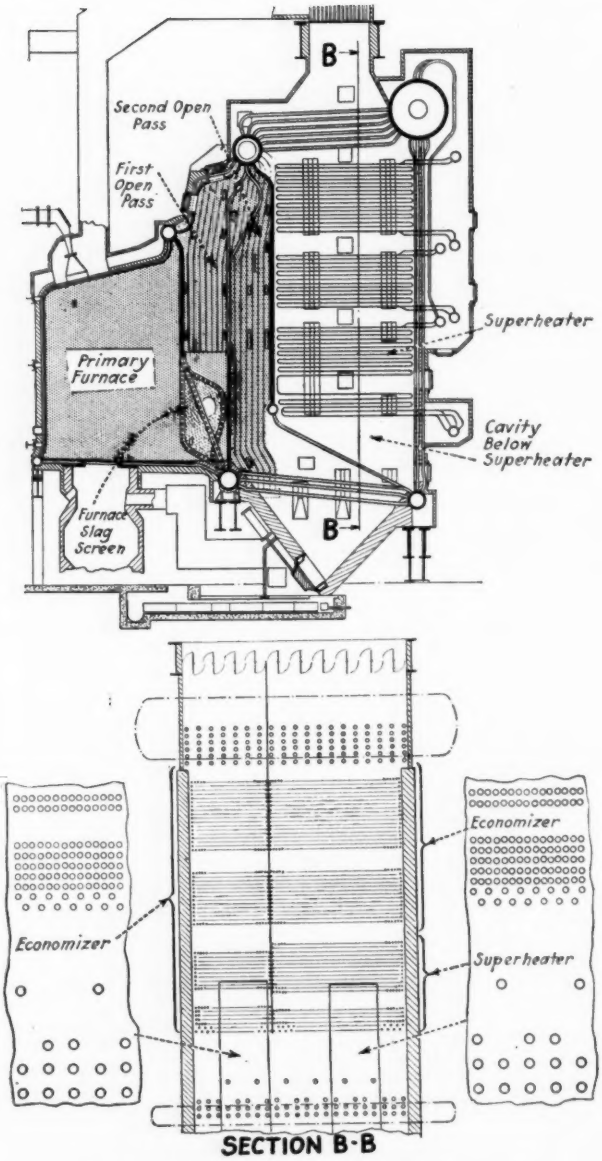

FIG. 8 BOILER UNIT WITH OPEN-PASS FURNACE
(See Figs. 9 and 10.)

In the secondary furnace similar calculations show an equivalent heat-receiving-surface temperature, item 26, of 2612 F and a slag fluid temperature of 2550 F. As a check in the actual furnace, the slag forms a sheet covering over the water-cooled wall and a slow flowing process takes place, maintaining an equilibrium condition without cleaning. The slag falls off in sheets from 1/2 in. to 1 in. thick when the boiler is removed from the line or sometimes when the output is reduced. The gas enters the boiler generating-tube bank at 2550 F, slightly below the fluid temperature, and leaves at 2120 F, slightly below the initial deformation temperature of 2170 F for the slag collected from that point.

In other words, the temperatures throughout the boiler tube bank are within the sticky range of the ash which collects there, and mechanical cleaning by means of telescopic deslaggers and retractable jets using steam-water mix are needed and are used regularly to keep this bank clear for gas flow and to keep it absorbing enough heat to pass gases of the correct temperature to

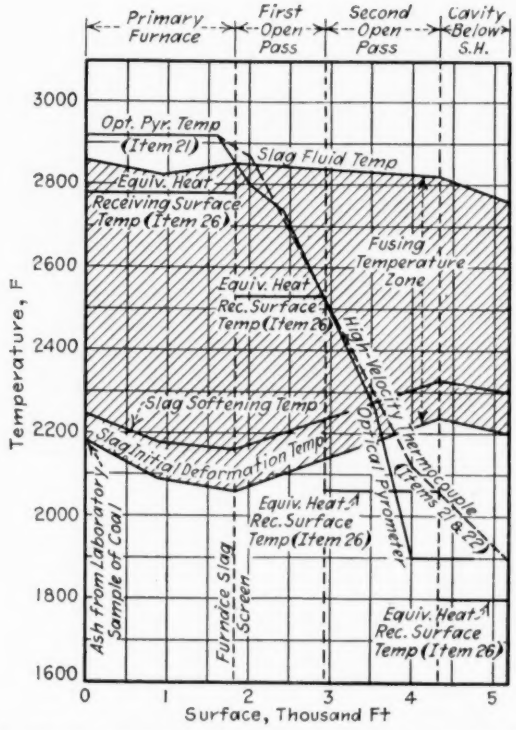

FIG. 9 GAS-ASH TEMPERATURE GRAPH FOR UNIT SHOWN IN FIG. 8, AT MEDIUM RATING

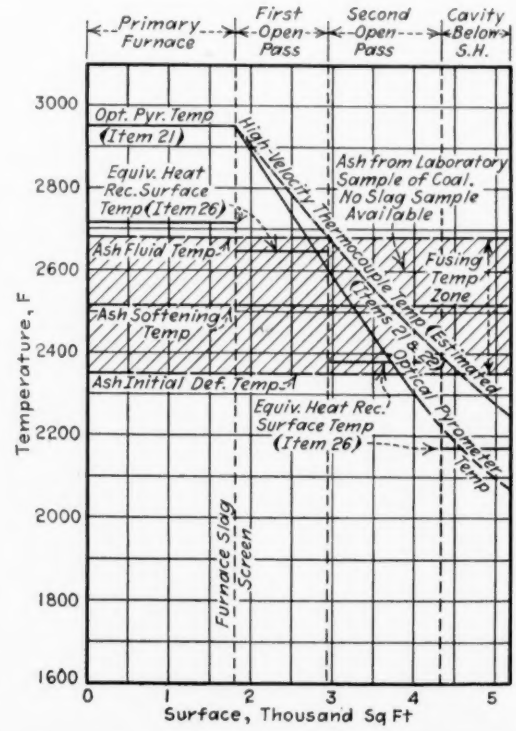

FIG. 10 GAS-ASH TEMPERATURE GRAPH FOR UNIT SHOWN IN FIG. 8, AT HIGH RATING

the superheater. There is no slag problem in the upper tubes of the boiler bank nor in the superheater, which checks with the temperatures and the slag characteristics.

This method of study is somewhat analogous to using Seger cones in ceramic work as a measure of furnace temperatures as related to the results desired in burning ware. The ash and slag supply a basis of comparison of effective results and enable performance results to be studied with greater assurance as to their accuracy and applicability to other designs.

The equivalent heat-receiving-surface temperature of the boiler generating tubes of 2225 F looks high, but it is to be remembered that it is a calculated temperature. However, these tubes are never thoroughly cleaned, for even the best of cleaning leaves a residual coating of ash which may be several hundred degrees above the tube temperature. An increase in ash or slag coating may raise the new surface temperature surprisingly high. While the equivalent black-body-surface temperature is not real and an emissivity of less than unity will lower it, the actual surface temperatures cannot be much lower and be in line with the behavior of the ash as observed at the various locations.

These equivalent black-body-surface temperatures will of course not be uniform throughout the secondary furnace and tube bank, but it is thought best for the time being to calculate them on the simple unity basis and plot them as horizontal lines until further studies can be completed. For the present it is thought this equivalent surface temperature will be useful in comparing results between different conditions such as methods of cleaning, effect of different kinds of coal, methods of firing, adjustment of excess air, and so on.

It should be noted that these data in Fig. 3 from the furnace of Fig. 2 are obtained when operating steadily at 600,000 lb of steam per hr and, for comparison with other graphs in this paper, the rate of liberation is 74,000 Btu per cu ft per hr in the primary furnace alone and 31,800 in the primary and secondary furnace combined.

The total input to the furnace is 833,000,000 Btu per hr, or 65,400 Btu per hr available per sq ft of total heat-receiving surface in the entire furnace and boiler generating-tube bank. The actual absorption in the primary furnace is 78,000 Btu per sq ft of wall surface per hr, while in the secondary furnace it is 30,500, and in the tube bank 15,600 Btu per sq ft of tube surface per hr.

The gas-ash temperature graph, Fig. 6, was obtained from a furnace, as shown in Fig. 5, operating at its full continuous-load condition. The ash is somewhat variable and the averages are shown in Fig. 6. The slag from this ash has a relatively high fluid temperature which, coupled with a tendency to form a sticky adhering formation at lower temperatures than indicated by its initial-deformation temperature, makes a troublesome cleaning and operating problem.

None of the rates of heat absorption in Figs. 5 and 6 are as high as the corresponding rates obtained from the furnace of Figs. 2 and 3, even though the rates of heat liberation are about 20 per cent higher and the heat input per square foot of total furnace-wall and boiler-tube surfaces (item 20) is about 10 per cent higher. This result is now believed to be largely due to the higher fluid temperature of the slag, which is about 2750 F as compared with 2550 F for Fig. 3. The nature of the slag structure, especially on the boiler tube banks, is also significant, as the same means for deslagging are much less effective in Figs. 5 and 6.

Another more direct comparison is between Figs. 6 and 7, where both have the identical cross section of furnace, but the latter is burning a different coal with lower-fusing ash than Fig. 6. The furnace of Fig. 7 is narrower in almost direct proportion to its output at full load, at which rate the data were obtained.

The observed behavior of the slag throughout the furnace and boiler of Fig. 5 with the different coals of Figs. 6 and 7 is consistent with the equivalent heat-receiving-surface temperatures.

The boiler of Fig. 8 has a rated continuous output of 300,000 lb of steam per hr. The test of Fig. 9 was run at 225,000 lb of steam per hr, or 75 per cent of its full-load conditions, with one kind of coal, and the test of Fig. 10 at 342,000 lb of steam per hr, or 14 per cent above full load with a different coal. Unfortunately, slag samples were not obtained from the furnace during the latter run, but the nature of the ash with low iron content would presumably produce a slag with little change in its fusing range from that of the laboratory determination from the coal ash, which is plotted.

The operation of this type of furnace, with two open passes and a small cavity between the last pass and the superheater, with no boiler tube bank whatever, has been very satisfactory.

The slag is easily tapped continuously from the primary furnace with ash of 2800 F fluid temperature and at ratings below 70 per cent of normal. The slag in the first open pass flows slowly back to the primary furnace, and this pass needs no cleaning or attention, which is also true of the primary furnace.

The second open pass accumulates some slag, but is more or less self-cleaning due to the down flow of gases and the gravity action on the accumulation which, with the coal being used, is near its initial-deformation temperature.

Some cleaning of slag from the screen tubes at the top of the first open pass is required. This is being done with a retractable-nozzle deslagger.

Single-jet retractable blowers are also used occasionally at the entrance to the superheater and economizer by-pass, to clear the slight amount of sponge ash which accumulates there.

The behavior of ash within a furnace is of such importance that a few comments regarding it should be kept in mind while discussing the subjects of temperature and rates of heat absorption.

In burning pulverized coal from modern direct-fired systems with turbulent burners in hot furnaces and the proper excess air, all but a small residue of the coarser coal is burned completely in the furnace and only residual ash particles remain. A microscopic examination of such fly ash discloses tiny fused black, brown, gray, white, and transparent spheres, together with crystals of unfused ash.

There are also some carbon or coke particles from the small residue of coarser coal present in the fly ash. A microscopic study of these is even more interesting and significant in connection with slag formation. Such a piece of coke has on its surface a number of beads of ash, many of which are fused into multicolored spheres and are the residue of ash in the coke which has already been burned from the surface of the particle. They are held to the coke by the adherence to small particles of ash which are only partly exposed at the surface of the coke. Many of these spheres and particles of carbon-free ash are continually falling free from the coke, hence the explanation for fly ash being so much smaller in size than if each particle of coal retained all of its ash as a single particle. The most significant result of this particle of coke with its nodules of ash is that its continued burning keeps its temperature above that of the carrying gas and the ash, being kept hotter, is more likely to stick to wall or tubes, holding the carbon where it burns still more rapidly due to the scrubbing action of the gases. As the combustion is completed, the residual ash is largely retained at a relatively higher temperature and is added to the accumulation of slag.

This is one explanation of the generally accepted fact that coarse coal and improper combustion are conducive to slag accumulations. The slag in boiler tube banks from fuel beds is largely carried up in the form of burning particles of coke rather than of free ash itself.

While it is well recognized that ash in coal is a complex sub-

stance and individual constituents of it vary in fusing temperature from as low as 1800 F to as high as 4000 F, it is treated as a mixture; in the laboratory, ash residue from a slowly burned out coal sample is formed into a cone-shaped briquet and its fusing-temperature range is determined in a muffle furnace and reported as (1) initial-deformation temperature, (2) softening temperature, and (3) fluid temperature. The initial deformation is that at which the cone starts to distort and is really indicative of when the lowest-fusing-temperature particles begin to soften and cement the higher-fusing particles. The softening temperature is that at which the cone has softened enough to turn the apex downward, or to bend the axis about 90 deg from its initial vertical position. This particular temperature has been referred to in the past as the fusing temperature and has been generally used as the important temperature in measuring the behavior of the ash and comparing the relative values of coal. When coal is to be burned in fuel beds this temperature is of value for comparisons, but it is now believed to be of little significance in large pulverized-coal-fired furnaces. The fluid or liquid temperature is important in connection with slag-tap furnaces and for a knowledge of the behavior of ash in water-cooled furnaces operating at temperatures above the fluid or liquid temperature of the ash, as most of them do at their normal and maximum ratings. In this paper "fusing temperature" is used as an inclusive generic term covering all three of the specific temperatures within the band just described.

Within a furnace or boiler unit, the ash collecting at any point may not be a true average of all that which is in the coal. Dense, hard-grinding particles, such as sulphide from pyrites, are more likely to be retained on the floor of a furnace. High-fusing-temperature particles are more likely to pass on through the entire furnace and boiler unit as fly ash, as they themselves are not sticky but they may be retained to some degree by adhering to sticky ash already retained on the surfaces. The particles which are molten have a double chance of being retained within the furnace, due to their sticking to cold surfaces, and surely to hot sticky surfaces.

Comparison of Methods for Measuring Furnace Temperatures

(*a*) The high-velocity thermocouple previously mentioned is the most accurate practical method now known for measuring gas temperatures.

(*b*) Certain forms of optical pyrometers (disappearing-filament type) are reasonably accurate for the highest-temperature zones of furnaces, where uniform temperatures prevail.

(*c*) Bare thermocouples have not been found particularly useful for gas-temperature measurement.

(*d*) Radiation pyrometers and other forms of elements sensitive to heat and light are being carefully studied, as it is desirable to know more than merely gas temperatures.

(*e*) It is desirable to know the temperature of slag particles floating in the gas stream, especially as they approach tube banks. Such slag particles are undoubtedly hotter than the carrying gases leaving a burner, if still within view of the hotter zones of the furnace; and cooler than the carrying gases when approaching cooler surfaces, especially when shielded from the radiant heat of the hotter zones. Perhaps a bare thermocouple of the proper size more nearly approaches the true temperature of the slag particles until some better method can be devised.

(*f*) It is desirable to know the temperature of floating particles of coke, especially just as they strike an arresting surface, also as they continue to burn when so arrested. No work has yet been done in this direction.

(*g*) A most important factor that should be known is the heat reflected and radiated from the wall surface. If this can be determined, it may give a more direct method than we now have of measuring the rate of heat absorption at the wall.

Summary

1 The fusing-temperature determinations on ash from a sample of coal, as now burned out in the laboratory according to A.S.T.M. standard methods, are not accurately indicative of the corresponding temperatures of the slag as formed in furnaces from the same coal. Many other data beside those shown here indicate much greater deviations. Usually the slag accumulated in the hotter zones near the burners and on the floor, or in the slag-tap section, is lower in all points than that determined from the coal sample by the standard method. There is a general tendency for the slag and ash collected beyond the hot zone to be higher in all significant temperatures.

2 Some ash or slag adherence takes place on all furnace walls, boiler, superheater, and other surfaces. So long as it adheres at all it tends to become cumulative. Dry nonsticky ash may maintain a close equilibrium by falling off due to gravity or being carried on by the normal gas velocity.

Sponge ash or even vitrified slag may fall off in pieces intermittently by its own weight, especially if the rate of combustion is changed from time to time, and the surface to which it adheres is not holding it too tenaciously. Continuous high-rating operation is usually conducive to continued accumulation of sponge ash or plastic ash in the zones where the ash is within the sticky-temperature range. This zone in the furnace should be as small as possible. It may be desirable to clean it by hand lancing or some deslagging means if the need for uniform conditions warrants.

The parts of the furnace where the temperature is maintained above the fluid temperature of the ash which deposits there, is kept at a more uniform condition than any other part because of the continued melting and running away, leaving a base of plastic slag. The lower the fluid temperature of the slag the greater the heat absorption in a given furnace with a given rate of heat input, and also the lower the gas temperature leaving such zone.

3 Ash and slag having a wide spread between the initial-deformation point and the fluid temperature are more likely to be troublesome than those with a smaller temperature range and a sharper melting point. With a wider spread like that in Fig. 6 from 2100 to 2730 F the fly ash must pass through a wide temperature range, and therefore a large surface exposure, before it is cooled from the liquid phase where it is easily handled, to the dry nonsticky stage. The coal of Fig. 9 covers even a wider spread from 2060 to 2850 F. In some furnace arrangements this might be extremely difficult to handle, although in the furnace of Fig. 8 no difficulty has been encountered.

4 A valuable method of comparing furnace-operating results has been discovered consisting of (1) taking accurate gas temperatures throughout a furnace, (2) calculating from them the rates of heat absorption in different zones, (3) calculating an equivalent heat-receiving-surface temperature for each zone, (4) taking samples of ash and slag from different portions of the furnace and determining the fusing-temperature range from such samples, (5) plotting these data as a gas-ash temperature graph against heat-absorbing surface, (6) comparing the data as shown on such graph with observed behavior of ash and slag in the furnace, and (7) comparing different furnaces, different coals, and methods of operation through the use of such graphs.

5 The equilibrium conditions with molten-slag-covered surfaces is a subject deserving further study. The data presented here were obtained under what were thought to be equilibrium conditions, brought about by long periods of operation at uniform load. However, only further continued observations will determine when equilibrium has actually been obtained.

Others who may follow this line of study should keep this in mind. For instance, if a unit that has been operating a long time at high rating is suddenly reduced to low rating, the reduced furnace temperature may cause a complete stoppage of flowing slag over the furnace walls and floor. Continued accumulation of ash will increase the thickness of slag until the furnace temperature is increased by the insulating effect, and fluid conditions are again restored. The ash accumulates more slowly at the lower rates of combustion. When the rate of heat input is again increased there will be a period of higher temperature until the surplus slag film is melted away.

6 The studies presented herein, indicate that the nature of ash in the coal being burned, has such an important bearing upon the operating results from furnaces, that proper selection of coal must be made for many, if not all, furnaces. It is believed that further studies along the lines herein set forth will enable furnaces to be designed which will permit wider latitude in the selection of fuel.

7 The superheater bank, usually consisting of relatively closely spaced small tubes, must be kept clean. This means that the fly ash should be below its sticky temperature, yet the gases should be as hot as possible for high superheat. The velocity and temperature of gases should be as uniform as possible to all parts of the entering area of the superheater for the protection of the tubes. Some cleaning device is needed, as a gradual accumulation of sponge ash or dust is inevitable. It should be kept uniformly clean, because if certain areas accumulate sponge ash and direct the flow of gases to limited portions of the superheater the higher gas-mass flow may quickly overheat such portions of the superheater tubes.

8 Colored moving pictures of furnace interiors have been helpful in studying ash and slag formation on heat-absorbing surfaces, with a view to obtaining better methods of removal and preventing the formation. By taking such pictures at high speed and from points close to the furnace doors, many phenomena can be seen in much more detail than from personal observation. Time and speed measurements can also be taken.

9 In conclusion, it should be remembered that this paper includes data from only four installations. The results were so illuminating that it was deemed to be to the benefit of professional progress to publish the data and method of comparison now, so that others active in this work can utilize what has been reported. Criticism and suggestions will be appreciated as an aid in developing and applying this method in studies which will surely be pursued further in the future.

Acknowledgment

Acknowledgment and appreciation are given to R. Shellenberger, Dr. H. F. Mullikin, and E. D. Grimison, associates of the author, for their diligent and constructive assistance in this work; without their help and cooperation the data here presented would not have been available.

Discussion

J. M. Drabelle.[4] This paper is particularly valuable to operating men who have in their charge large boilers and furnaces operating at high ratings.

For the last year the Iowa Electric Light and Power Company has been experimenting with the motion-picture camera and Kodachrome film for obtaining photographic records for use in studying stoker and furnace operation. Experience seems to indicate that colored motion-picture film is a valuable tool for obtaining a clear, concise, and readily examined picture of furnace operation. It should be borne in mind that, being in color, relative color values are not destroyed as they are when a furnace is observed through conventional blue-glass screens.

The equipment which we have been using is an Eastman Ciné Kodak equipped with an F-1.9 lens. To protect the camera from the intense heat of the furnace Aklo glass made by the Corning Glass Works, Corning, N. Y., has formed the shield through which the photographs have been taken. This glass has the peculiar property of transmitting light but not transmitting heat waves. Two screens of Aklo glass are used in series held loosely in a suitable frame. The lens of the camera is placed immediately back of the second sheet of glass. Up to the present time, no attempt has been made to use the conventional exposure meter. The diaphragm of the camera is stopped wide open. The resulting photographs have shown slag phenomena and burning phenomena very clearly, particularly on underfeed and chain-grate stokers. Formation of clinkers as well as the stratification in burning gas streams from the fuel bed are also depicted. To those having furnace trouble, this is a possible means of studying conditions within the furnace. Once the trouble is determined, a suitable remedy may be applied.

H. D. Harkins[5] and A. C. Flinn.[6] One of the most interesting points brought out in the paper is the conclusion that, for the same heat release, the transfer coefficient would be higher with coals having low-fusion-temperature ash due to the fact that the low-fusion ash forms a thinner, more fluid slag which offers less resistance to the flow of heat to the tubes. From this it would follow that low-fusion-ash coals would require a smaller amount of surface in the primary furnace or that, given similar conditions, a higher transfer rate would obtain in a slag-tap furnace, where the temperature must be such as to keep the ash fluid, than in a dry-bottom furnace. This indicates the possibility of building smaller and, consequently, cheaper furnaces for what have been considered the more difficult (low-fusion-ash) coals. Heretofore larger and more costly furnaces have been built for them.

The comparison between the furnaces, Fig. 2 and Fig. 5, shows about 19 per cent greater transfer rate in the primary furnace with the coal of lower ash-fusion temperature. However, it does not appear to have been proved conclusively that ash fusion is the direct cause or that other effects may not have contributed to the difference in heating rates.

For instance, Sherman[7] at Battelle Memorial Institute, in working on pulverized-coal flames from four types of bituminous coal, found variations in the emissivity coefficients and also in the initial flame temperatures. The emissivity coefficients varied as much as 30 per cent. Due to the fact that the coals having the highest emissivity also had the highest initial temperature, the heat radiated varied even more than this amount.

Since these data on radiation from the flames of several coals indicated a difference greater than that ascribed here to the difference in slag fluidity, the question arises as to whether emissivity or other similar effects may not have accounted for some of the difference in transfer rates?

E. A. Hitchcock.[8] It seems only a short time ago—about

thirty years—that I was with a group of engineering students in a new pumping station of the city of Cleveland. How we admired that pumping equipment, which was the "last word." And the boiler-room equipment! I can still see the highly polished brass feed lines and those shining gages. In one respect we could hardly believe our eyes for those gages stood at the unbelievable pressure of 180 lb per sq in. My conservatism relative to future developments led me to exclaim: "That is the limit!" What an unwise statement! It certainly cured me of making prophecies applying to the fields of engineering and science.

Nearly twenty years ago I was dining with Benjamin G. Lamme, who was for many years chief engineer of the Westinghouse Electric & Manufacturing Company. At that time the largest turbogenerators built were about 50,000 hp. I felt the limit had been reached but ventured to ask Mr. Lamme what in his opinion would be the limit in size of such a machine. His immediate reply was: "The limit is the customer's pocketbook." I little thought at that time I would see a verification of Lamme's statement, but I did—a 225,000-hp machine going through the Westinghouse shops and later in operation in the Richmond Street Station of the Philadelphia Company. Now I assume, the end is not yet.

The most startling advancement, as I see it, has been on the steam-generating side. This progress has not been easy sailing by any means. One very important phase is now being presented by the author. When he became acquainted in a practical way with the burning of bituminous coals, boilers having steam capacities of 7500 lb per hr at 150 lb per sq in. pressure were about the upper limit. Where are we now? One million pounds of steam per hour at 1500 lb per sq in. pressure or more and 330 F superheat. An increase in capacity of over 130 times the equipment of thirty-five or forty years ago, to say nothing of the increases in pressure and temperature.

It was my privilege, about thirty-eight years ago, to be associated with the author on various kinds of fuel and combustion tests. For about four years we "bled and died" together, he occupying the important position of "go-between" from coal pile to boiler furnace, usually of the Dutch-oven type, while I kept the records and fulfilled sundry other little jobs which required very little brawn and, I guess, a small amount of mentality.

To generate the steam by the shovel method was no bed of roses. It was no punching of buttons and watching of recording and indicating gages. The slicing and cleaning of fires, and the pulling of clinkers was a man-size job; at times an asbestos suit would have been acceptable. The progress that has been made in this particular direction is as great as from the labor of the galley slaves to the duties of the boiler-room crew of an oil-burning ocean liner.

It was, I am sure, this early experience with many kinds of coal, producing ash and slag of various characteristics, which convinced the author that here was one of the most difficult and trying problems in the use of fuel. Many were the times, after a few hours running, that the grate bars became so clogged with fused ash that a shutdown was necessary! The importance of considering this slagging factor in testing coals became so apparent that all clinker above a certain size was sorted from the total refuse and so recorded. My records show that this factor was first determined by us in April, 1899. This early experience was, I believe, the beginning of the author's interest in ash and slag, considered as among the most deterrent factors in the economical generation of steam. As a result, there soon followed determinations of the fusing temperature of ash. The importance of this factor is recognized today.

It was in November, 1911, that the author read a paper before the Ohio Society of Mechanical, Electrical, and Steam Engineers. His statements and conclusions in that paper[9] were based upon the results of twenty-eight complete heat-balance boiler trials with fuels, having ash-fusing temperatures running from 2210 to 2700 F, and also upon a valuable tabulation of thirty-two fusing temperatures of fuel ash, ranging from that of anthracite at 3150 F to bituminous at 2140 F. This tabulation included also the percentage of ash, and sulphur, and in several cases the iron oxide in the ash.

My purpose in calling attention to this early investigation work is to bring about a consciousness that slag was a recognized problem nearly forty years ago. It was controlled partly by brute force and awkwardness. It was the "imp" in the coal pile. Most of us have had experience enough to know that Mother Nature seldom surrenders her treasures without some tough work somewhere by someone. That coal imp is still with us, although our methods of handling him have changed greatly.

We are, I am sure, pleased that the author has come forward with suggested methods for comparing furnace operation. Support for his recommendations is the results obtained upon three types of furnace settings. In these investigations a most unusual and important feature was the application of colored moving pictures in studying furnace activity. They were obtained with considerable hazard to the observer. It is to be expected that, as a result of these investigations and those to follow, there will be advancements in furnace designs and reduced operation costs. However, I believe a marked increase in heat efficiency, even with the best practice of today is not to be expected, for it is not there to get.

Ten days ago I was at the Glenlyn plant of the Appalachian Power Company and there learned from M. P. Lawrence, superintendent, that their latest installation, a powdered-coal furnace with wet bottom, had a record of nine months of 24-hr continuous operation, with Pocahontas coal, generating approximately 350,000 lb of steam per hr and giving an efficiency of between 85 and 86 per cent. I understand a later installation at the company's Logan plant, having a capacity of 1,000,000 lb per hr at 1425 lb per sq in. pressure, dry bottom, is giving about the same efficiency with a bituminous coal of much higher ash content than the Pocahontas.

The experience of M. P. Lawrence with powdered coal at the Glenlyn plant has been so satisfactory that he agrees completely with those who believe the use of powdered fuel in large generating units is destined to become general. It is conceded, however, that at present the ash characteristics are important deciding factors.

For example in the Glenlyn plant is a chain-grate equipment 24 ft wide by 26 ft long, upon which bone coal with from 15 to 25 per cent ash works most satisfactorily. That coal condition would probably make combustion by the powdered-coal road difficult and impractical. As I see it, from my forty-five year point of view, the ideal combustion of coal is not reached yet; there are a few factors still to be licked. The author of this paper has handed to us, on asbestos gloves, some hot nuts to crack.

P. B. METCALF.[10] Too many statments have been made in the past by various people that pulverized-coal firing is a panacea for troubles encountered with any and all types of coal, in other methods of firing. It is gratifying to have the author's frank statement: "The studies presented herein, indicate that the

[9] "Fusing Temperature of Coal Ash and Its Relation to Rate of Combustion," by E. G. Bailey, *Journal* of the Ohio Society of Mechanical, Electrical, and Steam Engineers, November, 1911, pp. 53–67.

[10] Steam Engineer, New England Power Service Company, Boston, Mass.

nature of ash in the coal being burned, has such an important bearing upon the operating results from furnaces, that proper selection of coal must be made for many, if not all, furnaces."

The statement is made early in the paper: "If mechanical cleaning is applied to this area, and it is kept reasonably clean, the furnace may be too cold for stable ignition and efficient combustion, especially at lower rates." This conclusion appears to be at variance with other authorities on the subject, notably with a statement made by Henry Kreisinger,[11] who states: "Beyond the temperature required for quick ignition of the fuel, nothing is gained by going to higher temperature. In fact, there are experimental indications that high temperatures retard the combustion."

In view of this seeming conflict of conclusions on the subject, it would be helpful if the author could give further information toward clarifying the issue.

The explanation of why coarse coal and improper combustion are conducive to slag accumulations is most interesting and further emphasizes the need for fine pulverization with an absolute minimum of coarse particles.

J. F. Muir.[12] This paper, illustrated by motion pictures has the distinction, within the writer's experience, of being the first presentation of its kind dealing with the effects and significance of ash transformations as they occur in the boiler furnace.

The following comments are made as a member of the A.S.M.E. and not as an employee of any company.

One of the many points of importance brought out by the author and one that deserves repetition and emphasis is the fact that, in the design of the high-capacity boiler, it is not sufficient, as has been done heretofore, to take a single temperature value for the change in ash from and to its solid state in the combustion process. It is pointed out that, in setting up design fundamentals, it is necessary to give consideration to and make allowances for first, the initial-deformation temperature; second, the softening or plastic temperature, which has been commonly referred to as the fusion temperature; third, the fluid temperature which is the one that must be maintained in the slag-tap bottom. The author includes all of these three specific temperatures under the category of "fusion temperature," which classification incidentally might be referred to as the "fusion-temperature range," since it involves more than one temperature. While the application of this fusion classification in combination with the gas-ash-temperature graph to the design of the combustion system is quite complicated, nevertheless, these are definite advances in the development of design fundamentals having practical possibilities.

Operators of high-capacity units have recognized the significance of these three temperature classifications and have learned that combustion temperature, when properly concentrated to give complete combustion in the furnace, will, of course, liquefy any kind of ash. To avoid slagging of boiler, superheater, or economizer convection surfaces the gas-entering temperatures should, if anything, be below the softening or middle-temperature classification. Furthermore, to meet the operator's idea of slag prevention, gas flow should be uniform in all sections of the assembly and the velocity of the gas, entering the convection sections, should be relatively low to get away from adhesive impact of slag against tubes. The operator has also learned that for rapid and complete combustion, fineness of pulverization and high turbulence over the entire combustion zone are essentials.

It has been mentioned that slag in the furnace is inevitable, but it might be added that slagging is intensified to a great extent in units designed for high capacity, high-steam temperatures and high rates of heat liberation. Operating experience with units fired with pulverized coal during the last two years indicates that the greatest barrier to holding the boiler in service for extended periods is the deposit and accumulation of slag or ash while in a semiliquid or a plastic state in the convection sections, particularly those having narrow gas passages between rows of tubes.

The elimination of these troubles and to meet the more or less ideal conditions which have just been described might call for an appreciable increase in tube surfaces over that provided in many installations. The first cost would also be higher; but if an increase in the availability of the unit can be accomplished, the higher first cost might readily be warranted and approved. High availability, it should be emphasized, is the operating factor that is necessary to establish economic justification for the installation and for the money invested in the project.

It may be pertinent to mention that in some of the recent units the time of travel through the furnace, from the burner to the boiler-tube-bank inlet, is about 1 sec. During that extremely short interval the volatile and carbon in the coal are consumed while the ash liberated has been transformed from solid to liquid and back again to a solid, all of which process seems almost incredible in the space of time available. Under these conditions, it is not surprising that more than 50 per cent of the ash in various stages of plasticity passes through the assembly, requiring higher-cost collector equipment to prevent undue release of ash to the atmosphere.

One of the most serious troubles in the combustion system of the high-pressure and high-temperature units and the one, which possibly causes the most interruptions to service, is the stopping up of the gas passages in the convection-type superheater with slag and ash. Steam blowers in many cases have failed to dislodge accumulations, while hand lancing in many cases necessitates shutting down the boiler. Because of the inaccessibility of the superheater passages, the manual process is a slow, awkward, and expensive operation.

To superheat steam above 900 F, with superheaters of the convection type, at the entrance to the superheater section, requires a gas temperature close to 2000 F. With an ash-fusion-temperature range of, say, 1900 to 2300 F, it is next to impossible to cool the ash down to a more or less dry state until the ash particles have advanced a considerable distance into the superheater gas passages. Now, if the gas passages between the superheater tubes were large and the gas velocity relatively low or, say, in the order of 50 ft per sec, it is possible that the superheater would remain free from slag choking for long periods. However, superheaters have not been made with wide spacing; in fact, passages between tubes are actually less than 1 in. and gas velocities up to 100 ft per sec are quite common. These conditions may be satisfactory for ash of high-fusion temperature, but with ash fusion in the 1900 to 2300 F range and, particularly for gas carrying in suspension over 50 per cent of the ash content in the fuel, slag stoppages are quite likely to occur. It should be pointed out that these conditions refer particularly to boilers of the inclined straight-tube type with counterflow convection superheaters.

Why have close spacing and high gas velocity been adopted? As the author points out, the superheater for these high steam temperatures must absorb more than 25 per cent of the total heat produced in the furnace, which is an extraordinary job for any kind of a superheater. With this great amount of heat absorption, the unit must necessarily be compact to fit into restricted

[11] "Combustion of Pulverized Coal," by Henry Kreisinger, Trans. A.S.M.E., vol. 60, May, 1938, paper FSP-60-8, p. 289.

[12] Power Engineer, American Water Works and Electric Company, New York, N. Y. Mem. A.S.M.E.

accommodations. To hold the first cost at an acceptable and competitive point, small tubes and close spacings are desirable to obtain maximum rates of heat transfer.

With possible frequency of interruptions in service, caused by stoppages in superheaters of the closely spaced type, purchasers would, of course, be interested in developments which will minimize these interruptions to the greatest possible extent. With this end in view, the first consideration might be to avoid, if possible, this excessive concentration of closely spaced tubes and the second to lower the temperatures of the gas and the amount of ash in suspension entering the superheater surfaces.

If the superheater could be divided into two parts, transferring the final-temperature section to panels in the furnace where the superheating would be done by radiant heat, the remaining convection element would then operate at lower gas temperatures and would be called upon to absorb, say, about 15 per cent instead of 25 per cent of total heat produced in the furnace. Why not substitute sections of steam-cooled walls for water-cooled walls in the furnace, as has already been done in a few installations? It might be necessary to locate these steam-cooled walls in the upper section of the furnace to avoid exposing surfaces of this type to the extreme temperatures of the combustion zone.

Without doubt a combination superheater of this kind would be a great deal more expensive than a straight convection unit. Whether the results, as regards increased availability of the boiler, would be realized and whether the purchaser would feel justified in paying a much higher price is problematical. No doubt these things would take a long time to settle. Be that as it may, the fact remains that the convection-type superheater, in its present arrangement and design, restricts the availability of the modern boiler fired with pulverized coal. Operators can well afford to pay handsomely for an improvement in these operating conditions and they look hopefully to the future for an appreciable reduction in the loss of output and the high costs incident to removal of slag from superheater passages. Meantime the redesign and improvements in the arrangement of tubes in the convection elements of the boiler by the manufacturers may in the near future produce higher availability and an economical solution of slagging in the gas passages of these elements.

Availability and the production of steam-generating units for high pressures and temperatures that will deliver specified rated capacities without interruption for periods of 6 or 12 months or longer must be the objective. The central-station company cannot afford to add spare boiler capacity as was the usual practice ten years ago. There is no serious thought that slagging conditions, as they occur in the high-pressure and high-temperature boilers, will be instrumental in forcing a return to the almost forgotten spare-boiler installation. The results of the author's investigation and research constitute a definite advance in the development of units to cope properly with the slagging problem and should contribute greatly to improvements in boiler design and construction, in order to meet the operators' expectations as regards availability.

E. B. Powell.[13] This paper records an important step in the pathway toward scientific design of the steam-generating unit and one which brings attainment very markedly nearer. The research of Armacost, Gordon, Hottel, Mullikin, Schmidt, Uchida and Tanabe, and Wohlenberg, to mention some of the most recent investigators, was necessary in developing a sound theoretical basis for correlation and interpretation of data and in improving tools and technique. The work which the author describes represents, in the writer's opinion, the most comprehensive factual analysis of the practical aspects of heat transfer in the combustion and immediately related zones of the modern steam-generating unit that has so far appeared. Yet, as the author himself points out, this is but an initial step along a very promising pathway. I am sure we all hope that he may continue as his paper suggests. It would be of much assistance to those others who follow if he would supplement his paper by a specific statement of the methods which he employed in gas-temperature measurement. Precision in such measurement requires complete freedom from interference of surroundings and is particularly important when different surface arrangements are under analysis. The steam-power industry is again indebted to the author for his pioneering work.

[13] Consulting Engineer, Stone & Webster Engineering Coporation, Boston, Mass. Mem. A.S.M.E.

H. P. Reid.[14] The writer is particularly interested in the methods which were used by the author to measure gas temperatures at various locations in the boiler.

The difficulty in obtaining gas temperatures that are representative and usable in studying boiler and furnace operations is fully appreciated. For several years the writer has made use of the high-velocity thermocouple for research and test purposes and would seriously consider application of such thermocouples for continuous records, if a stable and satisfactory design could be obtained.

Table 2 contains representative data illustrating errors that may occur by the use of the protected thermocouple. These data were obtained from recent tests on the performance of a rotary cement kiln and the waste-heat boiler attached to it. Temperatures of the gases leaving the kiln were taken by both protected or shielded thermocouples and also by high-velocity thermocouples. The figures given are average for a number of readings taken during the test period.

TABLE 2 DATA ILLUSTRATING POSSIBLE ERRORS FROM USING PROTECTED THERMOCOUPLE

	Gas temperatures F leaving kiln			Boiler efficiencies, per cent, calculated from	
Test no.	By protected thermocouple	By high-velocity thermocouple	Temperature difference F	Protected thermocouple readings	High-velocity thermocouple readings
273	1465	1590	125	67	62
274	1540	1862	322	73	59

In the tests, Table 2, the waste-heat boilers were operating considerably below rating. This explains the low boiler efficiencies. It is believed they are representative for this particular type of waste-heat boiler installation.

Bernhard Schroeder.[15] The results of tests made on three different installations are of much value but insufficient as a basis for definite conclusions. No doubt more extensive investigations will be undertaken by many operating companies. In this way the problem can be much more rapidly solved for various kinds of coal.

Knowing how difficult it is to obtain reliable data on which to base conclusions, one is inclined to wonder what is the degree of accuracy of the data presented in the paper? For instance, when powdered fuel is blown into a furnace, the various-sized particles of fuel immediately start to distill off the volatile gases. If sufficient oxygen is present, the gases will be burned; if not, they will not be completely consumed. With the amount of excess air ordinarily present in a boiler furnace, such as given in the paper, namely, 14 to 25 per cent, it is not difficult to consider the furnace being filled with gases of almost any composition, together with solid particles of carbon. All of these can only be

[14] Operating Engineer, Universal Atlas Cement Co., Chicago, Ill. Mem. A.S.M.E.

[15] President, Sargent & Lundy, Inc., Chicago, Ill. Mem. A.S.M.E.

burned when coming into contact with the required oxygen. It would appear quite possible for the burning gases to pass through the primary and perhaps through the secondary furnace before finding the necessary oxygen to complete their combustion.

On looking over the author's calculations, it is evident that the combustion is assumed to be completed before the gases leave the primary furnace. If they are not, the calculations are all affected to some extent. Therefore, it is necessary that the completeness of the combustion should be established. In future work complete analyses of the gases should be made to determine this point.

The gases leaving the boiler may show 15 to 20 per cent excess air, but in actual boiler operation the proportions of excess air, as between the various burners, may be quite different. The distribution of coal in the burner itself often leaves much to be desired and, unless the turbulence is very great, a satisfactory fuel and air mixture is not obtained until the gases have entered the boiler tubes or even the superheater.

Until there is some radical change in the art of burning coal, slag in some form will always be present. If it can be determined where the slag shall be deposited, by suitably proportioning the heating surfaces and the gas temperatures, then adequate means can be provided for its removal with a minimum of trouble and expense.

V. J. Skoglund.[16] The data given in this paper are useful as a guide in the analysis of heat transfer by radiation in furnace cavities. It would be ideal if point-by-point heat-transfer rates (Btu per hr per sq ft) and temperatures could be calculated from fuel and air operating conditions for any type of furnace cavity, using only the fundamental laws of thermodynamics, heat transfer, and fluid mechanics. To do this is as yet impossible but, starting with simplifying assumptions based on experimental data, rational analysis may some day make a useful contribution to the solution of practical furnace-radiation problems. At present the furnace-radiation analyst is handicapped by the lack of reliable data on conditions within furnace cavities.

An unsolved analytical problem of practical value is the calculation of point-by-point heat-transfer rates (Btu per hr per sq ft) for specified temperatures and emissivities of gases and suspended particles which vary from point to point within a cavity. The following additional data, taken simultaneously with gas temperatures and the corresponding over-all furnace conditions, are necessary before undertaking the development of a solution for the foregoing problem:

1 Intensity of emission or total emissivity of the mass of gases and suspended particles within the cavity for all possible directions at different points on its surface; there is at present no practical way of measuring this and the first step would be the development of such a method.

2 Measured wall temperatures over all of the surface; in the ash and slag problem as discussed by the author, measured wall temperatures are needed to establish the significance of those deduced from fusion properties of ash and slag samples.

3 Approximate thickness and mean conductivity of the slag on absorbing surfaces; the thickness may still vary with time after a long period at a uniform load.

The author makes the statement, "(*g*) A most important factor that should be known is the heat reflected and radiated from the wall surface." Although a rational solution of the above unsolved analytical problem might be laborious, it would be very valuable inasmuch as it would include the determination of that factor as well as surface temperatures.

The author's method of calculating an "equivalent heat-receiving surface temperature" is very simple but, even though the Stefan-Boltzmann radiation law is used, the method should not be considered rational since the use of an average gas temperature and an emissivity of 1.00 are not consistent with the actual mechanism of radiation. The method is of value only if results can be correlated for a large number of different furnaces and coals. This may require the use of empirical values of emissivity differing in different zones instead of the value 1.00.

The paper includes the statement, "(*e*) It is desirable to know the temperature of slag particles floating in the gas stream, especially as they approach tube banks." Attention is called to the mathematical results of Wohlenberg and Wise,[17] which are a qualitative indication of Δt, the difference between gas and particle temperatures, for points not near cold surfaces. Although their analysis is for very much idealized furnace conditions, after studying their paper, the writer believes the statement in the summary applies to average values in actual furnaces, "Hence for any reasonable length of gas travel in the cavity the ash-particle temperature is substantially that of the gases except for regions close to cold surface." Where flow conditions are unsteady, as is usually the case in actual furnaces, instantaneous values of Δt might be considerable for particles accelerated relative to the gas stream in regions where the temperature gradient in the gas is high.

V. V. Soldatoff.[18] Although the author states that consideration of the efficiency of steam-generating units is not the object of the paper, it is of great interest to the writer to bring out this point when speaking of boiler furnaces. For the combustion of pulverized coal must be provided (*a*) time, (*b*) temperature, and (*c*) excess of air. These last two items are well taken care of in primary furnaces but not the item of time. One way to extend the time, in the writer's opinion, would be to place a furnace slag screen of full capacity in the proper place, so that the sticky particles of ash could be retained there, fused with the fluxes provided. The mass could slide down to the bottom of the furnace.

As long as one function of the primary furnace is the smelting of coal ash, more should be known about it. Besides the chemical analysis, its mineralogical structures should be known. For example, uncombined iron ore in the presence of coal or coke will supply oxygen for burning off the carbon. This would be carried to the upper parts of the boiler, spreading a deposit of dust there. This would not happen if the amount of flux necessary to fuse the ash could be blown in with the pulverized coal and thus complete the slag formation on the furnace slag screen. Bearing in mind that the initial temperature of gases is too high for direct application, the fluxing of ash will be justified.

The author points out that the temperatures of gases entering the generating tubes of the boilers, Figs. 2, 5, 7, and the second pass of the boiler Fig. 8, vary from 2500 to 2670 F. This proves that convection heat emission can be applied to the boilers if the vital portion of tubes be protected by a permanent covering, e.g., "porcelain enamel," and forced circulation of water applied to them. Porcelain enamel, which is a thin layer of refractory, would allow placing the boiler generating tubes immediately after the slag-screen tubes, giving a narrow space for possible dust collection. This would produce an insulating effect, but only for two or three rows of tubes.

[17] "The Distribution of Energy in the Pulverized-Coal Furnace," by W. J. Wohlenberg and D. E. Wise, Trans. A.S.M.E., vol. 60, 1938, paper FSP-60-19, pp. 531–547.

[18] Consulting Metallurgical Engineer, New York, N. Y.

Convection heating of water-tube boilers is not new. The same principle applies in Steamotive and Velox boilers but without any protection of their water tubes. This method should produce rapid steam generation with considerable economy of fuel and a decrease in the structural cost of the power station.

C. H. SPARKS.[19] The author's researches stress an important point; they illustrate conclusively that space requirements, in the larger units at any rate, cannot be met by drastic alterations to the system of generating the steam. The problem is essentially a furnace problem and the fact remains that the furnace will have to be designed upon principles which remain unaltered irrespective of whether natural or forced circulation is employed.

The author implies that dry-bottom furnaces are suitable for units up to 200000 lb evaporation per hr, but that for units larger than this slag-tap furnaces should be used. The interpretation to be placed on this statement is that the slag-tap furnace cannot be built as economically as the hopper-bottom furnace for evaporations of 200000 lb and under. In practice however, boiler units having hopper-bottom furnaces have been successfully built for evaporations as high as 450000 lb per hr. The heat release at the maximum continuous rating of such boiler units seldom exceeds 25000 Btu per cu ft per hr. Rates of heat release much in excess of this figure are not generally acceptable for the reason that the gases and entrained dust reach the boiler heating surface at a temperature above fusion point. In slag-tap furnaces in order to insure that the ash can be readily tapped, a high rate of heat release is maintained in the primary furnace and this normally results in a boiler approximately two thirds as wide as that which would be accommodated over an equivalent hopper-bottom furnace. The slag-tap furnace can be justified if it can be shown that, at a given load, a lower gas temperature entering the tube bank results, than that which can be attained when burning the same fuel in a hopper-bottom furnace designed for the same evaporation. Severe problems have been encountered in keeping boiler units clean and although deslagging has been successfully accomplished with some of the later designs of water sprays the problem of deslagging is indeed formidable.

The author seems to be of the opinion that the trouble of slagging is accentuated in a high-pressure boiler plant. There may be a number of reasons for this, one of which is that to justify the expense of high pressure, a high continuous load is usually carried, which gives the slag slight chance of breaking away naturally. Another reason may be that the steam temperature is high. This makes it necessary to reduce the amount of boiler-heating surface in front of the superheater so that the slag eventually forms on the small-diameter tubes of the close-pitched superheater surface. It is not improbable that engineers in the near future will endeavor to exploit the savings to be made by the application of high steam temperatures to low and moderate pressures. When this time arrives, somewhat similar slagging conditions on boilers operating at lower pressures may have to be faced.

E. H. TENNEY.[20] Looking back over the varied experiences of the last fifteen years, the ash and slag factor alone has in one installation or another determined such major elements of boiler performance as (*a*) the upper limit of output, (*b*) continuity of service, (*c*) furnace efficiency as limited by excess air, (*d*) the practical and economic value of a specific fuel, and (*e*) the level of operating costs. This paper is an important contribution to the practical analysis of this problem and as such is of interest to designers and operators.

The author suggests that dry-ash furnaces of large size may call for less turbulent burners. If by this is meant high-velocity burners, intended to maintain furnace turbulence, the writer agrees. A truly turbulent burner is one designed to create an intimate mixture of coal with the air needed for combustion at or near the burner. Such treatment has proved essential for the successful use of low-fusion-ash Mid-West coals where high furnace capacities are to be developed. It results in a more rapid heat liberation within a smaller furnace volume. This takes place with a clearer flame than is the case with the streamline burner. The increased time element contributes to the cooling of the ash to a dry condition. The clear flame permits unimpeded radiation to the furnace walls and results in a lower furnace temperature than is the case with "clouded" or so-called "insulated" burning. When furnace temperatures are permitted to reach 2800 F, cooling the ash to 2000 F is difficult. Recourse must be had, as the author points out, to the questionable use of water sprays on high-temperature boiler surfaces for slag removal in the boiler passages.

As he has suggested, it is important to explore the furnace to determine temperatures at various stages of combustion to make certain that the ash is cooled sufficiently before striking boiler surfaces or superheaters. Several years ago the writer made a series of observations on furnace temperatures, comparing turbulent and streamline firing. It was demonstrated that for low-fusing-temperature ash coal, proper mixing of the coal and air led to more rapid combustion and a relatively low-temperature furnace. This eliminated the necessity for creating high temperatures in one part of the furnace (for ignition or melting the ash) to be followed by the troublesome necessity of cooling the gases before reaching the boiler proper.

W. J. WOHLENBERG.[21] The author is to be congratulated on having presented effective visual evidence, by means of motion pictures, concerning some of the phenomena which occur in the pulverized-coal-fired furnace cavity. It was noted, among other things, that, under most circumstances, by far the larger percentage of fuel particles ignited and burned out very soon after entering the cavity. Such evidence confirms the results of calculation based on theoretical analysis of these conditions which are found in reference.[17] Thus it demonstrates, among other things, that the radiant mean positions of burning particles is not far removed from the point at which the fuel particles enter the cavity, when most of the air supplied for combustion enters with the fuel.

The author's method of arriving at surface temperatures is interesting. Investigation of this indicates that the results for the secondary furnace and boiler generating tube zones are not affected greatly by such variations of emissivity of the contents of the cavity which are likely to occur. Thus variation of actual emissivity values, from the assumed value of 1.0 to, say 0.5, changes the results for surface temperatures in these zones by only about 200 F.

However, for the temperature conditions which exist in the primary zone the results of calculation are extremely sensitive to emissivity values. A change here from the assumed value of unity to 0.5 changes the calculated results 2000 to 2500 F. It is essential therefore in this case that accurate data concerning the emissivity be available. The mere assumption that it is close to unity does not appear to be sufficient to justify any conclusions concerning surface temperature values arrived at on the basis of the assumption.

[19] Chief Engineer, Babcock & Wilcox, Ltd., London, England.

[20] Chief Engineer of Power Plants, Union Electric Company of Missouri, St. Louis, Mo. Mem. A.S.M.E.

[21] Professor of Mechanical Engineering, Yale University, New Haven, Conn. Mem. A.S.M.E.

As shown in reference,[17] ash particles in suspension contributed very considerably to the radiating power, i.e., to the emissivity of the contents of the cavity. This is true even on the basis of a single ash particle for each coal particle. The author implies

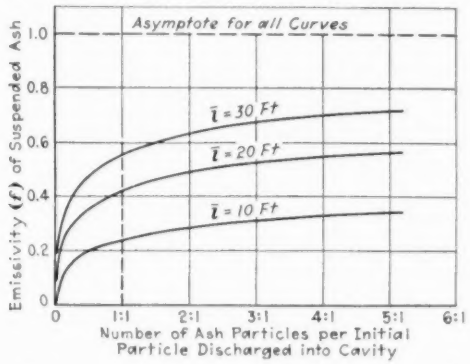

FIG. 11 INFLUENCE OF RATIO OF NUMBER OF ASH PARTICLES, FORMED PER INITIAL PARTICLE FIRED, ON EMISSIVITY OF CLOUD IN SO FAR AS PARTICLES ALONE ARE CONCERNED

(Ash particle surface A per lb fuel fired is 85 sq ft for abscissa ratio = 1:1, gas temperature T_g = 2500 F.A.)

that, on the average, there may be several ash particles per coal particle. If this is the case then radiation due to the ash particles is even more important than the results of reference[17] indicate in this respect. The author apparently based such implications on an examination of coarse particles. But by far the larger number of particles in a pulverized-coal sample are very small; in fact, so small that it is easily conceivable that many of them contain no ash, while others may be entirely ash.

In order to indicate the possible magnitude of effects of the above nature, curves shown in Fig. 11 were plotted. These are based on an application of Fig. 11, of reference.[17] It is assumed that each ash particle is an opaque sphere with a radiationally black surface. The radiant mean thickness of the cloud is $\bar{l}$. Differences of ordinate values, corresponding to differences in abscissa values, thus indicate the maximum amounts by which the emissivity of the cloud may be affected, because of variation in the number of ash particles formed per particle in the initial sample. The real differences would be less than those shown because, as the abscissa ratios increase, the ash particles become so small as to become more and more transparent to radiation. It is thus obvious that, until more is known about this state of affairs, the assumed ratio 1:1 used as a basis in reference[17] is probably safer than any other assumption which might be made in this respect.

Under (*e*) the author makes statements concerning the relation between temperatures of slag particles and other parts of the cavity. In this connection the reader is again referred to certain results in reference.[17] There it is conclusively shown that, thermal conduction between gases and ash particles is so powerful, the average temperature of the ash-particle surface must be very close to the gas temperature. This is true even when each fuel particle yields but a single ash particle. If, as the author implies, there are considerably more ash than fuel particles the difference between the temperatures of gases and ash-particle surface would be even less. The point is this: Thermal conduction between gases and particles has a far greater influence on the temperature of the particle surface than has radiation, if the particles are very small. The smaller the particles the greater is the relative influence of thermal conduction. Hence, the author's statements under (*e*), while probably quite true for the large particles, have less and less weight as the particles decrease in size. For the latter, the temperature will vary with that of the gases. If this varies due to local conditions, then the temperature of the small particle will follow substantially the variations of the gas temperature.

AUTHOR'S CLOSURE

Since the preparation of this paper a great many additional tests have been made, some on the same boilers and with the same kind of coal, others on additional boilers with different kinds of coal, sometimes varying the rating, the excess air, and other conditions. These later data definitely confirm the value of this method of measuring gas temperatures and using for comparison the calculated equivalent heat-receiving-surface temperature. They have shown that the rates of heat absorption in the primary furnaces of the slag-tap type vary closely with the adiabatic temperature and the actual slag-fluid temperature according to the Stefan-Boltzmann law.

Actual fluid temperatures of slag formed in a furnace may differ from those determined from the ash in the coal by the usual A.S.T.M. method due to segregation within the furnace and also due to the varying degrees of reducing and oxidizing influence on the iron in the ash in different parts of the furnace.

High rates of combustion seem to be beneficial from the standpoint of completeness of combustion, high rate of heat absorption, and large recovery of ash collected and tapped from a furnace.

The foregoing comments answer many of the questions raised in the discussion. Messrs. Harkins and Flinn properly bring out the importance of the radiating temperature as well as the receiving-surface temperature. Coal with low total-moisture content burned with high-temperature air and little excess air produces high furnace temperatures and correspondingly high rates of heat absorption. The temperature of the slag on the heat-receiving surface is an additional but independent factor.

Mr. Muir's comments are appropriate, and it is toward a more economical design of all parts of the furnace, boiler, and superheater that this method of testing is being actively continued.

The remarks of Messrs. Sparks and Tenney relate to the features of dry-ash removal. One point should not be overlooked, viz.: As furnaces become larger the relation between furnace volume and heat-absorbing surface changes materially. The Btu available per sq ft of heat-absorbing surface must be considered more than the Btu per cu ft of furnace volume. Long flame and delayed combustion usually give a lower peak temperature than does concentrated turbulent combustion, but as Mr. Tenney says, less slag trouble may result from properly arranged turbulent burners. This point should be further investigated with special reference to excess air and the fusing-temperature range of the ash as actually deposited, in comparison with that accredited to the ash in the coal by the A.S.T.M. method.

Professor Wohlenberg's discussion is much appreciated, and the data presented in the paper are inadequate to clarify some of the points which he has questioned. It is felt certain that additional and more thorough test data from the field will be helpful in learning more about furnace radiation. There is one point about the ash particles that certainly can be clarified by further field data. The author feels sure that there are very few, if any, particles of coal with no ash.

Dean Hitchcock's 38-year milestone makes one apologetic for not having accomplished more in that period of time. It now seems that the greatest hindrance in solving the slag problems of today arises from the fact that we learned too well the characteristics of slag in *fuel beds* and are only now beginning to realize that, when coal is burned in pulverized form, we must revise our methods of determining the ash-fusing temperature and approach the problem from a very different angle. We have

continued to obtain our laboratory data in a reducing atmosphere, and have then deposited the ash on furnace and boiler surfaces under varying conditions, often highly oxidizing with several hundred degrees difference between the two. We are well on the way toward making up for lost time, with a certainty that much more valuable progress is in sight.

Pulverized Coal-Tar Pitch as a Fuel

By E. W. CLARKE,[1] PITTSBURGH, PA.

This paper describes the method of adapting pulverizing equipment to burn fuel pitch, which is the hard residue remaining after the distillation of oils from coal tar when the maximum quantity of creosote has been removed. Early attempts to use this hard product as a fuel were beset with difficulties. However, a practical system was developed by the author in 1922 for pulverizing this fuel in a unit pulverizer and blowing it directly into the combustion space of a boiler through a nozzle designed specifically for its use. Since that time hard pitch has attained wide use as an economical and efficient fuel. The methods of firing fuel pitch are described by the author and specific examples of the results obtained are cited.

THE PRINCIPAL PRODUCTS of coal-tar distillation in the United States of America are road tar, creosote oil, and pitch. Not more than 2 per cent of the tar produced is used in making synthetic resins, dyes, and chemicals. The creosote-oil fraction varies from 15 to 60 per cent of the tar, depending upon the grade of pitch produced and the specifications of the wood-preserving industry in which the creosote is utilized. About 45 per cent of the creosote oil used in treating timber is consumed by the plants that treat railroad cross ties. Piling takes about 5 per cent, paving blocks 1 per cent, and construction timber 7 per cent of the creosote derived.

In 1908 about 55,000,000 gal of creosote were used for timber treatment. This steadily increased yearly to 108,000,000 gal in 1913, of which amount nearly two thirds were imported from Europe. When the outbreak of the World War reduced these importations, the American Tar Products Company, now the Tar and Chemical Division of the Koppers Company, was organized by the American Creosoting Company to supply its creosote requirements and to sell the surplus production in the American market. A ready market awaited the creosote but the opposite was true of the pitch, which is the residue left in the stills after distilling off the creosote from the tar.

This pitch is a liquid residue as produced in the stills and either flows by gravity or is pumped from them. At atmospheric temperatures it varies in character, depending upon the amount of oil distilled off from the tar, from a viscous, semisolid material to pitch hard enough for grinding. The point for stopping distillation is determined by the consistency of the pitch desired or by the specifications for the creosote, depending upon which is of the highest market value. Pitch comprises from 40 to 80 per cent of the tar, depending on the character of the tar and the hardness of the pitch.

The uses of distilled tars or pitches include saturant for roofing felts, protective coatings for iron and steel pipes, binder for aggregate in road construction by both hot and cold processes, surface treatment of roads by hot or cold applications, filler in block pavements, waterproofing walls below grade, built-up roofing, membrane waterproofing, saturating fibrous materials, binder in briquetting fuel, electric carbons, sealing and insulating compounds, core compounds, foundry facings, clay pigeons, and pitch coke.

Since the primary product of the newly organized American Tar Products Company was creosote oil, the bulk of the tar was distilled to give the highest creosote-oil yield, thus producing a hard pitch for which the demand was limited. This resulted in the need for a market to consume the hard pitch produced.

Early Experiments in Burning Pitch

Various attempts were made to use hard pitch as a special fuel. Pitch was mixed with coke breeze or noncoking coals to supply the cementing properties necessary for satisfactory coking. Pitch was mixed with coal and with ashes and used as fuel. The hard pitch had a softening point of 285 to 320 F. Attempts were made to liquefy it by heating and firing it with oil burners. However, all parts of the system had to be held at a temperature of about 500 F to maintain the pitch in a liquid condition. The suspended carbonaceous material, usually about 10 to 20 per cent, clogged up the oil burners and caused the abandonment of these experiments. To lessen these difficulties the liquid hard pitch was cut back with oil tar. At the Chicago plant of one tar distiller liquid hard pitch having a softening point of 280 to 300 F was cut back to a softening point of 145 F with oil tar and used for fuel under all its boilers and tar stills. The oil tar was obtained from gas companies operating water-gas sets. At the Philadelphia plant of the same company the boilers and tar stills were fired with a mixture of one part crushed pitch, having a softening point of 300 F, and two parts of run-of-mine coal burned on hand-fired grates. At the St. Louis plant of another tar distiller, a mixture of 40 per cent crushed hard pitch and 60 per cent coal screenings or coke breeze was used as fuel on Murphy stokers to heat boilers and tar stills.

The nuisance and added cost of these various methods of blending and mixing solid or liquid hard pitch with other fuels restricted such operations to the plants of the tar distillers and precluded the possibility of pitch making any headway in the open market as a fuel.

In 1922 the author took up the task of developing a better way to utilize hard pitch as a special fuel. At that time the opinion was generally held in the industry that the possibilities of burning pitch in pulverized form had been thoroughly investigated and that the difficulties were practically insurmountable. Prior to this, hard pitch had been pulverized for years with impact pulverizers with air separation and sold as the main constituent of core compound, which suggested the possibility of burning it as fuel, after running it through coal pulverizers. No difficulty was experienced in pulverizing it with the same type of machines as those used for core pitch. However, the heat radiated from the furnace caused the pulverized pitch to soften and to cake in the burners, soon plugging them shut.

Investigation of the patent literature showed that R. P. Perry and E. F. Stewart had been granted recent patents for air-cooled and water-cooled burners for pitch. Arrangements were made to borrow a small pulverizer and start experiments. The first step was to make burners such as those described in the Perry and Stewart patent and to conduct experiments with them. It was found that they had some tendency to clog when exposed to any considerable degree of radiant heat from the furnace. This suggested the idea that, if the burner could be located outside the furnace and the pulverized pitch could be discharged from it into

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

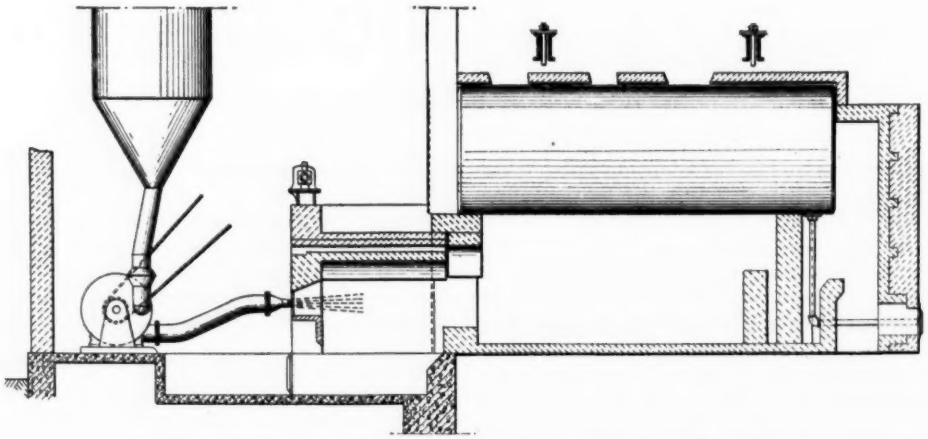

FIG. 1 PULVERIZING APPARATUS DESIGNED FOR BURNING FUEL PITCH

the furnace through an opening of sufficient size and shape so that the pitch would not impinge on any heated surfaces before being burned in suspension, the difficulties might be overcome. This was tried and found to be successful and a patent[2] was granted to the author on February 28, 1928, covering the apparatus and process. Fig. 1 shows the arrangement of the apparatus. The plants of the American Tar Products Company were then equipped to burn pulverized pitch instead of coal.

One thing that the hard pitch lacked was a name to identify it as a new type of fuel. The name "hard pitch," by which it was known to the industry, bore no relation to its use as fuel. Various designations were suggested, e.g., "burning pitch" or "furnace pitch." An excellent name was suggested by the oil industry's nomenclature and hard pitch was henceforth called "fuel pitch." Within a comparatively short time, fuel pitch became a stable article of commerce. The principal characteristics of fuel pitch are given in Table 1.

TABLE 1 CHARACTERISTICS OF FUEL PITCH

Proximate analysis	
Volatile matter, per cent	53.80
Fixed carbon, per cent	46.13
Sulphur, per cent	0.55
Ash, per cent	0.07
Ultimate analysis	
Carbon, per cent	93.71
Hydrogen, per cent	4.12
Nitrogen, per cent	0.98
Oxygen, per cent	0.65
Sulphur, per cent	0.44
Water, per cent	0.12
Ash, per cent	0.10

Softening point, 285 to 320 F
Calorific value per lb = 16,000 Btu
Weight by bulk = 50 lb per cu ft
Grindability, 150 Hardgrove

Fuel pitch can be pulverized in standard types of impact coal pulverizers with air separation. It requires only about one half the power that must be furnished for pulverizing coal and the wear on the pulverizers is negligible. The high volatile content of the pitch causes it to burn with a flame more like that of gas than pulverized coal, enabling the pitch to be ignited without preheating the furnace. Another characteristic is that dust explosions and puffs, which must be so carefully guarded against when burning pulverized coal, are entirely absent with fuel pitch.

Since pulverized pitch cannot be subjected to pressure without binding together, it cannot be used in central pulverizing plants where bins and screw conveyers are provided for the pulverized-fuel distribution. The type of equipment suitable is the unit pulverizer in which the pitch is pulverized and blown directly into the furnace. No preliminary drying is necessary since the moisture content of the pitch is usually less than 0.2 per cent. For the purpose of drying coal in unit pulverizers, it is customary to introduce heated air, but with pitch this is not only unnecessary but contrary to the nature of the material, since the heated air would soften the pitch in the mill and render it inoperative.

In proportioning combustion chambers, the same rules apply to pitch that determine the size for pulverized coal. Since the ash in pitch is about 0.10 per cent there is no difficulty with slag or ash removal. Furnaces fired with fuel pitch can be operated for months without shutting down for cleaning purposes.

MARKETS AND PRODUCTION METHODS

Because of the purity of the fuel, it can be used to replace gas and oil for chemical and metallurgical processes. Its low ash and sulphur content are especially desirable in the manufacture of highly alkaline materials by processes in which the combustion gases come in contact with the materials being produced; for example, high-purity chemical lime and sodium silicates.

A leading Midwestern manufacturer of lime found that the purity of the product from his rotary kilns was improved by firing them with fuel pitch instead of coal, due to the elimination of the ash from the coal, which acted as a source of contamination to the burned lime. Fuel pitch has been used in this plant for about thirteen years. Malleable-iron furnaces which had been fired with coal produced a stronger product when fuel pitch was substituted and this has proved to be another attractive market outlet. A furnace producing sodium silicate was successfully operated with fuel pitch which replaced oil at a saving in fuel cost. It is obvious that the tar distiller can demand premium prices if the use of pitch as fuel results in improved industrial products.

Fuel pitch is now produced either in flake form made on water-cooled drums and steel belts, or in crushed form processed by natural cooling in shallow open-topped steel tanks or bays built on the ground. From these it is reclaimed either by hand labor or mechanical means and then crushed to about $^3/_4$-in. size. From this point on to the pulverizers it is handled by the same type of conveying machinery and storage bins as used for coal. Neither crushed nor flaked pitch will solidify or bind together in bins or conveying systems, which facilitates its handling and makes it possible to ship it by trucks, cars, barges, or steamers without difficulty.

The heating values of fuel oil and fuel pitch are about 20,000 Btu per lb and 16,000 Btu per lb, respectively. On this basis,

[2] U. S. Patent No. 1,660,831.

the comparable values per ton for fuel pitch for various prices of fuel oil are as follows:

Fuel oil, cents per gallon	3	4	5	6	7
Fuel pitch, dollars per ton	6.85	9.12	11.36	14.71	16.00

Typical Fuel-Pitch Installation

The pioneer work with fuel pitch was done at a Wisconsin plant of the American Tar Products Company. After successfully demonstrating that pitch could be burned as a fuel commercially and equipping the boilers and stills at this tar-distilling plant for the purpose, a part of the surplus fuel pitch was sold for boiler fuel to a neighboring company. The boiler-room equipment at this plant included six 402-hp, 200-lb per sq in. pressure Stirling boilers, fitted with Foster superheaters which provided 100 F superheat.

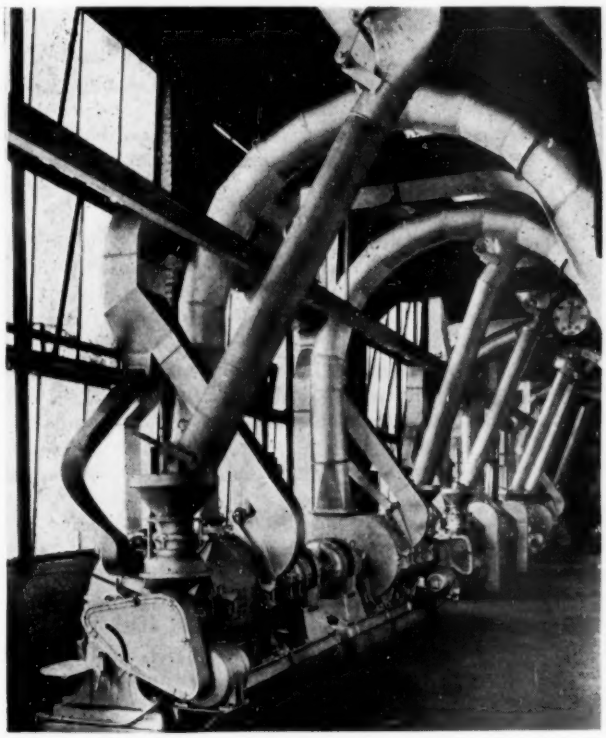

Fig. 2 A Typical Unit-Pulverizer Installation for Burning Fuel Pitch

The boilers were originally fired with stokers using coal as fuel. In February, 1926, the company purchased a unit pulverizer for one of the boilers and after removing the stoker remodeled the furnace by adding a small Dutch oven and lining the ashpit with firebrick.

After the first pulverizer had been installed and its operation compared with stoker firing, the savings were found to be of sufficient magnitude to warrant the installation of additional pulverizers. A second order for a unit pulverizer was placed five months after the first one was installed. In less than six months after the second pulverizer was ordered, a third machine was purchased so that three of the boilers were fired by unit pulverizers. The equipment permitted the use of either fuel pitch or coal as fuel. The pulverizers carried the boiler rating up to 200 per cent without difficulty.

The fuel pitch supplied to this plant at the outset had a softening point between 260 and 280 F, which is lower than that of the fuel pitch produced today. It had to be pulverized in machines where high friction losses were not prevalent and without the use of preheated air. Variable-speed control was used to drive the feed mechanism of the pulverizers in order to assure maximum flexibility. One pulverizer has handled 5500 tons of fuel pitch without the necessity of replacing any of the pulverizing elements. At the end of five months' operation, the second pulverizer had handled more than 2700 tons of fuel pitch without the casing of the machine having been opened.

Under average conditions the furnace temperature was about 2700 F; the CO_2, 14 per cent; the furnace draft about —0.10 in. water gage; and the stack temperature about 540 F at 175 per cent of boiler rating. The ash residue was cleaned out of the furnaces about once in every three months. The fuel pitch was very easy to ignite and a clear stack was readily maintained.

It will be realized from the foregoing that the maintenance costs on the pulverizers were most satisfyingly low. From a psychological standpoint, it is an interesting fact that the boiler-room operators preferred to burn pitch in the pulverizers rather than coal on the stokers.

The evaporation rate was 11.2 lb of water per lb of fuel pitch as fired. The fuel cost per 1000 lb of steam generated has been shown by carefully conducted test to be more than 23 per cent less than with coal fired on stokers. The pulverizers ran for hours at a time without attention. The additional capacity, supplied by the use of fuel pitch in the pulverizers, made possible the elimination from regular service of one of the boilers, even under the maximum demands for steam.

Some Observations on the Yield Point of Low-Carbon Steel

By JOSEPH WINLOCK[1] and RALPH W. E. LEITER,[2] PHILADELPHIA, PA.

A study has been made of the yield-point phenomena in low-carbon steel with the view of determining the mechanism of the transition of the metal from the elastic to the plastic state. Unlike copper and aluminum, low-carbon steel does not yield in tension until an excessively high elastic resistance has been built up. This high elastic resistance is the upper yield point. The upper yield point is believed to be of fundamental importance in the Lüders' line phenomena, and experimental evidence is given which supports this view.

THE peculiar behavior of low-carbon steel at the yield point has long been known and has been the subject of many researches both in this country and abroad. Of special importance has been the work of Nádai (1),[3] Siebel and Pomp (2), Sachs and Fiek (3), Rawdon (4), Kenyon and Burns (5), Gensamer (6), Gensamer and Mehl (7), Davenport and Bain (8), Fell (9), Deutler (10), Brinkman (11), and MacGregor (12).

The question of what is occurring during this singular behavior is not only of interest from a theoretical point of view, but is of great practical importance for at least two reasons: (*a*) The highly localized plastic flow, which occurs during the deep drawing of light-gage steel, gives rise to surface markings which seriously mar its appearance. If the forces causing the deformation are primarily tensile forces, these surface markings occur as depressions in the surface. Whereas, if the forces causing the deformation are primarily compressive, irregular lines of elevations occur. These surface markings are known as Lüders' lines, Hartmann lines, the Piobert effect, and, in the shop, as "stretcher strains." A photograph showing surface markings as depressions is shown in Fig. 1. And (*b*) a clear understanding of the significance and value of the yield point is, it would seem, essential to engineers engaged in the designing of structures.

The purpose of this paper is not an attempt to describe what causes the steel to behave in this peculiar manner, but an attempt to describe what the authors believe is taking place in the steel during its transition from the elastic to the plastic state. Its purpose, also, is to make some observations which will, it is hoped, serve to create a greater interest in this important field.

Deformation of Aluminum

In order to describe more clearly the phenomena which are occurring at the yield point of low-carbon steel, it will help if a description is first given of what occurs when aluminum is elastically and plastically deformed in tension.

There are, of course, two methods of deforming a metal in tension: (*a*) by actually hanging an increasing amount of dead weight on the metal; or (*b*) by deforming it at some given rate or rates by means of oil-pressure cylinders, screws, or the like. With the first method, the load is always present and obviously no drop in load can occur at any time. With the second method, the registered load is the resistance of the metal to the deformation being imposed upon it. The second method is the one most widely used, and is the one referred to throughout this paper.

At the instant deformation begins, the aluminum begins to offer a resistance to deformation and for a certain distance the load-deformation curve rises as a substantially straight line (13). So long as the curve remains substantially straight, the deformation is substantially elastic. But, when the deformation becomes so great that the resistance of the metal to elastic deformation is overcome, plastic deformation takes place. This is shown in Fig. 2. It is to be noted, too, that the metal exhibits a continually increasing resistance to deformation until the maximum load is reached; and also that the curve is smooth.

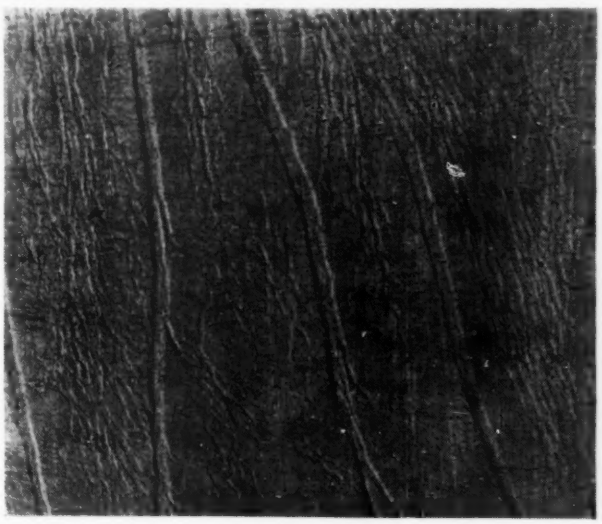

Fig. 1 Lüders' Lines or Stretcher Strains Shown as Surface Depressions

It should be further noted particularly that as the change from the substantially elastic state to the substantially plastic state takes place, the metal immediately offers a greater resistance to deformation, i.e., a higher load is recorded. In this case, the elongation is substantially uniform until the maximum load is reached.

Deformation of Low-Carbon Steel

When low-carbon steel is deformed, the metal appears to behave elastically in much the same manner, but when plastic deformation occurs there is a lowering of the resistance to deformation of the specimen and the registered load is lower. In testing parlance, this phenomenon is known as "the drop of the

Contributed by the Iron and Steel Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, New York, N. Y., December 5–9, 1938.

Discussion of this paper was closed January 10, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

beam." This is shown by the solid line in Fig. 3. Experiments have shown that substantial plastic deformation does not occur in a uniform manner as it does with aluminum, but occurs first at some point or points and, as the deformation proceeds, spreads until all of the metal has been so affected. The elongation required to produce complete plastic deformation varies with the speed of deformation, but under ordinary conditions is some 5 per cent.

Attempts have been made to analyze this behavior by mathematical equations designed to establish conditions which show when heterogeneous or homogeneous flow can take place. Attempts have also been made to explain the phenomenon by postulating that, unlike aluminum, a sudden weakening occurs in the metal, or, more scientifically, the metal temporarily exhibits a low rate of work strengthening.

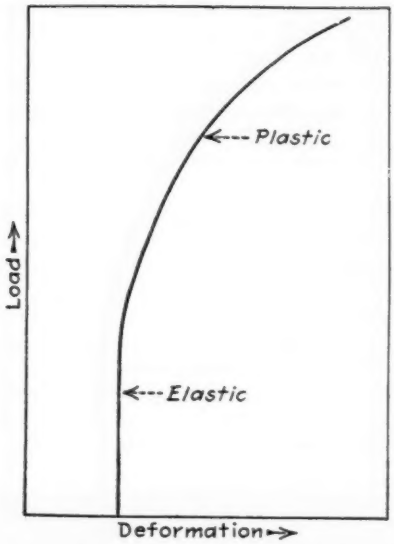

FIG. 2 LOAD-DEFORMATION CURVE FOR ALUMINUM

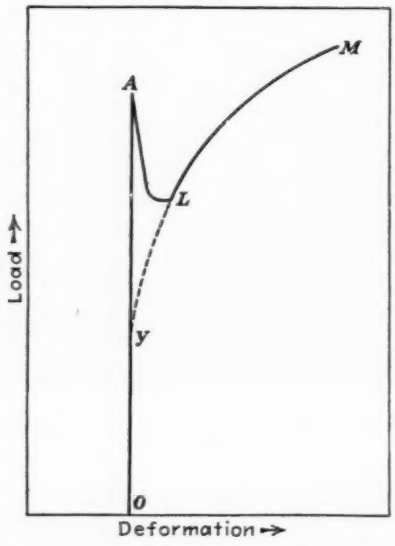

FIG. 3 LOAD-DEFORMATION CURVE FOR LOW-CARBON STEEL

None of these attempts is in accordance with the observations made in the authors' experiments. Mathematical equations cannot be established for this portion of the load-deformation diagram on the basis of homogeneous or heterogeneous flow because neither uniform nor nonuniform plastic flow is occurring! How can either of these be taking place when there are large portions of the metal which are not flowing at all? The authors believe also that there is not a sudden weakening but, indeed, a sudden strengthening of the metal undergoing plastic deformation.

It appears that, for steel to behave like aluminum, substantial plastic deformation should take place at the load Y in Fig. 3 and the load-deformation curve should be the curve $OYLM$. For some unexplained reason, however, the load Y is "overshot" and substantial plastic flow does not commence until the load A has been reached. This point has long been known as the "upper" yield point. Plastic deformation does not occur throughout the specimen at once, however, but first at one point. Therefore, at the instant plastic deformation commences, the plastically deformed metal finds itself overloaded, so to speak, with a resistance to further plastic deformation of only the load Y. The further behavior of this first increment of metal is dependent entirely upon its reaction to the precarious and unstable situation in which it finds itself. Because of the high load, it must deform plastically at a high speed, and it does so. The amount of metal forced to a great speed of deformation is governed by the amount of elasticity available in the other parts of the specimen and of the testing machine; and it is for these reasons that the downward path of the load-deformation curve veers away from the portion of the curve denoting elastic deformation.

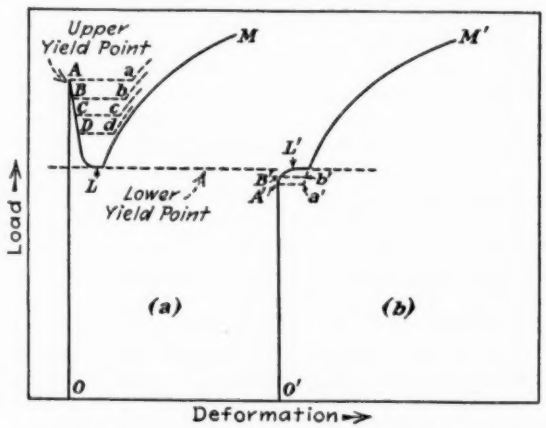

FIG. 4 LOAD-DEFORMATION CURVES WITH AND WITHOUT UPPER YIELD POINTS

The following is a more detailed explanation of what the authors believe occurs: When the load A, Fig. 4a, is reached, the first increment of metal deforms plastically at the high load which it has built up for itself while in the elastic state. And, since it now has the resistance to further plastic deformation of only the load Y of Fig. 3, it does what it is forced to do, namely, travel at a high speed along the dotted line A-a. At the next instant two other small increments, one on either side of the first, deform plastically at the load B an amount equal to B-b. The load on the specimen drops—first, because the metal has only the resistance to further plastic deformation of the load Y; second, because there is a concentration of stress at either end of the local constriction; third, because there is now present some metal which has been cold-worked, i.e., plastically deformed (the effect of this will be described in more detail later); and fourth because the increment's speed of travel is greater than the head speed of the testing machine.

The total load registered by the specimen never drops to the load Y but only to the load L, known as the "lower" yield point,

because a balance is reached between (*a*) the increase in resistance of the metal undergoing plastic deformation, i.e., work strengthening; (*b*) the increase in resistance of the metal because of the high speed of travel; and (*c*) the presence of metal in other parts of the gage length which has only been elastically deformed, and which must first be stressed to a value corresponding to the upper yield point before plastic deformation can occur in it too.

The extremely important point to emphasize is that, at the instant substantial plastic deformation is initiated, it is not necessary to have present the load which the metal has built up for itself while in the elastic state in order for further plastic deformation to occur. As opposed to this, the usual view, it seems, leads to as much information of the inherent properties of the metal as would be obtained by hanging a million-pound weight on a steel bar having a diameter of a quarter of an inch. After fracture, the bar would be considered (with a reduction in area of, say, 40 per cent) to have broken at a stress of the absurd figure of some 30,000,000 lb per sq in. This, of course, is true, but certainly no such stress as this was needed to cause the metal to fracture.

It has previously been considered that uniform elongation began when the load-deformation curve commenced to rise again at the termination of the yield-point elongation. But, if the authors' views are correct, uniform elongation does not begin until a load is reached at which all parts of the specimen have deformed the same amount that the first increment has deformed. In other words, the cross-sectional areas of the specimen taken when the end of the yield-point elongation has been reached should gradually increase from the smallest cross-sectional area of the metal first to deform plastically, up to the largest cross-sectional area of the metal last to deform plastically. And, furthermore, these areas should correspond to the elongations at the points *a*, *b*, *c*, *d*, and *L* of Fig. 4*a*. These points should not, of course, lie on the curve *LM* because of the greater speed at which these increments are deformed, and because of the short time these high loads existed.

Test on Steel Specimen

The following experiment was made in order to substantiate this. A highly polished and carefully annealed tensile specimen of low-carbon steel was prepared. The specimen was approximately 0.037 in. thick, had a uniform section 2.25 in. long and 0.5 in. wide, and the gage length was 2 in. The edges of the specimen were carefully smoothed and partially rounded to avoid any concentration of stress. It was then carefully aligned in a tension-testing machine (14) especially designed to give a constant head speed. The specimen was then pulled at the extremely low head speed of 0.0046 in. per min until the yield-point elongation had been completed. As is well known, Lüders' lines always start at the fillets of a test piece free from surface imperfections, notches, or the like, because of the inevitable concentration of stress at these points. For the purposes of this experiment, however, it was necessary to cause the Lüders' line to start near the middle of the gage length. Accordingly, two extremely small prick-punch marks were carefully made before the test on either side of the specimen at this point. These marks were, however, so small that an upper yield point was not removed from the load-deformation diagram.

During the test and while the load was dropping, pencil marks were made on the specimen at the boundaries of the spreading Lüders' line and at the same time were placed on the charted load-deformation curve. The specimen was then removed from the machine and careful measurements were made with point micrometers. After this, the specimen was replaced in the testing machine and, at the same head speed, was pulled a considerable distance beyond the yield-point elongation. The curve obtained is shown in Fig. 5.

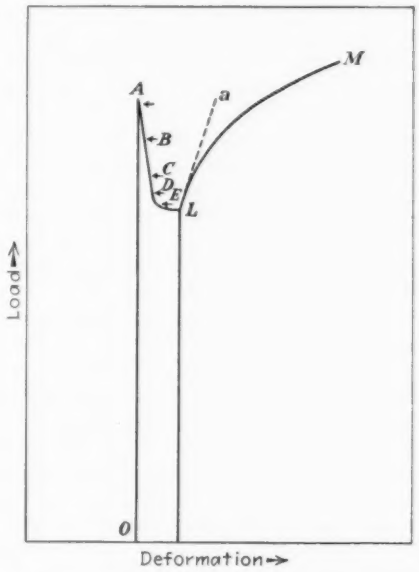

Fig. 5 Load-Deformation Curve for Data of Table 1

The measurements obtained are given in Table 1 and from these data the dotted line *L-a* in Fig. 5 was drawn. The small arrows indicate the loads which correspond to each set of measurements. The reason why this line does not coincide with the actual load-deformation curve has already been mentioned, viz., the greater speed at which these increments were deformed. These experimental data, it seems to the authors, definitely substantiate their views. These findings can be further supported by what is believed to be sound deduction of the existence of an upper yield point, and of the vital importance of this point in Lüders' line phenomena.

It is necessary, first, to describe a few experimental observations. As has been mentioned, the first substantial plastic deformation to occur is extremely local in character. That is, regions of only elastically deformed metal and regions of plastically deformed metal are present at the same time. This has been conclusively shown by placing extensometers on the elastically deformed regions and, after removing the load, noting that they return to zero. Careful visual observation of highly polished specimens show, also, no traces of plastic deformation in these regions.

It has also been conclusively shown by others and more recently by the present authors (14) that the horizontal portion of the load-deformation curve can be raised or lowered to an extraordinary degree by changing the speed of deformation. In spite of this, the same phenomena take place in exactly the same manner. The only difference is that the depth of the Lüders' lines is greater the higher the speed of deformation.

Now, since there are, during the stretching of a tensile bar, some regions which are only elastically deformed, these regions are not substantially in motion; that is, the elongation is taking

place only at the boundaries of the Lüders' line. And, since the horizontal portion of the curve can with changes in speed of deformation occur at almost any load level, an extremely pertinent observation, it seems, can be made: How is it possible for the only elastically deformed stationary regions to support the high loads produced by the deforming boundaries of their plastically deformed neighbors when these same elastically deformed regions would have yielded at a lower load had the speed of deformation been lower? In other words, how can the elastically deformed regions support, during a test carried out at a high speed, a load which is far greater than that which they could support if the test were carried out at a low speed? The absurdity of such a situation appears to be obvious. The only elastically deformed regions, therefore, must be able to withstand, in order to conform to this otherwise anomalous situation, a much higher load than that at which plastic deformation is occurring at their boundaries. If they could not, they too would yield at the same time. This higher load-carrying capacity of the elastically deformed regions results, the authors believe, is the phenomenon known as the upper yield point.

A further observation concerning the upper yield point follows: The load-deformation curve *OYALM* in Fig. 3 can always be obtained in annealed low-carbon steel of small or moderate grain size in either cylindrical or flat specimens if (*a*) the edges of the flat specimen are carefully rounded by polishing; if (*b*) the fillets on the specimens are large; if (*c*) great care is exercised in properly aligning the specimen in the testing machine; if (*d*) the surface is free from pits or scratches and other surface imperfections; and if (*e*) the specimen is free from any cold-worked material which might be present as a result of the machining operation, some local abrasion, or bending.

If, however, any or all of these precautions are not observed, an upper yield point is not obtained on the load-deformation curve. A localized spreading plastic deformation occurs, nevertheless, in exactly the same manner, but the resistance of the metal to the initiation of plastic deformation is lower, i.e., the registered loads are lower, and the loads at which the increments are deformed are lower. See Fig. 4*b*, lines *A'-a'* and *B'-b'*. And, as would be expected, the local constriction is less deep. Although the registered loads are lower, it is believed that the stresses are exactly the same as when an upper yield point is obtained. It is important to note from this figure two significant facts: (*a*) the horizontal portion of the curve, i.e., the load *L* is the same for a given steel and a given speed of deformation whether or not an upper yield point is obtained; and (*b*) the elastic limit does not coincide with the yield point as it does in Fig. 4*a*, but occurs at a lower load.

The Rate of Work Strengthening and the Stress-Strain Curve

The phrase "rate of work strengthening" is usually defined as: the slope of the stress-strain curve. The authors think that this definition is not a desirable one because work strengthening can only occur after plastic deformation has taken place. Indeed, it is plastic deformation which creates work strengthening. With this definition, however, the origin of the work-strengthening curve must be taken as the stress existing at the highest load which the steel can offer while in the elastic state. That is, the origin of the work-strengthening curve must be chosen as a stress existing when the metal is not in the plastic condition. According to this definition, then, the stress-strain curve through and somewhat beyond the yield-point elongation would be the curve *OYAPM* in Fig. 6. From this, it would be necessary to conclude that because the slope of the portion of the curve *AP* is low, the rate of work strengthening is low. It would seem that this definition leads to an erroneous conclusion.

The authors believe that the elastic condition must be totally divorced from the plastic condition in order to arrive at the proper rate of work strengthening. So long as there are regions of both conditions present at the same time, the true behavior of the metal in the plastic condition is obscured. As the authors see it, the influence of the upper yield point included in the definition should be removed. And the definition of the rate of work strengthening should be: The rate of increase of only the stress actually necessary to cause further plastic deformation in metal which has already been plastically deformed. To clarify, in Fig. 6 the rate of increase of stress actually necessary to cause an increment to deform plastically through the yield-point elongation is not the curve *AP* but the curve *YP*. That is, the stresses actually needed to cause the metal to deform through the yield-point elongation are the stresses S_1, S_2, S_3, ... The curve showing the rate of work strengthening then becomes the curve *YPM*. And it can be seen that the slope of the curve is greater during the yield-point elongation than at any other time. With this observation in mind, there is no necessity for postulating a negative rate of work strengthening (6) when the steel is tested in compression (in which no reduction of area is possible).

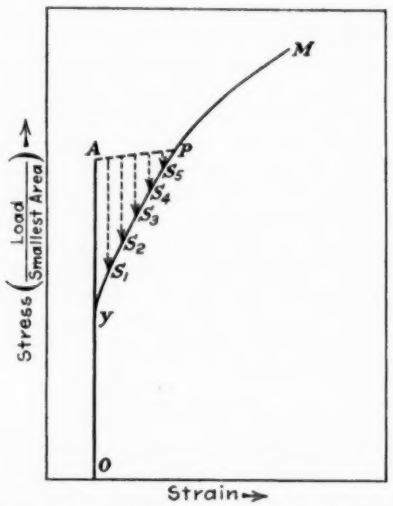

Fig. 6 Stress Strain in Relation to Work Strengthening

Other observations also indicate that this is correct. Hardness readings taken at the bottom of Lüders' lines formed at different speeds of deformation show the hardness curve to be rising in a normal manner. Of great importance, too, is the fact that if the steel is cold-worked slightly before testing in either tension or compression, all traces of the peculiar yield-point phenomenon completely disappear. The steel then behaves in exactly the same manner as aluminum, as shown by the curve *OYLM* in Fig. 3. That is, the load-deformation curve of cold-worked low-carbon steel is smooth (15), and substantial plastic deformation occurs at a much lower load.

Practical application of this has been made in the deep-drawing industry and special machines have been developed (16) to cold-work the steel a small amount before the deep-drawing operation is performed. In this condition, the steel does not show Lüders' lines (stretcher strains) after deep drawing and, because the deformation takes place uniformly, the deep-drawing properties are considerably improved.

The problem of what stress should be chosen for the yield point and the significance of the yield point raise questions which have not been given the attention they deserve. Experiments show that if an upper yield point is observed, the propor-

tional limit, the elastic limit, and the yield point occur at the same stress. On the other hand, if no upper yield point is observed, the elastic limit and the proportional limit occur at a considerably lower load, and the yield point, i.e., the horizontal portion of the curve, occurs at a slightly higher load than this.

What value, then, for yield point is important for engineering purposes: the stress at the elusive upper yield point (the stress at the drop of the beam); or, the lower yield point which, in ordinary testing procedure, is seldom noted? Should the horizontal portion of the curve be taken as the yield point when no upper yield point occurs? Is the stress at the load Y in Fig. 3 related to any other property of the steel, such as its fatigue strength? Of what significance to engineers is the upper yield point? Can it be obtained reliably? Is the absence of an observed upper yield point indicative of severe internal stress? (Locally cold-worked carefully prepared smooth specimens show no upper yield point.) Will a steel be thought to be of inferior quality because of a low proportional and elastic limit due only to failure to obtain an upper yield point? And, finally, what is the cause of the upper yield point anyway, i.e., the extremely high elastic strength of steel? These questions urgently need answers.

The authors wish to acknowledge the friendly and helpful advice and criticism of Dr. A. Nádai whose important work in this field is well known; and they wish to thank their colleague Dr. R. Eksergian for his interest and encouragement.

Discussion

E. A. Davis.[4] In the latter part of this paper, the authors object to using the slope of the first portion of the stress-strain diagram, line A-P in Fig. 6, as a definition of the "rate of work strengthening." This objection, the writer believes, is entirely justified, for the rate of work strengthening should be a measure of the manner in which the stress is increased due to the effect of strain alone. If the material is such that the stress under which it yields is affected by changes in the speed of deformation, then these influences must be taken into consideration before the rate of work strengthening can be determined. Ordinarily, this can be avoided by stretching the specimen at a constant strain rate. In a like manner, if the properties of the material change with time (e.g., age hardening, annealing, etc.), the stress under which it yields will also change. This influence must be taken into account in measuring the rate of work strengthening. This may be a negligible factor in short-time tests, but it becomes important in evaluating the results of long-time tests.

In the case of mild steel or wherever localized yielding occurs, it is practically impossible to test any given fiber or element at a constant strain rate. For example, the speed of the movable head on the testing machine can be adjusted so as to give 5 per cent over-all strain in 5 min, yet each element may strain 5 per cent in less than 1 sec, and very little can be said about the uniformity of the rate of strain during this interval. If it were possible to select some infinitesimal gage length so that the strain inside this length would be uniform and, if this could be tested at a constant strain rate, then the slope of this stress-strain diagram should furnish a true "rate of work strengthening." This curve can be made to fit the ordinary curve in the region near M in Fig. 6 by choosing the strain rate the same as that in the ordinary test in this region. In the part of the diagram usually known as the yield-point elongation, the curve for the constant strain-rate test will be below the line A-P because of the slower strain rate. This curve should correspond in some way to the curve $OYPM$ shown in Fig. 6. Just what the shape of this curve should be does not seem obvious to the writer, and he would like to ask the authors if they will further explain their reason for drawing the curve between points Y and P as they have.

A. V. de Forest.[5] This paper again draws attention to the great difficulty of interpreting the yield-point phenomenon both from the point of view of the metallurgist and of the engineer. One reason for this is that, due to the limitations of our present test machines and method of recording the stress-strain diagram, there is no clear distinction between the idiosyncrasy of the machine and the properties of the metal under test.

In this work and in many previous papers, attention has been drawn to the upper yield point and the conditions necessary to measure its value. This is found to depend greatly on freedom from stress concentrations due to shape of the test specimen, preparation of its surface, and particularly on eccentricity of loading. It is never measured at all under commercial testing conditions where special precautions are not taken. The value of the lower yield point is similarly never measured because of imitations in the speed of response, both of the weighing mechanisms of the testing machine and the strain-measuring equipment. Furthermore, both points are sensitive to test speed and to temperature. It is, therefore, high time that the whole problem be reexamined and if possible, an agreement reached as to how this point shall be defined and measured for engineering

purposes; how it is to be interpreted by engineers as a criterion of strength, and by metallurgists as a particular mode of deformation exhibited only under special conditions by special materials.

J. J. KANTER.[6] The authors showed in a previous paper[7] that the upper yield point of low-carbon steel sheet is influenced to an amazing degree by changing the rate of straining. They demonstrated a consistent rise in upper yield point with increase in straining rate for sheet steel about 0.036 in. thick of approximately 0.05 per cent carbon content prepared to five different grain sizes.

The fact that the upper yield point increases with increase in rate of straining suggests that the effective stress distribution at the yield point becomes increasingly homogeneous on a microscopic scale as the stress is applied. At stresses up to the upper yield point it is a fair approximation to say that the mode of deformation is essentially elastic and of uniform distribution. Beyond this point plastic deformation proceeds heterogeneously as the authors have demonstrated in Fig. 1. As stress increases the elastically deformed structure becomes increasingly less stable. Its existence as such becomes a transient condition. As the straining rate is increased, "snapshots" may be caught of this elastically deformed condition at somewhat higher loads, just prior to the plastic breakdown, which propagates at a rate governed to some degree by temperature.

Suppose the elastic straining were caused to proceed at a greater rate than that at which the propagation of plastic breakdown proceeds. Under this condition the microscopically homogeneous elastic-stress distribution might be preserved up to the rupture strength of the steel. Such a condition might well obtain in high-velocity tension impact tests, such as made by H. C. Mann[8] at the Watertown Arsenal, in which 0.35 per cent carbon steel exhibited a transition from plastic deformation of high energy absorption to brittle fracture of low energy absorption at impact velocities of about 30 ft per sec per in. of gage length. At striking velocities in excess of 30 ft per sec, it may well be that the upper yield point of the steel may be pressed to the point where it approaches the elastic cohesive limit of the material.

Consideration of the mathematical possibilities of dealing with the effect of straining velocities on yield point suggests at once the methods of statistical mechanics. We are dealing with a system, the elements of which are individually capable of undergoing an elastic type of deformation up to a cohesive limit. The energy necessary to reach this limit is, after a fashion, a measure of the individual yield point of the element involved. The upper yield point, which is measured for a particular aggregate of these elements subjected to a certain rate of straining, is a manifestation of a statistical average of states of strain. Due to the instability of the elastic state of deformation, once the stress has reached the point of instability, it is to be expected that but a fraction of the stressed elements simultaneously sustain the elastic strain necessary to attain the true upper yield point. The faster the rate of strain, the larger will be the proportion of elements simultaneously capable of sustaining the full elastic-cohesive effort without relaxation into slip. The kinetic oscillations of the particles comprising the steel conceivably contribute to the elastic instability which brings about yielding. Under rapid straining rates it is to be supposed that the kinetic oscillations are given a lesser opportunity to influence the elastic displacement and thus the unyielded steel is given a greater chance to persist at higher stresses.

If it be granted that the probability of kinetic disturbance underlies the inception of yielding in steel, it is to be inferred that the Maxwell-Boltzmann distribution law might be applied to correlating upper yield points with the straining rates at which they occur. In this law the chance of a number of eligible elements, out of a large number, being involved in an event is shown to be exponentially proportional to a quantity repre-

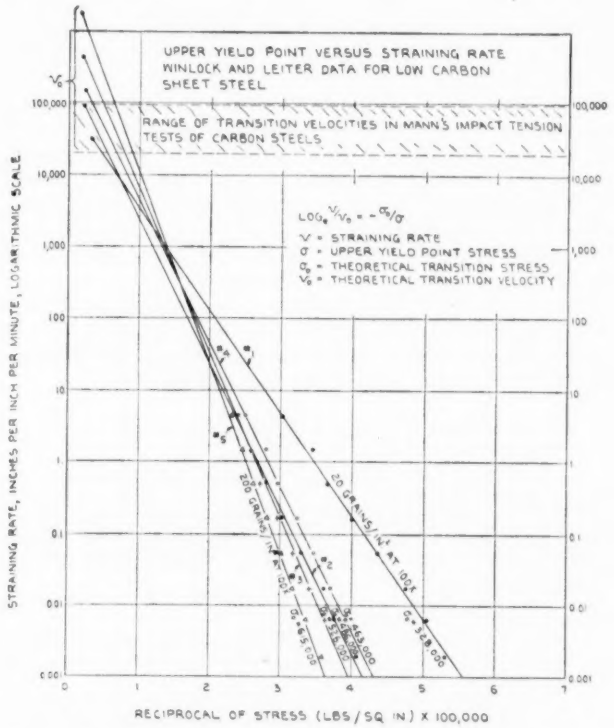

FIG. 7 CLOSE AGREEMENT BETWEEN STRAINING VELOCITY ESTIMATES AND RANGE OF TRANSITION VELOCITIES FROM MANN'S VARIABLE-VELOCITY IMPACT TESTS ON CARBON STEELS

senting a ratio between the actual energy required to produce the event and the average energy available. In the case at hand, the event with which we are dealing is elastic deformation to the full cohesive effort without degradation to slip. The probability that is expressed by the exponential function should involve the proportionate occurrence of such an event. The exponential quantity will be that ratio between the observed upper yield point and the true elastic-cohesive effort at which the elements of the steel reach a brittle rupture.

The testing of this theory upon actual data suggests employing a semilogarithmic plot of log straining rate as a function of the reciprocal of the upper yield stress. A straight-line alignment upon such a chart fulfills the requirements of the Maxwell-Boltzmann distribution law. The straining rate V is, in effect, a measure of the total number of events which occur during a time interval, while the upper yield stress σ is the average of all conditions of stress acting. The true elastic-cohesive effort of which the steel elements are capable will be a constant, σ_0, and associated with yielding under this full effort will be a straining-rate constant, V_0. The equation relating upper yield point and straining rate is thus

$$V/V_0 = e^{-\sigma_0/\sigma}$$

[7] "Some Factors Affecting the Plastic Deformation of Sheet and Strip Steel and Their Relation to the Deep-Drawing Properties," by J. Winlock and R. W. E. Leiter, Trans. of the American Society of Metals, vol. 25, Mar., 1937, pp. 163–185.

[8] "High Velocity Tension Impact Tests," by H. C. Mann, A.S.T.M., vol. 36, part 2, 1936, p. 85.

The five sets of data for effect of straining rate on yield point which the authors have published are strikingly correlated by this expression. The range of values for the constant σ_0 is in accord with similar values arrived at through other considerations. Values for this same sort of constant may be estimated from the breaking strength of cold-worked wires. The measurements made by E. A. Davis[9] on the effect of loading rate upon upper yield point, together with the Winlock and Leiter results on effect of straining rate, afford another means of estimating the magnitude of constant σ_0. The ratio between loading rate and straining rate is a value dimensionally equivalent to σ_0. Computations of this ratio from the results given for materials of similar physical characteristics, at equivalent yield points, give values for σ_0 of the same magnitude as determined from the slopes of the log straining rate versus reciprocal yield-stress plot.

If the value of σ_0 is accepted as representative of a transition-point yield stress, the straining velocity, V_0, associated with the point may also be estimated. The values of V_0 so computed are in surprisingly good agreement with the range of transition velocities found in Mann's variable-velocity impact tests on carbon steels at Watertown Arsenal as charted on the semilog diagram. See Fig. 7.

These observations suggest that additional work should be done to correlate the effects of straining rates on yield points over wider ranges of velocity than have been reported upon. The semilog chart shows a considerable gap of straining velocities between those explored and those corresponding to the range of impact velocities which have been studied. It would be a matter of considerable theoretical as well as practical significance if the Maxwell-Boltzmann distribution equation could be demonstrated to fit the yield-stress–straining-rate data over the entire range from tensile-testing speeds to impact velocities.

Authors' Closure

The authors wish to thank Mr. Davis, Dr. de Forest, and Mr. Kanter for their very helpful discussions.

[9] "The Effect of Speed of Stretching and Rate of Loading on the Yielding of Mild Steel," by E. A. Davis, *Journal of Applied Mechanics*, Trans. A.S.M.E., vol. 60, Dec., 1938, p. A-137.

The reasons for choosing *YP* (a continuation of the curve *PM*, Fig. 6), as the curve indicating the rate of work strengthening at the beginning of plastic deformation are as follows: (*a*) The curve *OYPM* is the stress-strain curve of metals, such as aluminum and copper, which show no Lüder's-line phenomena. (*b*) Hardness readings taken at the bottom of Lüder's lines, formed at a different speed of deformation, show the hardness curve to be rising in a normal manner. (*c*) If the steel is cold-worked very slightly before testing, the stress-strain curve has the shape shown by the curve *OYPM*. (*d*) The slower the speed at which the test is carried out, the shorter the yield-point elongation and the lower the load at which the horizontal portion of the load-deformation curve occurs. (There is, however, a yield-point elongation at even the lowest speed of deformation.) At decreasing testing speeds, a continuation of the curve *LM*, Fig. 3, approaches the elastic portion of the curve. Even though its position is lowered, its general shape is not changed.

The authors agree with Dr. de Forest that the upper and lower yield points are sensitive to test speed and to temperature, but do not believe that the ability to obtain the lower yield point accurately is limited because of the speed of response, etc., of the testing machine, when ordinary testing machines and ordinary testing methods are used. (It is, of course, difficult with a beam-type machine to obtain accurately the load to which the resistance of the metal drops unless the yield point is of considerable magnitude, but with a hydraulic machine this value can be obtained readily.) The rigidity of the testing machine, etc., affects the position of the downward course of the load-deformation curve, as the authors pointed out in their paper, but the ordinary testing machine does not affect the value of the lower yield point *if a constant load is obtained during the yield-point elongation*.

The authors are especially indebted to Mr. Kanter for his carefully prepared and constructive discussion. It would be well to emphasize, however, that no increase in the magnitude of the elastic forces due to speed alone can take place. The raising of the upper yield point by speed must then be due either (*a*) to the load-deformation curve not being elastic up to the upper yield point, or (*b*) to some sort of locking of the crystalline grains which is affected by the speed of test.

Five Years' Progress of Oil and Gas Power

By HOWARD E. DEGLER,[1] AUSTIN, TEXAS

The last "Five Years' Progress of Oil and Gas Power" has been primarily that of constantly lowering the engine weight, decreasing the bulk, increasing the flexibility, and lowering the installed cost per horsepower. With these worth-while improvements also came better performance, lower fuel consumption, and a more quietly operating engine. These gradual changes and improvements have broadened the field of application to such an extent that, from the first development, running into hundreds of pounds per horsepower and turning over at from 100 to 150 rpm, engines have been reduced in weight and increased in speed to an extent that now offers possibilities for universal application. Undoubtedly, the Diesel engine is recognized today as one of the most economical and reliable prime movers known, and is fast taking its place in applications for which it seemed unsuited a few years ago.

THE LAST five years, 1933 to 1938, have been devoted to the development of many new lines of lightweight high-speed engines and the improvement of the established heavy-duty types of oil and gas engines. The total installed horsepower has been doubled during this period and the field of application of oil and gas power has been extended enormously. The best performance of modern Diesel engines will go as low as 0.35 lb of fuel per bhp-hr; in fact, one foreign 5500-hp engine uses only 0.329 lb per bhp-hr with 18,000-Btu fuel, corresponding to a thermal efficiency of 41 per cent. Several Diesel aircraft engines have shown the remarkable economy of 0.32 lb at full load and cruising speed.

Diesel-Type-Size Standardization

The Diesel engine has been subject to progressive refinement and to continued increases in size. The largest Diesel engine in the world was installed in 1933 in the Copenhagen, Denmark, electric-light plant. This unit is of the solid-injection two-stroke-cycle double-acting type; each of the eight cylinders has a 33-in. bore and a 59-in. stroke; and at 115 rpm the engine delivers 22,500 bhp. One manufacturer has offered to build a 40,000-hp engine; another engine of 80,000 hp has been proposed for installation on a ship. America's largest units are the 24 × 36-in. 7000-bhp eight-cylinder two-cycle double-acting HOR engines at Vernon, California, and Salt River, Arizona. Larger capacity per unit has been sacrificed by other builders in favor of the greater simplicity of construction of single-acting engines that results from freedom from stuffing boxes and crossheads, and greater simplicity of piston cooling and of valve-operating mechanism.

Above 1000-bhp and below 4000-bhp capacity, two-cycle engines are favored almost three to one; and above 4000 bhp this type is used exclusively. At present there are no four-cycle double-acting engines, but of the large two-cycle units about half are double-acting. Considering only capacities within the range of both types it is clearly a choice between the simplicity and accessibility of the single-acting engine and the smaller space requirements and smaller number of cylinders for a given power of the double-acting type. All large Diesel engines have vertical cylinders. In sizes between 300 and 1000 bhp, the use of the two- or four-cycle engine is a matter of choice; many builders make both types.

Marked advances have been made in standardization, not only in the general design of the Diesel engine, which has been toward simplification of lines and centralization of control, but also in the design of many of its component parts. Rotative speeds range from 2000 rpm for small high-speed engines to from 120 to 150 rpm for large heavy-duty Diesel engines, and piston speeds from 1500 fpm in small engines to 1000 fpm in large ones.

Gas-Engines and Gas-Burning Diesels

The gas engine has found new ways to make the most of the numerous pipe-line extensions bringing gas fuel to many parts of the country. Once principally used in steel mills, gas plants, and oil fields, gas-powered units now find acceptance in the general power field. The modern gas engine like its oil-engine counterpart is generally a vertical multicylinder unit operating at higher speeds. It is versatile, burning many gases including sewage-sludge gas and butane. The largest vertical gas engine is a 2200-bhp unit at Carlsbad, New Mexico, with eight 23 × 28-in. cylinders. It operates on the four-stroke cycle at 240 rpm. The effect of the present economic trend upon oil- and gas-engine design is shown by the introduction of an increased number of convertible Diesel-gas engines capable of operating on either liquid or gaseous fuels. The gas-injection two-cycle engine with improved scavenging features is giving as good fuel economy as the four-cycle types without the loss of any of its inherent advantages of simplicity, compactness, low first cost, and low maintenance.

One of the outstanding Diesel-engine developments made in recent years (1936) is a dual-fuel engine of the two-stroke cycle type (fundamentally air-injection with port scavenging) that will burn either oil or gas. The advantages of this engine are appreciated when it is understood that the unit can actually burn either fuel without making any major changes in the engine, and further, that either fuel is burned on the Diesel two-stroke cycle. With an eight-cylinder 1500-bhp dual-fuel Diesel engine installed in the municipal power plant at Lubbock, Texas, comparison of the cost of producing power with oil or gaseous fuel shows the advantage to be greatly in favor of the latter. With natural gas at 13.5 cents per 1000 cu ft, the average gas-fuel cost was $0.00172 per kwhr, while with oil as used by other Diesel engines in this same plant costing 3.1 cents per gallon, the cost was $0.0032 per kwhr. This amounts to a reduction of 46.2 per cent for the gas-burning Diesel engine.

Heavy-Duty Diesel Progress

Considerable progress has been made in the development and application of alloy materials and welding, and in precision manufacturing methods. Controlled pressure lubrication, more careful consideration of fuel-injection methods and combustion, and better scavenging have also contributed much to the perfection of modern engines. Diesel-engine installations in communities have been silenced and isolated to prevent noise and vibration. Adequate intake and exhaust silencers are available, as well as engine mountings using cork, helical springs, and the like. In general, more stress has been put on better filtration of

[1] Professor of Mechanical Engineering, University of Texas. Mem. A.S.M.E.

Presented at the Annual Meeting of The American Society of Mechanical Engineers, New York, N. Y., Dec. 5–9, 1938.

Note: Statements and opinions advanced in papers are to be understood as individual statements of their authors, and not those of the Society.

fuel oil, lubricating oil, and air before entering the engine. The near future will undoubtedly see the general application of the exhaust-gas turbosupercharging of four-cycle Diesel engines.

While there has been a trend in recent years toward lightweight high-speed engines, some manufacturers have not departed from the heavy-duty type of Diesel engine with which they have been so successful. Undoubtedly, they are not convinced that these newer trends will give the kind of performance which the more conservative designs are giving and which many users of Diesel equipment expect. Many of the Diesel engines now produced in the United States are being built under foreign patents, although American ideas of simplicity and accessibility are constantly modifying the designs. The greater use of large Diesel engines is one of the trends that is noticeable in this field; but America, because of conditions more favorable to the use of coal and natural gas, lags behind Europe in its adoption of the larger sizes. Weights per horsepower range from 25 to 300 lb with an average of 80 lb.

Other design trends, based upon unprecedented progress during this five-year period, indicate higher speeds, further weight reduction, greater unit output, supercharging, greater use of double-acting cylinders, more compactness, greater use of small engines, more gas-Diesel units, incorporation of accessories in the engine enclosure, the use of welding for frames and other parts, more complete enclosure, simplified control, higher mean effective pressure, increased use of normally wasted engine heat, combination of Diesel engines with existing steam plants to improve heat balance, wider application as auxiliary power to main generating units, also the starting, controlling, and stopping of Diesel units automatically in accordance with load requirements or with a minimum amount of personal supervision.

Some authorities doom the four-cycle engine, because the two-cycle type has no valves, has smaller cylinders, requires less floor space, weighs less, has lower first cost, and needs less maintenance. Others think it is not doomed, claiming that two-cycle units present greater cooling problems, are harder to lubricate, have lower mean effective pressures, require excellent scavenging equipment, frequently require supercharging, and present some cylinder-wear problems.

Each Diesel-engine manufacturer seems to have a different idea of the grade of fuel oil required for his product. Hence, ever-increasing demands have been made upon the petroleum industry to supply various grades of fuel oil for the many types of Diesel engines. During the last five years several engineering societies (The American Society of Mechanical Engineers, American Society for Testing Materials, and the Society of Automotive Engineers) have undertaken for the first time to prepare specifications for standard Diesel fuel oils for the mutual advantage of engine designers, manufacturers, and operators, and the petroleum industry. A tentative classification covering five grades of Diesel fuel was issued by the American Society for Testing Materials in September, 1936. Purchase of fuel according to this classification with resultant criticisms and comments should aid in developing a permanent series of specifications for Diesel fuel oil. The diversity of opinions regarding specification limits and the relative importance of the various items indicate the need for improved and continued cooperative work between engine builders, engine users, and oil refiners. In any case, for the good of the industry, the engine owner should be spared the trouble of purchasing fuel to too-rigid specifications.

Until the last five years, development of speed-regulating equipment for Diesel and other internal-combustion engines had lagged behind that of governors for the other two principal prime movers, steam turbines, and water turbines. The recent application of the hydraulic governor to Diesel and gas engines has resulted in close speed regulation and constant stability over the entire speed range. A hydraulic governor does not depend for its power on centrifugal force or inertia acting on a large mass, hence the size of the unit can be considerably reduced as compared to an equivalent mechanical governor for the same engine.

Smaller Diesels for Wider Applications

Many authorities see the greatest future of the Diesel engine in motive power such as that for portable industrial service, long-haul truck and bus transportation, lightweight high-speed trains, and other uses wherever its compactness and efficiency are effective. In marine work, the Diesel engine means low-cost operation and no fire hazard; in airplanes, greater dependability, reduced fuel cost, longer cruising range, and reduced fire hazard. But the automobile presents a different problem. Car owners in the United States today pay for easy starting, quick acceleration, surging speed, and smokeless exhaust but not fuel economy. Diesel engines have not proved as satisfactory for these desired characteristics as the present-day gasoline engine, but medium-compression spark-ignition oil engines approximating the Diesel principle may be used in the near future and make possible the wider adoption of Diesel engines for automobiles in this country.

Some of the long-established Diesel manufacturers devoted the last five years to the development of completely new lines of high-speed engines and to the improvement of their existing heavy-duty units. These companies and other manufacturers are producing high-speed Diesel engines that compare favorably with gasoline engines in power, speed, size, weight, ease of starting, performance, and reliability. Many of these units have been used in tractor, truck, and portable construction equipment; in 1937 over 80 per cent of the total number of engines manufactured had a capacity of less than 100 bhp. As compared with gasoline engines, the possibilities are evident when the following specifications of a typical high-speed Diesel engine are considered: Four cylinders, $3^3/_4 \times 4^1/_2$ in.; piston displacement, 199 cu in.; rating, 62 bhp at 2600 rpm; weight, 12 lb per bhp; and electric starting.

Not since the inception of railway travel has any mode of transportation aroused the public interest and captivated the imagination of railroad men so much as the first Burlington Diesel-powered *Zephyr*, the lightweight passenger train which on May 26, 1934, made its historic long-distance nonstop run from Denver to Chicago in 13 hr 5 min at an average speed of 77.6 mph.

Two developments which have been of great significance to the career of the high-speed Diesel engine, and have perhaps made that career possible, are the use of improved bearings of new alloys and the advance in the refining and compounding of lubricating oil. Not long ago all bearing metal was of babbitt, very satisfactory in its way for slower-speed heavier engines. The introduction of bearing metals containing silver and higher percentages of lead has permitted great increases in allowable unit bearing pressure on main, crank, and piston-pin bearings. Comparable results have been obtained in a different way by the use of "needle bearings," or roller bearings with rollers of very small diameter. Engine maintenance has been simplified by the use of what are termed "precision bearings," namely, thin steel bearing shells lined with a very thin layer of bearing metal. Such bearings require no fitting and when worn are thrown away and replaced.

A few years ago Diesel-engine lubricating oil was of the uncompounded mineral type, of either paraffinic or asphaltic base. Now there are addition agents available for the promotion of a number of desirable qualities. Some of these addition agents increase oiliness under normal conditions; others promote film

strength in order to preserve lubrication under abnormal conditions. Ring sticking, not long ago the cause of much trouble with high-speed units, has been materially decreased by the use of other additives. Unfortunately some of these additives are corrosive to some of the newer bearing alloys, but petroleum technologists are constantly at work on the problem and a solution is probably only a matter of time.

Auxiliary Combustion Chambers

With increasing speeds the principal design problem of any Diesel engine is in its injection and combustion system, and this has been the subject of much study and experimentation for the purpose of obtaining clean combustion and low rates of fuel consumption. Experience has shown that a high degree of turbulence in the combustion chamber just prior to fuel injection is necessary to obtain the desired results; however it was found that application of the methods employed for low-speed engines was not practicable in the case of high-speed units. Hence a new departure seemed necessary and accordingly various forms of auxiliary combustion chamber have been evolved to produce this turbulence. This chamber is generally located in the cylinder head and is completely water-cooled.

The auxiliary combustion chamber is in no sense a precombustion chamber, but contains all of the clearance volume, except that necessary immediately over the piston in order to secure sufficient mechanical clearance. Gratifying results have been obtained with this type of combustion chamber in that it has led to cleaner combustion and higher mean effective pressures. This design removes the spray valve from the center of the cylinder head, thereby permitting the use of one intake valve and one exhaust valve of large size instead of two of each, as is necessary with the centrally located spray valve if restriction of air flow is to be avoided. The location of the spray valve at the side of the cylinder head makes it accessible and shortens the length of the fuel line from the injection pump.

A departure from conservative ideas is represented by the development of the two-cycle high-speed opposed-piston Diesel engine. The compactness of the engine and its efficient scavenging will continue to be contributing factors in the wider application of these engines, especially for submarine and aircraft purposes.

Standardization of Engine Parts

An interesting feature of modern Diesel engines, especially high-speed types, is the increased use of parts made by specialty manufacturers. This applies not only to injection equipment and governors but also to bearings, valves, and, in the smaller engines, to pistons and cylinder liners. This makes possible the furnishing of parts made of superior materials at considerable savings in cost. In these smaller engines, drop-forged connecting rods are used. Their use effects a large saving in the weight of reciprocating parts and makes possible the safe operation of these engines at much higher speeds than could be attained with rods having ends of the marine type.

Trends in High-Speed Engines and Aircraft Engines

The future high-speed industrial Diesel engine will probably develop up to 150 bhp per cylinder, weigh from 10 to 15 lb per bhp, run at speeds up to 3000 rpm with piston speeds of 2000 fpm, and occupy less than $^1/_2$ cu ft per bhp. Present choice between four-cycle and two-cycle engines appears to favor the former. The argument that, because the four-stroke cycle has become the generally adopted system for high-speed gasoline engines, it must also be better for high-speed Diesel engines, is without value. Inasmuch as the simple two-cycle Diesel engine offers great possibilities with a high specific power output for a relatively small floor space, designers will consider more seriously ways and means of improving scavenging methods and lowering the fuel consumption of this type of engine. Design problems to be considered include: Higher compression ratios to insure a high temperature; increased speed of injection and good turbulence of the incoming fuel charge; a combustion chamber shaped to give rapid heating of the fuel spray; a long free fuel spray; cooling of the injection nozzle; use of the automatic or unit-injector type of fuel nozzle; and the all-important problem of scavenging.

The high-speed Diesel engine possesses many inherent qualities that render its application to aircraft purposes not only attractive but also desirable from the points of view of safety and economy. The German Junkers line of liquid-cooled opposed-piston Diesel engines has done more than all other engines put together to popularize the Diesel engine for aviation. Their first flight was made in 1929, but since that time development and successful application have been rapid. These engines are used extensively on the fast twin-engined (600 to 800 bhp each) ten-passenger airliners in daily service in Europe and on the flying boats which carry mail across the South Atlantic. It was with a Junkers four-engined flying boat, that the world's long-distance seaplane record was broken early in 1938 in a nonstop flight of over 5000 miles from England to Brazil. The weight of these engines is about $1^3/_4$ lb per bhp with Prestone (liquid) cooling.

At the present time the Junkers organization has its 1200-bhp engine on test and is proceeding with the construction of a 2000-bhp Diesel which may be ready for its tests in 1939. The 1200-bhp unit will be suitable for transatlantic and long-range aircraft, and in this respect will be the equivalent of our 1500-bhp gasoline engines because of smaller frontal area and lower fuel consumption. Paul H. Wilkinson, one of America's foremost Diesel aircraft-engine authorities states, "The 2000-hp engine will be far ahead of anything we have, or will have, in the United States. With a diameter of 39 in. and a weight of less than 1 lb per bhp, this powerful liquid-cooled two-cycle engine will be hard to beat. When its crankshafts are turning over at 3000 rpm there will be 144,000 power impulses per min from the 48 pistons of this square-type 24-cylinder engine—approximating the smooth power flow of the turbine."

With the exception of the work carried out by Guiberson in the air-cooled radial-engine field, aircraft Diesel development in the United States has not been supported by the government. The Guiberson Company has been fortunate in being able to continue this development, but its engines of 340 bhp are still on the restricted list. A modification of this engine is a 265-bhp unit recently adopted by the Ordnance Department to power medium-size tanks, for which service this type of engine has many decided advantages over gasoline engines. Other present-day American designers who have developed Diesel aircraft engines of considerable promise are Deschamps, Godfrey, and Lawrance. It is unfortunate that the government is not actively and financially supporting these developments which are so vital to our national defense and also to the safer and more economical operation of our commercial air lines.

Discussion

Oliver F. Allen.[2] Professor Degler has given a fair and constructive résumé of Diesel progress in this country during the last five years. In condensing such a report into the space and time available, an author must understress certain phases of the development which others might have elaborated upon.

[2] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

Without in any way criticizing his excellent paper, the writer wishes to call attention to some aspects of Diesel development which may justify a little more attention.

Considering developments in this country, in England, and on the European continent, it seems to the writer that the only outstanding progress has been made in land transportation.

Five years ago a few Diesels had been installed experimentally in busses and trucks in the United States. Only one or two Diesel manufacturers were then giving serious consideration to automotive applications. But at the Motor Truck Show, Port Authority Building, New York, last month, seven makes of commercial Diesels were shown for truck and bus service in sizes from about 100 hp up to 300 hp including both four- and two-cycle designs. There have been installed within the last few months, or are now on order, between 300 and 400 of the bus and truck engines of one make shown there.

In England, from a few trial installations five years ago, the use of Diesels in passenger vehicles has had such rapid growth that 5656 compression-ignition vehicles were registered in England at the end of October, 1937. This was an increase of over 2000 compared with a year before.

For many years, several hundred switching locomotives powered by Diesel engines have been in use here and abroad and Diesel-powered passenger trains were in regular service in Europe and in experimental service in this country prior to 1933 but, as the author points out, the long-distance runs of the light-weight passenger trains in 1934 inaugurated a development in passenger rail transportation by Diesel engines which has been growing by leaps and bounds ever since. This development is not limited to the United States although this country is the leader in long-distance high-speed Diesel passenger trains, some of which regularly reach schedule speeds exceeding 100 mph and go thousands of miles without changing locomotives.

There are now in service a considerable number of units of about 900 bhp at about 750 rpm of both the two- and four-cycle types. However, these weigh from $1^1/_2$ to 2 times as much per horsepower as the truck and bus engines. They are assembled to make many 1800-hp and some 3600-hp locomotives, and the designs of more powerful ones are already developed both here and in Europe.

Furthermore, in England there are already at least three Diesel-engine models which are now available for private automobiles.

Since 1933, land transportation by Diesel power has emerged from the experimental stage into a major industry.

The writer heartily agrees with what the author has said about the cleanliness and ease of operation of the gasoline passenger automobile as compared with the Diesel and, in this country where the cost of fuel is not a great factor, it is difficult to see how the Diesel pleasure vehicle can advance very rapidly. In Europe where the fuel cost is a much more important factor, there will be a more rapid development.

The development of double-acting Diesel engines has not been unqualifiedly successful and there is still considerable hesitation about using them except for special applications. On the one hand, the simplicity and other advantages of the single-acting type influence many users to restrict Diesel plants to such unit sizes as are available in single-acting engines; and on the other hand, recent improvements in small high-pressure high-temperature steam installations tend to decrease both the size of the unit and the size of station in which the steam plant is generally more attractive than the Diesel plant.

The author is perhaps too conservative in his reference to rotative and piston speeds. At least one European manufacturer offers four-cycle single-acting engines of over 2000 bhp at 250 rpm and 1180 fpm piston speed for regular power plants. Small light-weight engines are now designed for piston speeds up to 2000 fpm.

In his reference to gas engines, the author referred incidentally to the use of sewage gas in sewage treatment works. The number of these installations is increasing and their size often reaches well over a thousand horsepower in a single plant.

As is pointed out in the paper, more attention is being paid in this country to the supercharging of four-cycle engines than ever before. Attention is also being given to the supercharging of two-cycle engines. After all, the question of supercharging versus using a larger engine is primarily economic. If the combination of first cost and operating cost for a given application is less with the supercharged engine than with the conventional engine, the user will naturally take the supercharged combination, but if there is no economic gain he will prefer the simpler conventional design.

Closely affiliated with supercharging, as the term is ordinarily used, is the problem of better scavenging and higher volumetric efficiency with resultant higher mean effective pressures in conventional engines both two- and four-cycle. These are important aspects of employing higher pressures for supplying air to engine cylinders which have frequently been overlooked.

In referring to the two-cycle engines, it should not be overlooked that there are successful engines of this type both here and abroad using a combination of ports and poppet valves in the heads; in some designs the scavenging air is admitted through poppet valves and in others the exhaust is through the poppet valves.

As to fuel, there has been a tendency on the part of manufacturers to produce engines designed to use fuel having almost inflexible characteristics and therefore compelling the user to buy always a particular fuel for which the engine is designed. The continued growth of the Diesel-engine business would be facilitated by a policy on the part of designers and manufacturers of producing engines of greater flexibility in the matter of fuel requirements.

In the matter of improvements in speed control, it should be pointed out that there are Diesel central stations now in regular operation supplying thousands of secondary clocks which keep time accurately, and that both control equipment and Diesel engines are now available which will give the uniformity both in voltage and frequency needed for the best laboratories and equal to that supplied by the big steam stations.

The paper refers to auxiliary combustion chambers which are quite the fad now for high-speed engines. Precombustion chambers also continue to be used. In spite of the extensive use of some of these special designs, the plain open combustion chamber such as is used in the Junkers engine continues to be favored by many designers of good engines.

The standardization of injection equipment has been carried forward successfully by a few of the leading manufacturers as to their own product but, in view of the wide variety of pump designs, the many methods of controlling the metering and injection, as well as the wide divergence in nozzles and injection timing and pressures, it can hardly be said that injection equipment as a whole has been standardized.

The writer has felt for a long time that the life of the light-weight high-speed engine would be less than that of the old heavy-weight conventional engine, but some figures that have come to his attention during the last several months have made him doubtful. Now it rather looks as if the higher-speed light-weight unit, due to better design, better utilization of materials, and other characteristics, will have a maintenance cost per unit of power rather less than that of the old conventional engine.

In the matter of fuel economy, there seems to be very little

difference between the two- and the four-cycle engines of equally good design. For instance, the Junkers engines have a fuel economy quite equal to that of any conventional four-cycle engine.

PAUL H. WILKINSON.[3] The writer would like to add a few supplementary comments to the excellent paper of Professor Degler, which it is hoped will be of value in substantiating that section dealing with the Diesel aircraft engine. The author refers to the use of the Diesel in daily service in Europe, and to its flight across the ocean. Data which have recently been received from Deutsche Lufthansa, the only major international air line in the world using Diesel-engined aircraft, confirms his statements and should prove interesting inasmuch as they represent the result of several years' practical experience with the engine under varying conditions of air-line operation.

One interesting set of figures gives the mileage flown with Diesel-engined aircraft on its air lines. Starting with 1634 miles in 1931, there has been a substantial increase. In 1937, a distance of 1,166,023 miles was flown with the Diesel in regular scheduled operation. For 1938, the mileage should show a still greater increase inasmuch as they have further expanded their activities with this type of power plant.

With regard to the number of hours flown, Deutsche Lufthansa's figures show that up to the end of 1937 a total of 46,767 hr had been flown with aircraft equipped with Junkers Jumo 204 and Jumo 205 Diesels. The number of these engines in active service at the end of 1937 was 48, apart from engines in reserve. The fuel consumption obtained was 0.35 lb per hp per hr under regular air-line operating conditions.

While at first the overhaul period for the Diesel aircraft engines was every 200 hr, Deutsche Lufthansa states that this period has now been increased to 350 hr which compares favorably with the 500-hr period recently attained with the gasoline engine. It must be remembered that the Junkers Jumo Diesel cruises at approximately 80 per cent of its total power output compared with about 60 per cent power output for the gasoline engine, which accounts for most of the difference between their overhaul periods.

According to the latest information on the subject, Deutsche Lufthansa has found the Diesel to be satisfactory for short-range, medium-range, and long-range flights. With regard to short-range flights, approximately 28,000 miles a week were flown with the Diesel in 1938 over air routes in Europe, none of which exceeded 425 miles in length. On some of these routes stops were less than 50 miles apart which effectively discounts assertions that the Diesel cannot be used to advantage on any but long-range flights. The equipment used for the most part comprised standard Junkers Ju-86 ten-passenger air liners powered with two 600-hp water-cooled Junkers Jumo 205-C Diesels.

Flights that are now considered to be in the long-range category for gasoline-engined aircraft, are within the medium-range category for Diesel-engined aircraft. A typical example is the weekly air-mail service operated by Deutsche Lufthansa between Bathurst in British Gambia on the west coast of Africa and Natal in Brazil. Since 1936 this ocean flight of 1890 miles has been flown with Diesel-engined aircraft. In 1938 four twin-engined Dornier Do-18 flying boats powered with 600-hp Junkers Jumo 205-C Diesels with a pay-load capacity of 800 lb have been carrying the mail across the South Atlantic on regular schedule.

Numerous long-range flights with Diesel-engined aircraft have been carried out by Deutsche Lufthansa across the North Atlantic. This has given people in the United States an opportunity to see the Diesel in regular scheduled service. In the course of these transatlantic flights they completed 48 nonstop crossings over the 2400-mile route between New York and the Azores, a 100 per cent record which far exceeded the achievements of the gasoline-engined airplanes of Pan American Airways, Imperial Airways, and Air France in this field of endeavor.

The total mileage flown by Deutsche Lufthansa's Diesel-engined mail planes in the course of their survey flights across the North Atlantic amounted to 152,360 miles compared with 27,720 miles for Imperial Airways, 24,370 miles for Pan American Airways, and 8600 miles for Air France over the transatlantic route. The fastest eastbound trip of one of the four-engined Blohm & Voss Ha139 seaplanes with its four 600-hp Junkers 205-C Diesels was made in 11 hr 53 min at a speed of 202 mph. Westbound, the fastest trip took 13 hr 40 min at a speed of 176 mph. These seaplanes carry a crew of four and have a pay-load capacity of 1210 lb between New York and the Azores.

For transatlantic operations in 1939, Deutsche Lufthansa is taking delivery of a number of four-engined Dornier Do-26 flying boats powered with 600-hp Junkers Jumo 205-C Diesels. It is their intention to fly these airplanes nonstop between New York and Lisbon, covering the 3400 miles between these points in about 17½ hours. A crew of four and a pay load of 2500 lb, consisting of five or six passengers and 1000 lb of mail, can be carried on these flying boats which will take off from the water as is customary for passenger craft. The Dornier Do-26 flying boat cruises at 193 mph, and has a maximum flight range of 5600 miles.

This information received from one of the World's leading air lines relative to the performance of Diesel-engined aircraft, should be sufficient proof that the aircraft Diesel can do all that is claimed for it. In view of the tremendous strides being made with the engine abroad, it is to be hoped that the United States government will not continue to jeopardize our progress in aviation by "restricting" low-powered Diesel aircraft engines such as the Guiberson, or by withholding financial aid from those who are competent to build large engines suitable for long-range commercial and military aircraft.

EDGAR J. KATES.[4] The author is to be congratulated upon his success in handling the difficult job that was assigned to him. In the writer's opinion, two additional items of information deserve to be recorded.

First, in the matter of fuel-oil standardization, the A.S.M.E. Oil and Gas Power Division is entitled to recognition as having originated the movement the recent progress of which the author cites. In June, 1928, G. H. Michler of the Standard Oil Company of New Jersey read a paper on Diesel fuel-oil specifications at a meeting of the Oil and Gas Power Division held at The Pennsylvania State College. The discussion of this paper resulted in the formation of a subcommittee of the Oil and Gas Power Division. The committee functioned actively and one year later, again at an Oil and Gas Power Division meeting at the same place, Wiley H. Butler presented a progress report of the A.S.M.E. Research Committee on Diesel Fuel Oil Specifications (the committee into which the original committee had been transformed). The cooperative society work now in progress is a direct outgrowth of that start made by this Division.

The second matter which the writer wishes to mention is in connection with aircraft Diesel engines. Without attempting to detract in any way from the success and commercial progress that has been made by the Junkers engine, one should not forget that the Packard Company in this country designed and built a Diesel aircraft engine by means of which the world's first long-distance Diesel airplane flight was made in May, 1929. The author mentions the present-day American designers who have

[3] Aircraft Consultant, New York, N. Y.

[4] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

developed Diesel aircraft engines of considerable promise. This would be an appropriate time also to pay tribute to the memory of Captain Woolson of the Packard Company who was responsible for the development of that first American aircraft engine and who died in the cause before his work was done.

H. W. BUKER.[5] With reference to the statement about "piston speeds of from 1500 fpm in small engines to 1000 fpm in large engines," the writer believes that 1200 fpm would be more nearly correct for the piston speeds of large engines. For example, the 22,500-hp engine in Copenhagen has a piston speed of 1130 fpm and an outside limit of 1200 fpm on big engines is not out of the way at the present time.

L. N. ROWLEY, JR.[6] With a paper as authoritative and comprehensive as this, it is difficult either to correct statements or to amplify them. However there are one or two small points that might bear further discussion.

First, with reference to the data on two- and four-cycle engines: The author states that "In sizes between 300 and 1000 bhp, the use of the two- or four-cycle engine is a matter of choice; many builders make both types." This might be construed to mean that in this size range, both types are more or less equally used. However, an analysis of annual tabulations of stationary Diesel-engine installations for 1936, 1937, and 1938 shows that the four-stroke cycle is used about twice as often as the two-stroke, while below 300 bhp the ratio is even greater. This is not meant as a recommendation for either type; it is merely a statement of fact based on present practice.

Mention of the combination of Diesel engines with existing steam plants is extremely interesting. Of course this combination may be equally effective in a newly designed plant. In either case the Diesel is a welcome aid to the power-plant designer faced with the problem of matching prime movers to power and heating or process loads. By adding to the number of possible combinations, it makes it easier to meet specific cases effectively and several Diesel-steam plants are demonstrating this fact at the present time. On the other hand, such a combination means a heavier investment in many cases and this added cost must be compared with possible operating economies before coming to a decision.

As a general thing more attention is given today to the accessory equipment that goes to make up a complete Diesel plant; technical developments in this field have kept pace with engine improvements. When accessory equipment is overlooked or given inadequate consideration, it is probably because the internal-combustion engine is considered as practically a complete power plant in itself. Present indications are that this kind of thinking is passing as it becomes generally recognized that careful selection of accessory equipment pays in operating efficiency and freedom from troubles.

Outstanding perhaps, are improvements in jacket-water cooling equipment. Cooling-tower size has been decreased for a given capacity and special designs for indoor or other close-quarter installations have been developed. The evaporative condenser, second cousin to the cooling tower and widely used in air-conditioning practice, has been applied to jacket-water cooling, with compactness and low first cost listed among its advantages.

Indicative of a trend away from past hit-or-miss methods of operation is the increasing use of instruments, particularly pyrometers.

Possibly stimulated by the efforts of the Oil and Gas Power Division to accumulate reliable data on performance and costs, plant operation is becoming more systematic. Maintenance is scheduled and maintenance needs and costs are carefully studied. More operating engineers are keeping comprehensive records of both cost and performance and these records are used as a guide to purchasing, operation, and maintenance.

M. P. CLEGHORN.[7] The author deserves commendation for the excellent paper he has presented. It gives a splendid review of the advances in this field in the last few years. It would seem, however, that in a discussion of this type mention might well be made of some of the places where advance has not been made as it should have been.

Much has been said regarding lower fuel consumption and better operating characteristics, but except for one brief sentence no mention was made regarding engine improvements for burning the low-grade fuels. As a matter of fact, engines are demanding better fuels which in turn mean more expensive fuels and this reacts against the present advantage of the Diesel engine in the small power plant.

Every time a new advance is made in the quality of a fuel, the engine manufacturer steps up the performance of his engines to take advantage of this new fuel, even though the fuel cost is greater. The cry for power-plant-Diesel performance to approach that of the automotive Diesel has led the engine builders to ignore the caution they should consider against still further narrowing the field of possible fuels.

The mere fact that fuels of high quality are becoming available generally for vehicle engines makes the engine purchaser feel that there will always be an adequate supply of such fuel and that the price should remain stable. But little account is taken of the probability that the demand for high-grade fuels will be greater for transportation needs and may overshadow the demand for the low-cost fuels for power plants.

The chemistry of fuels has already reached the point where practically all the low-grade stocks can be transformed into high-grade fuel, with a further curtailment of the supply of heavier grades. This can only result in an increased price charged for the lower-grade fuel. Further use of gas oils in furnaces and for household heating brings this fuel into a favorable sellers' market with a continuous trend toward higher prices. Any improvement therefore in the ability of the power-plant Diesels to handle low-grade fuels will relieve the pressure for high-grade fuels and slow up the gain in price.

At the present time high-grade Diesel fuel for trucks and busses is selling at retail in the Middle West for from 11.5 to 12.1 cents per gallon. Since the two main advantages of the Diesel engine are lower fuel consumption and lower price per gallon, the manufacturers of these engines may find themselves in an embarrassing position unless they can utilize satisfactorily the low-grade lower-priced fuels.

In view of these trends it would seem that the time is ripe to urge further development work on engines which will use fuel oils below the level of furnace oils, and to urge caution in choosing and installing power-plant engines having fuel requirements approaching those of the automotive Diesel. The rise in price of Diesel fuel oils, predicted for many years, apparently is facing us now.

O. D. TREIBER.[8] The summary of progress for the last five years in oil and gas power has a significant phase which seems to justify emphasis. This is the advent of the high-speed Diesel engine into American manufacturing. It is significant because American production methods with attending reduction in unit

[5] Chicago-Pneumatic Tool Co., New York, N. Y.

costs open vast fields of applications heretofore impossible or impractical because of cost, weight, and size. Large-quantity low-unit-cost production requires a substantial investment in tooling together with carefully organized operations for quick and accurate duplication of parts and their assembly. However it makes economically possible the use of these engines in automotive equipment, tractors, and a myriad of industrial applications where the owners can enjoy the inherent low operating cost of a Diesel engine.

Low first cost is made possible not only by production methods but also by ratings at higher speeds which allow of reductions in weight and size to values which are comparable with gasoline engines. In fact the company with which the writer is associated has a line of four models and eight sizes all of which are dimensioned for interchangeable mountings with gasoline engines of corresponding sizes and horsepower.

Some idea of the significance of this important contribution of a "new tool" to the power-using world may be had from some comparisons. About fifteen years ago Diesel engines were sold for marine and stationary purposes at prices about a hundred times those of high-production gasoline engines stripped of accessories. Ten years ago Diesel prices were down to from 50 to 60 times gasoline-engine prices. The differential would buy gasoline for the life of many installations. Now with high-production tooling, prices of high-speed Diesels have been reduced to from a fifth to a tenth of the last low figure and to from 5 to 10 times those of gasoline engines.

Consequently, high-speed Diesel engines are now available for a great many applications not economically possible in the past, such as in trucks, tractors, motorboats (both pleasure and commercial), rail cars, industrial locomotives, power shovels and all kinds of excavating machinery, farm machinery, pumping plants, and electrical generating units. Even multiunit powerhouses of large aggregate capacity are feasible and practical.

It might be argued that high-speed engines will not last as long as the slow-speed units. This is granted (the higher the speed the shorter the life) but with the present knowledge of metallurgy and the mechanics of internal-combustion engines, their life is being lengthened sufficiently, it is believed, to warrant the use of high-speed Diesel engines even where requirements for continuity of power are most exacting.

The advantages are not only a great reduction in original investment but low costs of repairs and replacements. Furthermore the time required for overhauling and rebuilding is obviously much less on either a basis of unit power or engine unit than on large slow-speed engines.

There is no intention herein to depreciate the importance of large Diesel engines. They will continue to fulfill a requirement distinctly outstanding. But it is desired to call attention to the importance of the high-speed Diesel engine as a new power tool.

E. S. Dennison.[9] The writer would like to amplify the portion of the paper in which the author referred to the advantages that have accrued from the use of auxiliary combustion chambers. With small engines using the four-stroke cycle, the use of such chambers has made it possible to raise the mean effective pressure for rating the engine from about 80 lb, as it was some years ago with an open combustion chamber, to between 105 and 110 lb, now an almost equally conservative figure. It has also enabled the cylinder pressure in the high-speed engine to be brought down in one case at hand to a little under 700 psi whereas with open combustion chambers that pressure is often 1000 psi. It has enabled the pressure in fuel-injection systems to be brought down from between 6000 and 8000 psi for direct injection, to pressures from 4000 down to 2000 psi with an auxiliary combustion chamber. Furthermore it has made the timing requirements much less rigorous than they were, so much so that it is often possible to dispense with any adjustment of timing to correlate with speed.

Now in contrast to all that the auxiliary combustion chamber has done for the small high-speed four-cycle engine, it is well to question what it has done for the small two-cycle high-speed engine. In so far as the writer knows, auxiliary chambers are not now and have not been successfully applied to the latter and an interesting question today is whether they can be. As is well known, there is the unfortunate tendency of exposed metal parts in a two-cycle combustion chamber to burn away, and whether that will prevent the use of auxiliary chambers in these engines is an open question. The writer is a little pessimistic on that point.

Now if the two-cycle engine must use an open combustion chamber with high cylinder pressure, high injection pressure, and exacting requirements as to timing, the four-cycle type is left with a decided edge from the maintenance standpoint. As long as materials are used that are responsive at all to heat or to pressure and that have any tendency to wear, such wear is going to be more effective in the two- than in the four-cycle engine. Consequently the writer believes that although the small two-cycle engine may have an advantage as to weight perhaps and is about equal in economy, nevertheless, from the operator's standpoint the four-cycle will continue to have an advantage. These comparisons do not apply at all in the case of large engines where both types use an open combustion chamber.

Author's Closure

The author wishes to thank each of the gentlemen who have by their discussions contributed further information of interest to make the paper more complete, more interesting, and better historical material for future use.

He was glad to have Mr. Dennison's defense of the four-cycle high-speed Diesel engine with an auxiliary combustion chamber in comparison with the two-cycle engine and direct injection, and also to have Mr. Rowley's data showing that the relative use of the four-cycle and the two-cycle engine in that particular class was a two-to-one ratio rather than an even break.

Concerning preliminary papers on Diesel fuel-oil specifications and some of the related factors that engineers and engine users had been talking about over a period of years in this so-called preparatory fuel work that was being done, the author still believes that there was nothing definite accomplished along the lines of fuel standardization before the year 1933. However, the Oil and Gas Power Division of the A.S.M.E. does deserve much credit for having sponsored papers on this subject and contributing valuable suggestions during the preliminary years of uncertain Diesel-fuel requirements.

The discussion of Mr. Kates concerning the Packard engine was noteworthy, but the author is not personally familiar with developments previous to 1933. It might be said that the Packard was the forerunner of the Guiberson engine because the latter is also a radial aircraft type, but with many new features. Captain L. M. Woolson[10] indeed deserves considerable credit for his Packard Diesel aircraft-engine development and the author is glad that his name was mentioned in this meeting.

It is interesting to note that each of the discussers of this paper said something about fuels and their combustion. The author would like to reiterate in closing that these are the two important factors that designers, manufacturers, and users will continue to write and talk about in years to come, the two most important considerations in the progress of oil and gas power.

Attack on Steel in High-Capacity Boilers as a Result of Overheating Due to Steam Blanketing

By EVERETT P. PARTRIDGE[1] AND R. E. HALL,[2] PITTSBURGH, PA.

In recent years a number of failures have occurred in certain portions of boilers operating in the pressure range near 1400 psi. Many of these failures have occurred under conditions such that oxygen corrosion or scale could not be considered as the cause. Characteristically the tubes have shown internal attack along the top, generally with definite grooving and the production of black magnetic iron oxide.

The fundamental cause of this type of failure is steam blanketing. In a tube which is only slightly inclined to the horizontal, the steam inevitably tends to rise to the top and move along it. This introduces a considerable resistance to the flow of heat from the tube wall to the fluid, and causes the top of the tube to become more or less seriously overheated. Boiler water of normal alkalinity passing through the tube and touching the overheated surface is concentrated to an excessive degree, with resultant attack on the steel. As has been shown by Berl, the rate of oxidation of steel by water at high boiler temperatures is greatly accelerated by increase in concentration of sodium hydroxide.

Condensed case histories of occurrences of this type of failure in a number of high-pressure boilers are presented. These histories include failures in ash screens in dry-bottom furnaces, floor tubes in slag-bottom furnaces, and slag-screen and top-row tubes in straight-tube cross-drum boilers.

From certain of the case histories it is evident that the dissolution of the steel along the top of steam-blanketed tubes may be stopped or greatly retarded by eliminating caustic alkalinity from the boiler water. This, however, does not affect the fundamental cause, and may merely postpone trouble, as indicated by other case histories in which steam blanketing has resulted not in dissolution of the steel, but in serious cracking.

It is concluded that the best chance of obviating the difficulties which may result from steam blanketing is so to design the surfaces exposed to high rates of heat input that steam blanketing cannot occur, or where slightly inclined tubes must be used, to protect them so that the rate of heat input will be sufficiently low to avoid excessive overheating of the metal.

IN THE LAST few years, a number of new boilers in the 1200 to 1400-psi range have lost tubes located in positions inclined at only a small angle to the horizontal. These failures have occurred in the majority of cases under conditions which precluded ordinary scale formation or oxygen corrosion, and have been characterized by a tendency for the tubes either to waste away internally along the top or to crack in this region, without excessive deformation.

This type of failure has been attributed to a variety of causes, but no systematic correlation of the information available from plant experience has yet appeared. It is the purpose of this paper to present such a correlation of a number of typical case histories in the hope that the problem will thereby be clearly defined, so that appropriate steps may be taken to meet it.

A paper such as the present one would have been impossible without the cooperation of the engineers and executives of the various companies, who in many cases have released data and information hitherto unavailable for publication, even when, as in a few cases, they disagreed with the interpretation made by the writers. The factual statements are, it is hoped, beyond argument, although the discussion based upon them is freely offered for criticism.

Certain concepts essential to a proper appreciation of the details in the case histories are introduced first, and after the experiences at the individual plants have been presented, a comprehensive and consistent interpretation of the observed facts is attempted.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

FUNDAMENTAL CONCEPTS

When heat is transmitted to a vertical or highly inclined tube in a boiler at rates ranging up to 100,000 Btu per sq ft per hr characteristic of contemporary design, no difficulty is ordinarily encountered. The steam bubbles tend to separate immediately from the tube wall and the highly turbulent flow of steam and water up through the tube maintains a high surface conductance of heat from the metal to the boiling water. No actual data covering the high-pressure range are known to the writers, but at atmospheric pressure the surface conductance for boiling water may vary from 1000 to as high as 4800 Btu per sq ft per hr per deg F. It is probable that, at the higher pressures also, the resistance to the flow of heat from the steel tube to the water is of the same small order of magnitude as the resistance of the steel wall of the tube itself. The temperature of the inside of the wall accordingly does not run much above that of the water in the tube, perhaps exceeding it by 100 F under the most severe conditions.

Film Boiling

At extremely high rates of heat input in laboratory apparatus, it is possible to produce on the heat-transfer surface a continuous layer of vapor which acts as an insulator and accordingly increases the temperature drop from the metal to the water. The experiments of Sauer, et al. (1)[3] at atmospheric pressure show, however, that the maximum rate of heat transfer corresponding to the

[3] Numbers in parentheses refer to the Bibliography.

transition from ordinary to film boiling for water at an iron surface was 413,000 Btu per sq ft per hr. McAdams[4] has suggested that film boiling is not likely to occur in an actual boiler even in the portions of the heat-absorbing surface exposed to the most severe radiation.

Steam Blanketing

Even though film boiling may not constitute a problem in steam generation, the insulating effect of a blanket of steam must be considered in the case of tubes which are inclined at only a slight angle to the horizontal, such as the ash screens in dry-bottom furnaces and the floor tubes in slag-bottom furnaces of contemporary design. In such tubes, the heat transfer is downward to the top of the tube, while all of the steam generated in it inevitably tends to rise and move along its ceiling.

Even with moderately high heat input, the steel at any given point is probably wetted frequently by intermittent splashing of water against the top, and its temperature is thereby kept comparatively low. High rates of radiation to a tube may, however, produce an almost continuous steam blanket, with a resultant great increase in temperature. When water does strike against the overheated metal, a sudden drop in temperature would be anticipated.

Considering tubes in various positions, from the horizontal to the vertical, it is obvious that increase in the inclination will tend to make less probable the development of a nearly continuous steam blanket. From another viewpoint, the heat input necessary to produce an overheating of 500 F in the wall of a tube will vary progressively from some lower value for a horizontal tube up to the probably much higher value necessary to establish film boiling in a vertical tube.

Lack of data for high boiler temperatures and pressures precludes more than a rough estimate of the temperature conditions set up in a steam-blanketed tube. However, the highest value measured by Poensgen (2) for the surface conductance from steam at 100 psi and 412 F to the wall of a 3.75-in. pipe at 388 F was 70.5 Btu per sq ft per hr per deg F. If an admittedly long guess is made that the surface conductance might be 150 for heat transfer from an ash-screen tube to steam at 1400 psi and 590 F flowing along its top, then a heat input to the top of the tube of 75,000 Btu per sq ft per hr would raise the temperature of the inner wall 500 F above that of the steam in equilibrium with water in the tube.

The difference in temperature distribution resulting from a surface conductance of 150 to steam in a blanketed horizontal tube on one hand and of 1500 to boiling water in a vertical tube on the other hand is shown graphically in Fig. 1. The temperatures indicated, even though obtained by simplified calculation from assumed values, are probably of the correct order of magnitude.

Change in Microstructure Due to Overheating

If the top of a tube be actually overheated as suggested in Fig. 1 for a sufficiently long period of time, a definite change will be produced in the microstructure of the steel; the iron carbide originally present in the customary lamellar grains of pearlite will form globular particles of cementite.[5] Table 1, from the work of Bailey (3) shows how the time necessary to develop this spheroidized structure increases with decrease in the temperature to which the steel is subjected. The lowest temperature at which spheroidization may develop over a long time is unknown. On the basis of creep tests, White, Clark, and Wilson (4) state that spheroidization begins to be noticeable

[4] Private communication from W. H. McAdams.

[5] The change in structure is well illustrated in Fig. 5.

TABLE 1 TIME REQUIRED TO SPHEROIDIZE ANNEALED LOW-CARBON STEEL (3)

Temperature, C	Temperature, F	Time, hr

675	1247	7.5
700	1292	3

in plain carbon steel after about 4000 hr at 1000 F when the stress is sufficiently great. A spheroidized region in a boiler tube may therefore be regarded as evidence that the metal temperature has exceeded this level.

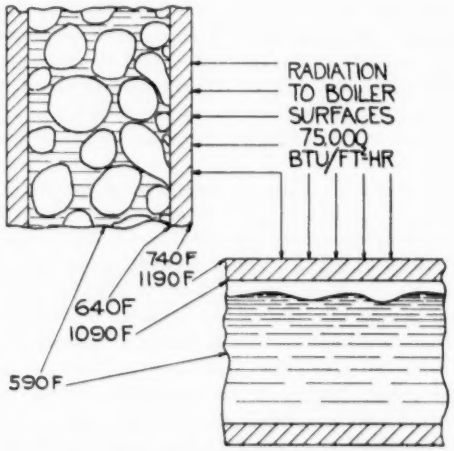

FIG. 1 COMPARISON OF TEMPERATURE CONDITIONS IN A VERTICAL AND IN A STEAM-BLANKETED HORIZONTAL TUBE

(Surface conductances of 1500 Btu per sq ft per hr per deg F from steel to boiling water and of 150 from steel to steam have been assumed.)

Excessive Local Concentration of Boiler Water

While steam blanketing tends directly toward overheating, indirectly it produces an equally serious effect. Normally, the concentration of dissolved substances in a boiler water will be low, but if this water is thrown intermittently against the excessively hot ceiling of a steam-blanketed tube, local concentration to any imaginable degree is possible.

Very soluble substances may be deposited as solids either on the top or at the water line on the sides of such tubes, decreasing correspondingly the concentration of these substances in the main part of the boiler water. The "hiding out" of phosphate and other soluble salts when boilers are operated at high ratings, followed by the reappearance of these substances in solution when the steam output is lowered has been observed in a number of boilers placed in service in recent years. The most potentially serious result of localized excessive evaporation is the high concentration of sodium hydroxide developed from a boiler water containing only 50 or 100 ppm of this substance.

Effect of Sodium Hydroxide on Oxidation of Steel by Water

What a concentrated solution of sodium hydroxide at 590 F will do to steel has been shown by Berl and van Taack (5) whose data are reproduced in Fig. 2. The vertical scale represents the extent to which carefully sized steel powder was oxidized when agitated for 7.5 hr in contact with solutions of sodium hydroxide of the concentrations shown along the horizontal scale. A minimum in the attack at 0.7 g per liter or 700 parts of NaOH per million parts of water is followed by a progressive increase at higher concentrations.

That water, even when free of dissolved oxygen is a powerful

oxidizing agent with respect to steel is not always recognized, because as soon as the reaction

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2$$

commences, it is slowed down to an almost infinitesimal rate by the protective coating of Fe_3O_4 which is one of the products. Because the role of dissolved oxygen in helping to destroy the protective effect of this oxide coating has been recognized, mechanical deaeration has been so perfected in recent years that water containing only 0.005 ml per liter may be fed to boilers, and the use of chemical scavengers such as sodium sulphite and ferrous hydroxide has been developed to remove even this last trace. Every pound of water in a boiler, however, contains 0.89 lb of combined oxygen which is available to oxidize the steel surfaces whenever and wherever the water can penetrate the thin barrier of oxide.

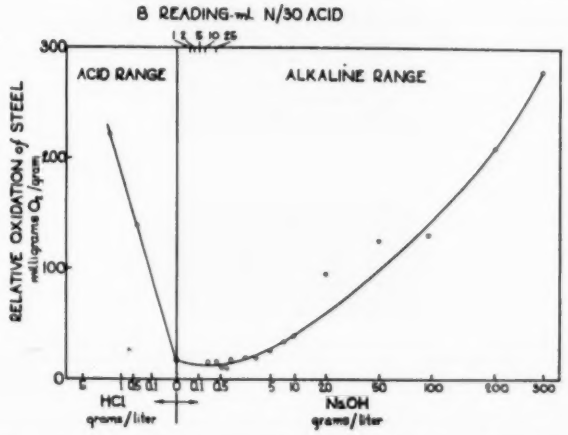

FIG. 2 EFFECT OF HYDROCHLORIC ACID AND OF SODIUM HYDROXIDE ON THE OXIDATION OF STEEL BY REACTION WITH WATER AT 590 F (FROM BERL AND VAN TAACK.)

(In each test five grams of sized steel powder was agitated in contact with solution in a bomb for 7.5 hr, and the extent of the reaction was measured by the degree of oxidation of the steel. Concentrations are plotted on a cube-root scale in order to show adequately the data over the wide range covered.)

The retarding effect of low concentrations and the accelerating effect of high concentrations of sodium hydroxide on the reaction of water with steel at high temperatures is believed to be due largely to the effect of this substance on the protective oxide, which may be regarded as a membrane full of minute pores through which water is always diffusing to the metal beneath to continue the reaction. A dilute solution of sodium hydroxide apparently helps to develop an oxide film which is less permeable, while a more concentrated solution tends to open it up, and a very concentrated one actually destroys it by forming soluble iron complexes.

Hydrogen Brittleness

Hydrogen, the second product of the reaction of water with steel, when produced in the atomic state at the surface of the metal, diffuses readily into it, causing a decided loss in ductility without decreasing the tensile strength. When high concentrations of sodium hydroxide produce accelerated attack of water on steel, it is therefore reasonable to expect that the steel may become more brittle, in the same manner that it does when pickled in acid (6).

Cracking as a Result of Thermally Induced Stresses

If the ceiling of a tube is repeatedly first overheated, because of the development of a steam blanket, and then suddenly quenched by water striking the surface, the reversed stresses set up in the steel may well lead to cracking of the stress-corrosion type.

Imperfect Circulation of Boiler Water

Steam blanketing may develop not only in nearly horizontal tubes receiving heat by direct radiation from the furnace, but also in tubes which, by reason of the sometimes unpredictable circulation in boilers, carry an inadequate flow of water. In straight-tube cross-drum boilers, for example, it is not uncommon to find the top-row tubes steam-blanketed near the uptake header, with definite evidence of a water line or even rope scale on the sides of the tubes.

CASE HISTORIES

From the preceding, it is evident that steam blanketing of tubes may lead not only to overheating, but also to accelerated attack on the steel due to the excessive concentration of normally alkaline boiler water, or to cracking by stress corrosion. These difficulties are not new. However, few case histories have been reported as completely as those of a 450-psi cross-drum boiler by Hanson (7), of 45-atm cross-drum boilers at Merseburg by Ziegler (8), and of the first 100-atm bent-tube boilers at Mannheim by Marguerre (9). A number of specific cases in which the authors believe that steam blanketing has constituted a problem will therefore be presented.

SLAG-SCREEN TUBES IN A STRAIGHT-TUBE CROSS-DRUM BOILER

South Amboy Station

The South Amboy Station of Jersey Central Power and Light Company comprises three 1400-psi straight-tube cross-drum boilers which went into service successively between Oct. 1, 1930 and Feb. 14, 1931. In these boilers, which are 40 tubes wide, the even-numbered tubes of the bottom row were originally bent downward, as indicated in Fig. 3, to form a slag screen, and the slope of the short, nearly horizontal section was 1.5 deg. Failure of these screen tubes along the top of the nearly horizontal section near the bend upward has occurred at intervals throughout the history of the station, while failure of the alternating straight tubes in the bottom row has been infrequent.

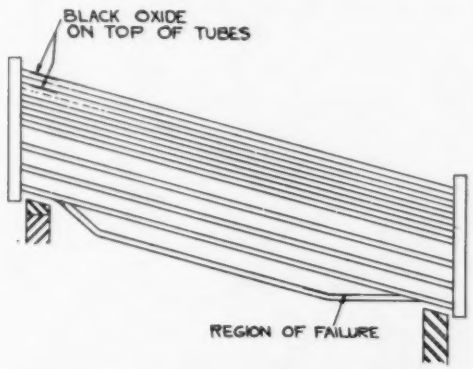

FIG. 3 ELEVATION OF GENERATING TUBES AT SOUTH AMBOY STATION

History of Failures. Interpretation of the early records is somewhat uncertain, because both oxygen corrosion and scale formation may have contributed to tube failures. When the plant started up and for some time thereafter, the pH of the boiler water was low and the oxygen content of the feed rose intermittently to 0.1 ml per liter, while considerable amounts of raw well water were introduced as make-up. After slightly less than two years of service, it was necessary to replace the en-

tire bottom row, both straight and drop-leg screen tubes, in boiler 1 toward the end of July, 1932, following individual failure of six tubes during the spring of that year.

Sporadic failure of screen tubes during the period from 1933 to 1936, always along the top of the nearly horizontal section, led to the decision to increase the slope of this section from 1.5 to 3 deg. On Apr. 25, 1936, all of the drop-leg tubes in boiler 1 were replaced with tubes rebent to give this increased slope. The 3-deg tubes were then installed in boiler 3, five on June 18, one on July 6, and the remaining fourteen on Aug. 23, 1936; and in boiler 2, two on June 9 and one on Oct. 26, 1936, and the entire twenty tubes on March 20, 1937.

In spite of the increased slope, replacement of tubes continued in the same discouraging manner, as indicated in Table 2. On

TABLE 2 TUBE REPLACEMENTS SUBSEQUENT TO INSTALLATION OF COMPLETE NEW SLAG SCREENS WITH 3-DEG SLOPE IN NEARLY HORIZONTAL SECTION

Date	Boiler	Tube	Time in service, months
8/13/37	3	38	11.7
1/26/38	3	16	17.0
		24	17.0
3/28/38	1	6	23.0
		8	23.0
4/26/38	1	4	24.0
7/1/38	3	16	5.0
		18	22.2
7/15/38	1	6	3.7
		8	3.7
8/25/38	1	4	4.0

July 1, 1938, tubes with a slope of 6 deg along the nearly horizontal section were installed as Nos. 16 and 18 in boiler 3. Shortly thereafter, however, it was decided to eliminate the drop-leg tubes altogether, and to replace them by straight tubes. This change was made in boiler 3 on Aug. 5, 1938.

Evidence of Overheating. One factor influencing the decision to abandon the slag screen was a study of tubes 6 and 8 removed from boiler 1 on March 28, 1938. Tube 6, which had developed a leak, and tube 8 which had not cracked but which was in a state of incipient failure, both showed typical attack along the ceiling of the horizontal section near the bend upward. The tube wall

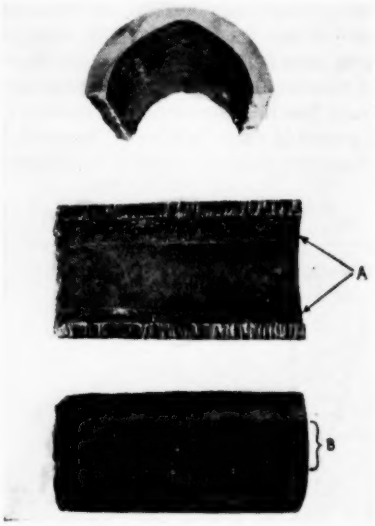

FIG. 4 APPEARANCE OF TOP OF NEARLY HORIZONTAL SECTION OF SCREEN TUBE FROM A 1400-LB STRAIGHT-TUBE CROSS-DRUM BOILER

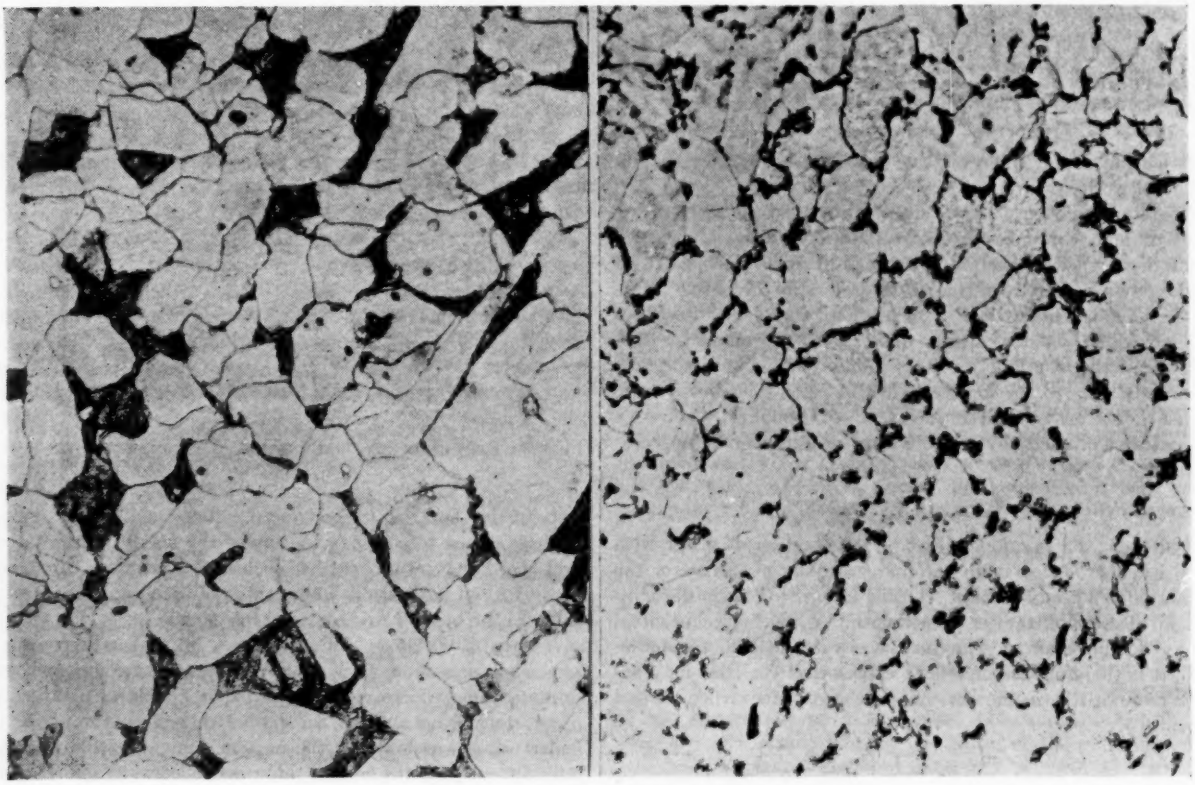

FIG. 5 MICROSTRUCTURE (×500) OF SPECIMENS OF TUBE

(Left: From side of tube, showing normal appearance. Right: From top of tube, showing severe overheating.)

had been thinned down as indicated in the cross section of Fig. 4, and at each side of the band of attack, which was covered by a thin relatively smooth coating of black magnetic iron oxide, there were narrow sharp grooves. The rest of the internal surface showed the typical appearance of old scale in the process of disintegration.

That the tops of the horizontal sections had been overheated was suggested by an external band of red oxide about 3 in. wide, which tapered off along the upturned portion of the tube. Conclusive evidence to this effect was obtained by metallographic examination of specimens cut respectively from the side and from the top of tube 8 at a point in the horizontal section 6 in. from the upward bend of the tube. While a microstructure typical of a seamless tube was observed in the side wall, extreme breakdown of pearlite and the formation of rounded particles of cementite characterized the top of the tube, as shown in Fig. 5.

Boiler-Water Alkalinity. An attempted correlation between the monthly average values for alkalinity and pH of the boiler water on one hand and replacement of screen tubes on the other

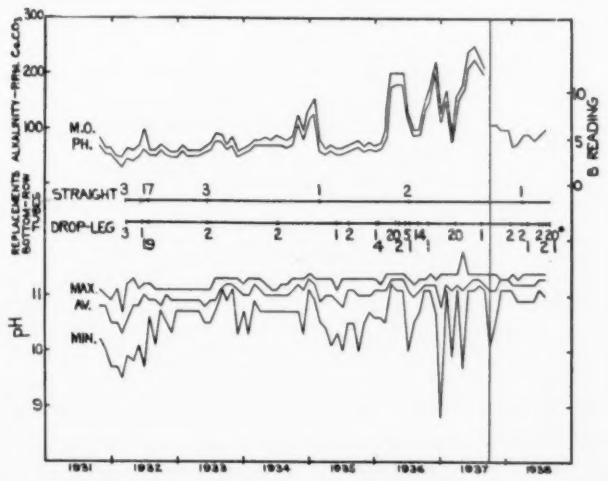

FIG. 6 RECORD OF SCREEN-TUBE REPLACEMENTS AND OF MONTHLY AVERAGE VALUES FOR ALKALINITY AND pH OF BOILER WATER

(Alkalinities are expressed as determined by titration to end-points of phenolphthalein (PH.) and methyl orange (M.O.), and by titration to end-point of phenolphthalein in the presence of an excess of barium chloride (B reading). While the results of the first two methods of titration of a boiler water do not allow calculation of the concentration of sodium hydroxide, multiplication of the B reading by 13.3 gives the approximate value for NaOH in ppm.)

in Fig. 6 suggests that the considerable increase in alkalinity of the boiler water early in 1936 may have accentuated the attack along the ceiling of the screen tubes and necessitated the immediate replacement of tubes which had been losing metal slowly during the preceding years. The maintenance of a moderate and carefully controlled alkalinity subsequent to Oct., 1937, did not, however, obviate the continued failure of the new screen tubes installed in all three boilers during 1936 and 1937.

That the replacement of the drop-leg tubes by straight tubes is likely to solve the problem is indicated in Fig. 6 by the fact that, while more than eighty of the former had been replaced since 1932 and prior to August, 1938, only seven of the straight tubes alternating with them in the bottom row had failed during this period, and most of these failures were due to external cutting by water and steam from leaking drop-leg tubes.

Attack in Upper-Row Tubes. While up to the present it has constituted a minor problem in comparison with the failure of screen tubes, some attack has also occurred, as indicated in Fig. 3, along the top internal surfaces toward the uptake header in the two upper rows of tubes in the boilers at South Amboy. During an inspection of boiler 3 in August, 1938, it was estimated that not more than 0.02 in. of metal had been removed. The attack apparently was more pronounced in the row next to the top than in the top row, but showed in all tubes in both rows. Only one tube in these rows has been replaced during the history of the plant, tube 16 of the top row of boiler 3 on Sept. 11, 1935, but it is apparent that the same condition exists here, though to a less serious degree, as in other straight-tube cross-drum boilers discussed in this paper.

TOP-ROW TUBES IN A STRAIGHT-TUBE CROSS-DRUM BOILER

San Antonio Station B

On Aug. 28, 1931, two top-row tubes failed in the 1250-psi boiler at Station B of San Antonio Public Service Company (10). This straight-tube cross-drum boiler had been operated intermittently for only about seven months, with B reading[6] held generally between 1 and 4, and phosphate between 20 and 60 ppm of PO_4, although occasional higher values were observed.

Failure occurred along the top of the tubes, near the uptake header. In addition to the two actual failures in the top row, many tubes in the upper four rows had been damaged, as attested by the considerable quantities of magnetic iron oxide in the top half of each tube. The attack was localized toward the right side of the tube bank; the iron oxide was thickest in the top-row tubes of headers 24, 25, and 26, and thinned out in 27 and from 23 back to 13, with practically none in 12. The tubes in the second row were in about the same condition as those in the first. In general, the oxide seemed to be thickest about 3 or 4 ft back from the uptake header, thinning out progressively toward the header.

In addition to the magnetic iron oxide still in place along the tops of the tubes, large quantities of this substance in the form of powder were found lying in the central portions of the waterwall

[6] B reading is the number of ml of $N/30$ acid required to titrate to the phenolphthalein end-point 100 ml of a boiler-water sample to which an excess of barium chloride has been added to precipitate buffer salts such as carbonate and phosphate.

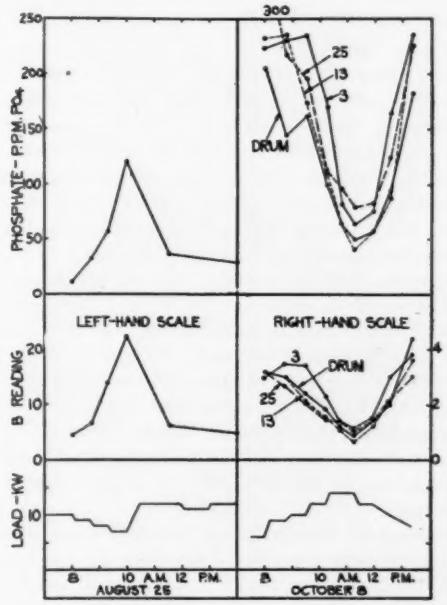

FIG. 7 INVERSE VARIATION OF BOILER-WATER CONCENTRATION WITH LOAD AT SAN ANTONIO STATION B

(Multiplication of the B reading by 13.3 gives the approximate value for NaOH in ppm.)

headers, apparently carried there and dropped by the circulation of the water.

"Hiding Out" of Soluble Compounds. For some time previous to the failure, the tendency of phosphate and alkalinity to disappear from the boiler water had been noted. Tests on Aug. 25, three days before the tubes let go, indicated that, when no addition of conditioning chemicals was made, the concentrations in the boiler water tended to vary inversely with the load. Although it did not seem credible at the time, the data, reproduced in Fig. 7, now may be interpreted as definite evidence of excessive local evaporation to substantial dryness in some portion of the boiler during operation at the higher loads, followed by return of the deposited substances to solution during subsequent operation at lower load. This hiding out of dissolved substances was observed repeatedly during later tests when samples were taken not only at the original sampling point in downtake header 3, but also in downtake headers 13 and 25, and from a perforated sampling line running the length of the drum. The data for Oct. 8 in Fig. 7 show how the concentrations changed in the same general manner with load at all four sampling points. As the load was raised progressively, both the alkalinity and the phosphate decreased; when the load was dropped they again increased.

Correlation Between Tube-Wall Temperature and Oxidation. Loss of dissolved substances from the boiler water during the test on Oct. 8 did not produce any consistent corresponding increase in the temperature of the top-row tubes as measured by thermocouples. However, during the period from Oct. 1, when the boiler was first returned to operation following the tube failures, until Oct. 16, there was a gradual increase in the tube-wall temperatures, with the highest values developing in the region where the heaviest formation of oxide had previously been observed. Inspection at this time showed that the oxide was developing as before, and that the largest amounts were in the tubes of header 23. Correlation of the temperature measurements with the observed condition of the tubes showed that the deposit of black oxide had accumulated only in those tubes which had exceeded 800 F during the operating period. Measurement of the internal diameter revealed that there had been little actual loss of metal from the tubes.

Changes in Baffling and Circulation. Experimentation with deflection baffles in the downtake headers to direct more of the flow into the upper rows, and with direct introduction of feed into the tops of the downtake nipples showed less promise during brief test runs than did a rearrangement of the baffles. The original monolithic baffle, resting on the top-row tubes and extending from the downtake headers nearly halfway along the tubes, was removed, and an alloy-steel baffle of similar extent was placed just under the superheater. At the same time a short baffle was installed, extending back from the front headers between the third and fourth rows from the top. The effect of these changes was to divert the upward flow of gases through the tube bank toward the rear, thus decreasing materially the heat input to the upper ends of the top three rows of tubes and increasing the heat input to the lower ends. During a run from Jan. 5 to 14, 1932, after this change had been made, the highest temperature observed in a tube wall at a load of 18,000 kw was 821 F, and the temperatures averaged approximately 200 F lower than during the previous run.

Extension of the short baffle 2 ft farther from the uptake header to still further deflect gas flow away from the upper ends of the tubes in the first three rows; installation of small restriction baffles in all downtake headers between rows 5 and 6 from the top; and replacement of the feed trough by a 4-in. pipe along the drum with 1-in. nipples extending downward into the tops of the downtake tubes solved the overheating problem early in March. At a load of 19,200 kw the maximum tube temperature was 613 F.

Recurrence of Trouble. An interesting postscript to this case was written into the record in 1938. For more than 6 years, from March, 1932, until July 22, 1938, the boiler had operated with no signs of any further difficulty with overheating of tubes. On the latter date the top-row tube of header 27 ruptured 6 in. from the uptake end. Inspection revealed black oxide deposits in this and adjacent tubes. At the end of the next operating period, from Aug. 5 to 20, the replacement tube had developed a coating of black oxide on the top quarter of its circumference extending over about 10 in. from 3 to 13 in. in from the end of the tube and increasing in thickness from the edges to a maximum of 0.25 in. at the center.

The reason for the reappearance of this old trouble was found in the removal of the end superheater tube immediately above the affected region. This tube had developed a leak and had been cut out and the header openings plugged during September, 1937, but all except the bottom two loops were left in place. Because the dead tube was found to be burning away, it was removed during the annual inspection in March, 1938, and the open space partially closed off by a vertical alloy-steel baffle running upward from the front edge of the inclined baffle under the superheater. Later, on May 25, the empty space toward the front of the boiler from this vertical baffle was partially filled with tile. Apparently, however, heat transmission to the top-row tubes was appreciably greater than when the dead superheater tube had been in place.

During the latter part of August the vertical metal baffle was removed, and the space formerly occupied by the bottom loop of the superheater was completely filled in with tile. When operation from Aug. 27 to Sept. 19 revealed continued though greatly decreased attack, a small protecting baffle was installed covering the upper ends of the top-row tubes in headers 25 to 27 for a distance of 27 in. from the headers. This effectively prevented serious overheating; the highest temperature observed was 720 F. While other changes may be made to reduce tube-wall temperature still further, the problem no longer seems serious.

Inclined Tubes in Generating Sections

Springdale Station

Failure in tubes in the generating section has occurred in the three 1300-psi boilers at Springdale Station of West Penn Power Company. These boilers, numbered 2, 4, and 6 respectively, are of the cross-drum sectional-header type with two-stage furnaces, and are rated to produce 500,000 lb of steam per hr.

The generating tubes are illustrated in elevation in Fig. 8. The first failure occurred in boiler 4 on Sept. 30, 1937, after about three weeks of service, when the top generating tube in header 17 ruptured along the top about 2 ft from the uptake end. During the subsequent 15 months, similar attack necessitated the replacement of 5 more top-row generating tubes and 2 division-wall tubes in boiler 4, 2 top-row and 1 division-wall tubes in

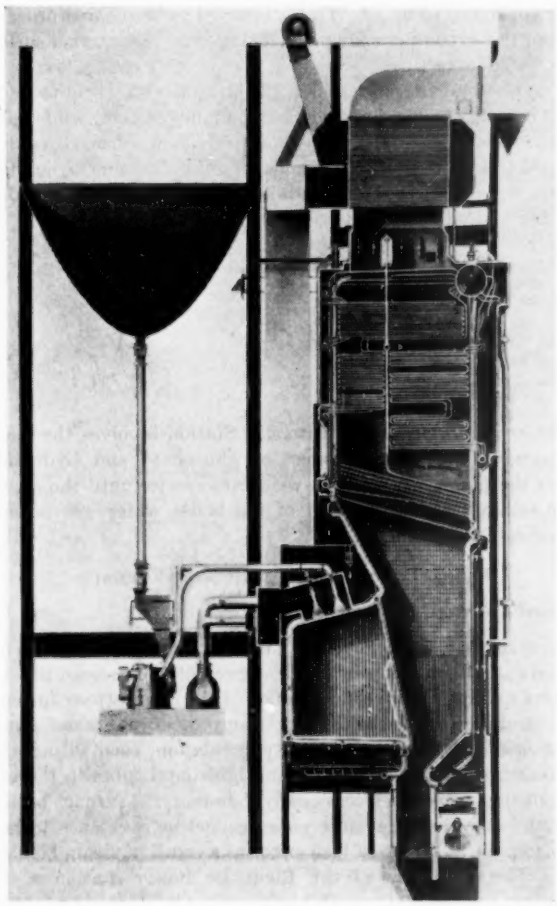

FIG. 8 CROSS SECTION OF 1300-LB BOILER AT SPRINGDALE STATION

boiler 6, and 1 screen tube in boiler 2. The type of failure is indicated in Fig. 9, top.

In the meantime, cores extending from the uptake headers to within about 18 in. of the downtake headers were installed in the top row of generating tubes in boiler 6 in an effort to obviate steam blanketing. This, after about 15 months' service, led to failure of these tubes along the bottom about 3 ft from the downtake end where a deposit of the composition shown in Table 3 accumulated, plugging the lower half of the annular space between the core and the tube wall. This deposit, almost entirely magnetic iron oxide and metallic copper, was partially loose material which had settled out of the water. The cross section of Fig. 9, bottom, shows the harder mass developed in place by oxidation of the tube wall. This was so hard and so firmly bonded to the metal that it was not loosened by turbining prior to removal of the tube.

Altogether, 12 of the 28 tubes of the top row have been replaced in boiler 6 as a result of this type of attack along the bottom toward the downtake end. The full-length cores have been removed, and other means of obviating steam blanketing are being tested.

The water conditions in the boilers at Springdale are indicated in Table 4.

TABLE 4 RANGE OF BOILER-WATER CONDITIONS IN 1300-PSI BOILERS AT SPRINGDALE STATION

Boiler	B Reading, ml			Phosphate, ppm PO_4		
	Maximum	minimum	Average	Maximum	minimum	Average
2	6.3	3.9	4.6	71	13	50
4	12.0	0.3	5.0	141	6	49
6	15.3	0.9	5.5	205	13	76

NOTE: Multiplication of the B reading by 13.3 gives the approximate concentration of NaOH in ppm.

Waterside Station

In the 1400-psi boilers which went into service at Waterside No. 2 Station in 1938, the roof of the furnace proper is formed by a straight-tube section, as indicated in Fig. 10. This section, 41 tubes wide, comprises 20 banks 3 tubes high, alternating with 21 banks 4 tubes high.

Boilers 4A and 4B had been in service several months when boiler 5A was started up about the middle of July, 1938. On Aug. 12, the top tube in the sixth header from the east end of 5A ruptured, and adjacent tubes were found slightly swollen. A month later, on Sept. 14, a second failure occurred, this time in the top tube in the twelfth header from the east end. Both of these headers are 4 tubes high.

Samples of the first tube failure showed little or no loss in wall thickness and little accumulation of oxide on the internal surface, but the steel was badly cracked both longitudinally and transversely over a considerable area, as illustrated in Fig. 11. In the case of the second failure, the wall thickness had been considerably reduced and a heavy coating of magnetic iron oxide was present, while the failure was rather localized, as shown in Fig.

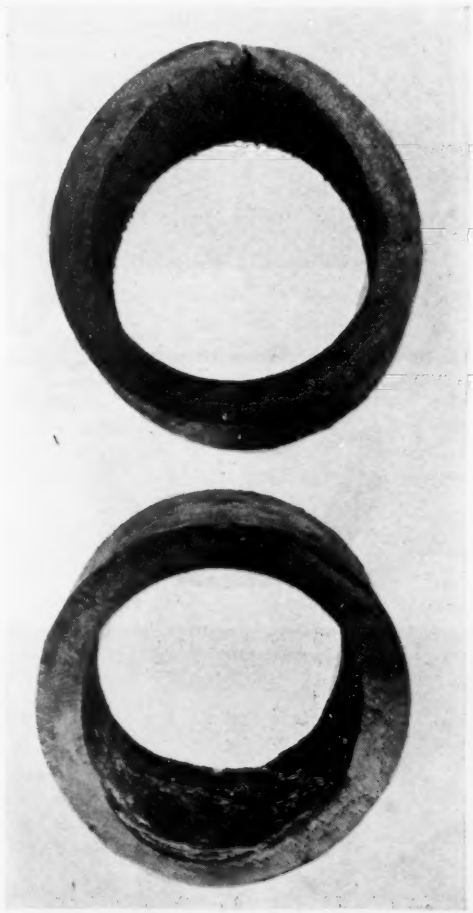

FIG. 9 CROSS SECTIONS OF FAILED TUBES FROM 1300-LB BOILERS AT SPRINGDALE STATION

(Top: Tube cracked along top as a result of steam blanketing. Bottom: Tube oxidized along bottom as a result of accumulation of sediment between core and tube wall.)

12. In both cases the damage was limited to the bottom half of the tube near the uptake header. Other tubes removed from the boiler, including one thought to be relatively undamaged, showed fine cracks in an early stage of development.

Microscopic examination of specimens from the damaged areas by F. E. Foster of the Research Bureau of the Consolidated Edison Company revealed that the cracks were intergranular, as is apparent in Fig. 13. This is believed to be the first observation of this type of cracking developing from the internal surface of a boiler tube.

The photomicrographs of Fig. 13 also show the steel to be almost completely decarburized near the inner surface, while spheroidized cementite, indicative of excessive overheating, is evident beyond this decarburized zone. In other specimens, various stages in the disappearance of the original lamellar pearlite could be observed.

(Units Nos. 4 and 5, Waterside No. 2 Station.)

TABLE 5 RANGE OF BOILER-WATER CONDITIONS IN BOILER 5A AT WATERSIDE STATION JULY 19 TO SEPT. 14, 1938

	Concentration, ppm		
	OH	PO_4	pH
Maximum	88	160	11.4
Minimum	2	15	10.8
Average	29	51	11.2

Boiler-water control at Waterside Station involves the maintenance of low concentrations of phosphate and hydroxide. From the time that boiler 5A went into service until the second tube failure, the composition of the boiler water was normal, as indicated in Table 5.

FLOOR TUBES IN A SLAG-BOTTOM FURNACE

Rivesville Station

As stated by Caldwell (11), "The corrosion sometimes associated with overheating or deficient circulation in screen tubes is absent generally in the floor tubes of the slag-bottom furnace. The insulating nature of ordinary slag protects the water-cooled floor against overheating or faulty circulation, even with highly concentrated heat-release rates and horizontal tubes in the bottom of the furnace." Occasionally, however, the furnace bottom and the slag on it may interpose insufficient resistance to heat flow to prevent failure of floor tubes as a result of steam blanketing. The experience of the Rivesville Power Station of the Monongahela West Penn Public Service Company is a case in point.

The floor of the primary furnace in this 1300-psi straight-tube boiler contains 28 tubes about 18 ft long, nearly horizontal, with a slope of only about 1.5 deg. These tubes, which were studded over the top half, were originally covered with about 1 in. of

chrome ore. Their location is indicated in the simplified cross section of Fig. 14.

The boiler went into service on Oct. 29, 1937. On Dec. 27, 1937, floor tubes 10 and 16 failed along the top, followed by tubes 14 and 18 on Dec. 30. Inspection revealed that the chrome-ore refractory had been worn away in the center of the floor, directly under the burners, exposing the ends of the studs, which were badly burned, some having lost as much as half the original metal. The center 20 tubes were then replaced, leaving only 4 of the original tubes at each side of the floor, the thickness of the layer of chrome ore was increased to 4 in., and provision was made to retain about 1 in. of molten slag on top of the chrome ore.

All of the 20 tubes which were removed had been attacked along the top, most of them for about two thirds of their length. Each tube showed sharp lines of demarcation along the sides, below which the steel was undamaged, but above which there were many deep pits. The actual failures were small holes in the tops of the tubes where the wall had been thinned until it yielded under the internal pressure.

Lying in the tubes and in the header into which they discharged was a large amount of loose black magnetic iron oxide, which was easily washed out.

The alkalinity and phosphate in the boiler water during the 2 months from the time the boiler was placed in service until the failures occurred were normal, as indicated in Table 6. During the year 1938 following the changes in the furnace floor, the alkalinity averaged somewhat higher than during the time prior to the failures, and the phosphate remained at about the same level, but no signs of further attack on the floor tubes were observed. Apparently, the considerable increase in the thermal insulation above the tubes so reduced the heat input to them as to minimize overheating and excessive localized concentration of the boiler water, even though the tubes, as a result of their nearly horizontal position, may still tend to be steam-blanketed.

TABLE 6 SUMMARY OF BOILER-WATER CONDITIONS IN 1300-PSI BOILER AT RIVESVILLE STATION PRIOR TO FAILURE OF FLOOR TUBES

	B Reading ml	Phosphate, ppm PO_4
Maximum	8.5	100+
Minimum	1.4	20
Average	4.9	70

One adverse result of decreasing the heat input to the floor tubes has been an increased temperature of the gases entering the tube banks, with a resultant tendency to choke up the boiler with slag, which at times makes it impossible to maintain superheat.

ASH SCREEN IN A DRY-BOTTOM FURNACE

Port Washington Station

The experience of Port Washington Station of Wisconsin Electric Power Company[7] with failure of screen tubes along the top has already been described in some detail (12) but will be reviewed here, together with supplementary information, because of the decided similarity between this case and the others described in this paper.

This boiler went into service in December, 1935. In October, 1936, the first tube failure in the ash screen was replaced. How serious a condition existed was realized in December. Four outages were necessary on Dec. 4, 17, and 26, 1936, and Jan. 3, 1937, to replace screen tubes which were found to have been grooved internally along the top. Newly installed tubes were thinned down to the point of leaking during 5 days of operation from Dec. 21 to 25. When a failure suddenly occurred on Jan. 12, it was decided to replace all questionable screen tubes.

[7] Formerly The Milwaukee Electric Railway and Light Company.

FIG. 15 CROSS SECTION OF SCREEN TUBE FROM PORT WASHINGTON SHOWING GROOVING ALONG TOP

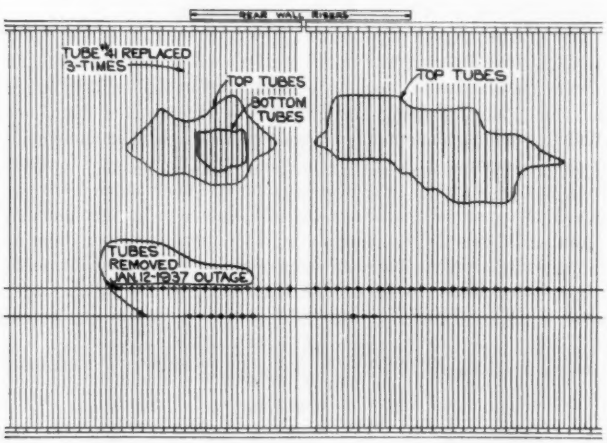

FIG. 16 AREAS OF ATTACK IN ASH SCREEN AT PORT WASHINGTON STATION

The typical appearance of the grooving of the screen tubes is indicated by the cross section in Fig. 15. Examination of the 41 top-row and 10 bottom-row tubes removed immediately after the outage on Jan. 12 demonstrated that the attack had been limited to two areas of the water screen about one third of the distance from the rear to the front headers, as shown in the plan sketch in Fig. 16. In the smaller left-hand area, 5 bottom-row as well as 14 top-row tubes had been damaged; in the larger right-hand area, the trouble was apparently confined to the top row, as the 3 bottom-row tubes removed showed no thinning along the top.

The replacement tubes were bent to give an increase of 0.5 deg on the average slope of 5 deg for the original design. Due to the natural sag of the tubes, the actual slope in the zone where trouble occurred was probably about half the average value.

Boiler-Water Conditions. In the search for some means of obviating further trouble, attention was concentrated on adjustment of the composition of the boiler water to maintain a protective coating on the tube surfaces, using the concentration of hydrogen in the steam as a measure of the rate at which the steel was being attacked. After the controlled formation of calcium-sulphate scale, on one hand, and the use of increased amounts of phosphate, on the other, had failed to limit the apparent rate of corrosion, it was observed that the lowest rates of hydrogen evolution frequently coincided with the lowest values for the alkalinity of the boiler water.

From December, 1935, when the boiler went into regular service, until the attack on the screen tubes first was recognized as a serious problem in December, 1936, the phenolphthalein alkalinity of the boiler water, expressed as ppm of NaOH, had been maintained generally between 20 and 30, and the phosphate concentration, expressed as ppm of Na_2HPO_4, was similarly controlled within the general limits of 50 and 70, as indicated in Fig. 17. After replacement of tubes during a week-end outage, the alkalinity was increased to an average value of 70 ppm for the period from Dec. 21 to 26. When the next week-end inspection revealed that, during the week, a new tube had been thinned to the point of leaking, the alkalinity was again raised and was held at a comparatively high level, ranging from 130 to 220 ppm of NaOH, until the failure of a tube on Jan. 12, 1937, led to the general replacement of tubes in the screen.

When the boiler was again placed in operation on Jan. 25, the alkalinity and phosphate were varied experimentally, while the rate of hydrogen evolution was watched as an indication of what

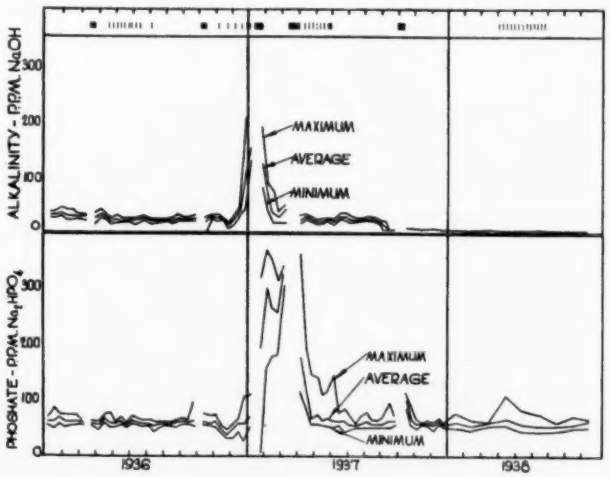

FIG. 17 RECORD OF ALKALINITY AND PHOSPHATE CONCENTRATION IN BOILER WATER AT PORT WASHINGTON

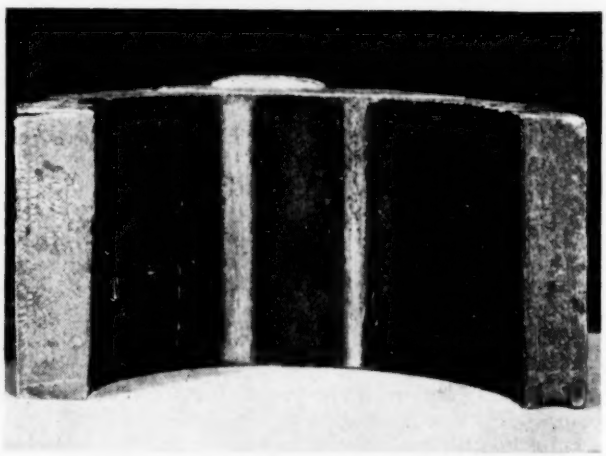

FIG. 18 APPEARANCE OF INTERNAL SURFACE OF TOP HALF OF SCREEN TUBE FROM PORT WASHINGTON AFTER OPERATION WITH LOW ALKALINITY IN BOILER WATER

(Central dark band is a thin continuous coating of magnetic iron oxide. Gray bands are exposed edges of thin layer of iron phosphate which covers remainder of surface, but is in turn covered by and intermixed with black magnetic iron oxide.)

was happening in the screen tubes. Alkalinity was progressively decreased until by the middle of February it was back in the range held during the major portion of 1936. In the meantime, phosphate concentrations were greatly increased, and held at a high level until the boiler was taken out of service in the middle of March. Specimen tubes removed at this time demonstrated that no appreciable attack had taken place since the January outage. Subsequently, the phosphate concentration was progressively lowered. For somewhat more than four months, from the latter part of April to the first part of September, both the alkalinity and the phosphate were controlled at the levels initially maintained during the first year of operation. A decision to reduce the alkalinity still further was put into practice about the middle of September, 1937, and since that time it has been held at an average value of 5 ppm of NaOH.

Removal of two more specimen tubes from the ash screen during the October, 1937, inspection confirmed the conclusion drawn

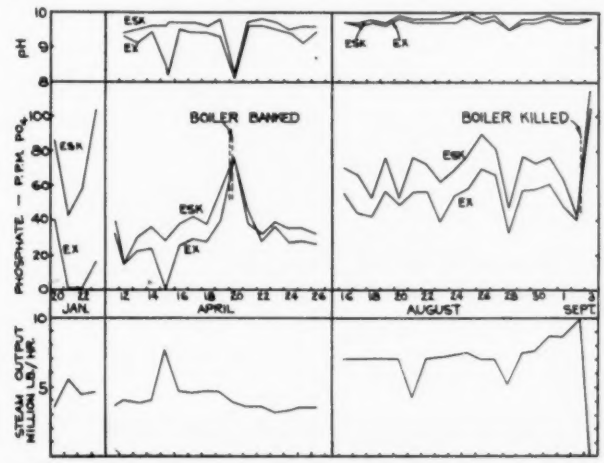

FIG. 19 COMPARISON OF TENDENCY OF SCREEN TUBES OF OLD AND OF NEW DESIGN TO STEAM-BLANKET

(Sample EX from special sampling line at top of tube of old design delivered substantially pure steam on Jan. 21 and 22 and on Apr. 15; during period from Aug. 16 to Sept. 3, no such steam blanketing was indicated by similar samples from line in tube of new design. Samples ESK came from skimmer in the east 48-in. drum.)

from the hydrogen measurements during the preceding few months that practically no attack had occurred. When four new tubes were installed in place of those removed previously and at this time for examination, the rate of hydrogen evolution went up, however, to 3 times its base value for about a week, indicating some reaction of the fresh metal surfaces with the boiler water. Pressure and load were decreased 20 per cent and the phosphate concentration was increased until the hydrogen evolution again came back to its base value corresponding to the loss of about 2 oz of iron per day from the entire unit, including the superheater.

Study of Internal Surfaces Under the Microscope. To ascertain the extent to which conditions at the internal surface of an ash-screen tube during the later period of freedom from attack differed from those during the period when failures were experienced, the polarizing microscope was applied to a study of the specimens illustrated respectively in Figs. 15 and 18. It was found that two substances were present on each of the two specimens, first the anticipated black magnetic oxide Fe_3O_4 and second, a crystalline substance similar to the natural mineral ludlamite,[8] which is regarded as a ferrous hydroxyphosphate.

[8] The crystalline substance present on the surface of the tubes was transparent, faintly blue-green, birefringent with minimum and maximum indexes of 1.655 and 1.700, and showed a definite cleavage apparently rectangular or nearly so.

Drewry has previously reported partial analyses (12) indicating that an iron phosphate was present on the internal surface of a tube removed during the later period of trouble-free operation. The microscopic study of the specimen shown in Fig. 18 has shown that the iron phosphate, which is readily dislodged from the tube in minute fragments comprising many crystals, is present over the entire internal surface of the specimen, with the exception of a dark band, 0.5 in. wide, along the top of the tube, where the steel is covered only by a thin, uniform film of iron oxide. The iron-phosphate coating is particularly evident in two gray bands, readily visible in Fig. 18 at either side of the central band. Elsewhere, the iron phosphate is partially covered by and intermixed with minute particles of Fe_3O_4, which give a black appearance to the surface.

That some slight attack had taken place along the central band at the top of the tube was evident even on visual examination. Under the microscope the surface appeared as smoothly rounded hummocks and valleys. The depth of the attack was, however, only of the order of 0.001 in.

Only a small amount of iron phosphate was found during micro-

scopic examination of the specimen illustrated in Fig. 15, the internal surface of which was coated chiefly with black magnetic iron oxide. At the top of the tube where severe attack had occurred, this coating was thin and continuous, resembling that at the top of the practically undamaged specimen.

Logan Station

During October, 1937, a 1325-psi boiler went into operation at Logan Station of Appalachian Electric Power Company. This boiler, designed to produce 1,000,000 lb of steam per hr at a total temperature of 925 F, was operated intermittently at low loads during the fall of 1937. During a trial run from Dec. 5 to 8, inclusive, the output was raised to 725,000 lb per hr for a few hours, but averaged only 540,000. During the next operating period, from Dec. 15 to 25, the maximum and average outputs were, respectively, 550,000 and 440,000 lb per hr. Similar operation commencing Dec. 28, 1937, was terminated Jan. 7, 1938, by the development of a leak in a top-row screen tube, No. 2 from the southeast corner.

Study of Early Failures. The failure occurred about 6 ft from the side-wall header on the top of a portion of the tube that had been depressed approximately 7 in. by falling slag. Examination of this tube after removal showed that it had been attacked internally along a strip from 0.5 to 1.2 in. wide on the top of the tube. This region of attack extended over the portion of the tube between 4 and 9 ft from the side-wall header.

Inspection of the other top-row screen tubes after removal of handhole caps on the headers revealed similar corrosion, quite severe in the first six or eight tubes in each corner, but slight in the central portion of the furnace. To determine whether the tops of the tubes were steam-blanketed, a special sampling line consisting of a stainless-steel tube with an internal diameter of 0.09 in. was installed in the tube 17 NE, at the middle of the furnace. The end of the sampling line was turned upward and held in position close to the top of the tube at a point 6 ft from the side-wall header.

When the boiler was placed in operation on Jan. 20, comparison of the samples removed from the special sampling line EX, with those from the skimmer in the east 48-in. upper drum ESK, gave definite evidence of steam blanketing. As shown in the first section of Fig. 19, the phosphate concentrations of the EX samples from Jan. 20 to 23, inclusive, were always low compared to those of the ESK samples, and in two cases, substantially pure steam was issuing from the special sampling line. On Jan. 23 the run was terminated by the failure of a second top-row screen tube, 5 SE, along the top in the same manner as 2SE had failed previously.

An attempt to measure tube-wall temperatures by means of chromel-alumel thermocouples was made during the next test period, beginning Jan. 28. While the renewed tube 5 SE, which had been covered with protecting blocks, showed a temperature of only about 600 F during the brief life of the couples, the next tube 4 SE which had been left uncovered, simultaneously averaged 1250 F on the top and 640 F on the bottom, when the steam ouput of the boiler was 450,000 lb per hr. That the overheating indicated by the thermocouple was not fictitious was proved by the failure of this tube on Jan. 31 and by its appearance after removal and sectioning, illustrated in Fig. 20. Beginning at the upper right, the cross sections represent the condition of the top half of the tube at successive 1-ft intervals from the side-wall header. The grooving apparently began between 4 and 5 ft from the header, was deepest at about 6 ft, and continued to between 9 and 10 ft.

The appearance of the internal surface of the section from 6 to 7 ft from the side-wall header is shown in Fig. 21. The actual crack is about 3 in. from the 6-ft (left-hand) end. Specimens cut

FIG. 24 SECTION NEAR EXTERNAL SURFACE OF CRACKED ASH-SCREEN TUBE FROM LOGAN STATION, SHOWING PENETRATION OF OXIDATION ALONG GRAIN BOUNDARIES, ×1000
(Note also accumulation of globular iron carbide at grain boundaries.)

for metallographic examination from the side and from the top of the 7-ft end showed no significant difference in structure, as may be seen in Fig. 22, indicating that 9 in. from the point of failure the tube had not been overheated sufficiently to produce spheroidization. A specimen cut from the region of the fracture was, however, definitely spheroidized, as illustrated in Fig. 23, while the fine cracks near the main fracture at the external surface showed oxidation working inward along grain boundaries, as in Fig. 24.

Attempts to Obviate Attack. Since the most serious attack was evident in the screen tubes at the corners of the furnace, an attempt was made to improve circulation by removing the five top-row tubes in each corner, plugging tube holes 1, 2, 4, and 5, replacing each tube 3 with a new tube, and inserting baffles in the side-wall headers to isolate these sections from the central portions. In each of these corner sections there then were left a total of five tubes, one in the top row and four in the bottom, where previously there had been nine tubes. It was hoped that this change would nearly double water velocities through the remaining tubes.

While these changes were being made, the profile of the attack along the top of each tube on the south side was measured by a special calipering device, and series of thermocouples were peened into the tops of tubes 3 and 6 in each corner and tubes 17 NE

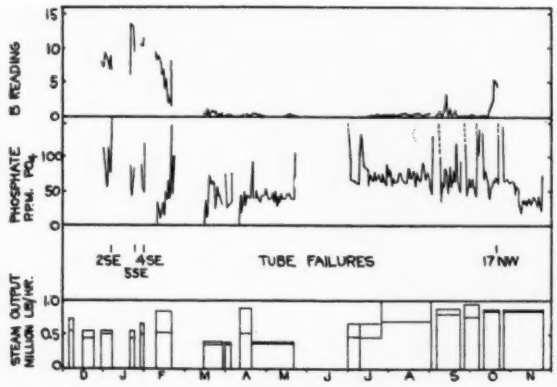

FIG. 25 RECORD OF LOAD, BOILER-WATER CONDITIONS AND FAILURES OF ASH-SCREEN TUBES AT LOGAN STATION

(Upper line for load indicates maximum, lower line average for each operating period. Multiplication of the B reading by 13.3 gives the approximate value for NaOH in ppm.)

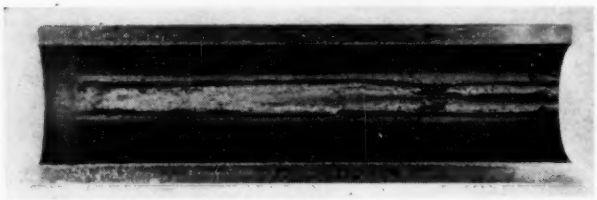

FIG. 26 INTERNAL APPEARANCE OF TOP OF ASH-SCREEN TUBE AT LOGAN STATION AFTER TWO MONTHS OF OPERATION WITH LOW BOILER-WATER ALKALINITY

(Replacement tube 6 NE, in service Mar. 14 to May 21, 1938. White deposit is iron phosphate.)

and SW at the center of the screen. When the boiler went into service on Feb. 9, however, the thermocouples failed within from 17 to 28 hr, before the steam output had exceeded 600,000 lb per hr. Although the maximum temperatures recorded in each tube during this brief period at the start ranged only from 640 to 730 F, appreciable attack occurred before the boiler was taken off the line on Feb. 21. On calipering, it was found that all tubes had lost some metal and that tubes 3 and 6 in both the SE and SW corners had suffered the most. The maximum decrease in wall thickness, approximately 0.1 in., had occurred in tube 3 SE about 3 ft from the side-wall header.

With the efforts to improve conditions by increasing velocity of flow apparently unsuccessful, two alternative procedures were urged: First, modification of boiler-water conditions in an attempt to stop the attack by chemical means, and second, modification of the design of the ash screen to eliminate or minimize steam blanketing along the top of the tubes. Since replacing the ash screen would involve rather considerable expense, and since the type of attack in question had apparently been obviated at Port Washington by decreasing the alkalinity of the boiler water (12), it was decided to maintain "Port Washington conditions" during the next operating period.

Operation With Low Alkalinity. As indicated in Fig. 25, the alkalinity was maintained at a low level not exceeding a B reading of 1 from March 14 to 28; in the succeeding periods from March 31 to April 4 and from April 11 to May 21 this maximum limit was further reduced to 0.25. During these periods the steam output did not exceed 500,000 lb per hr except on Apr. 14 and 15; a maximum of 880,000 was attained on the latter date. This relatively high rating again produced definite evidence of steam blanketing from the EX sampling line, at that time located in tube 3 NE. As shown in Fig. 19 the sample from this line on April 15 contained practically no phosphate and had a pH of only 8.2, while the samples taken simultaneously from the skimmer in the east 48-in. drum showed little change from the preceding day.

After this brief trial at higher ratings, the steam output was dropped to 460,000 and then to about 350,000 lb per hr for the rest of the period of operation, which terminated May 21. Measurements revealed little further loss of metal, but whether this was due more to low alkalinity or to low rating could not well be decided. The black bands previously observed along the tops of the tubes were still present, but were bordered and partially covered by a white deposit, evident in Fig. 26. This shows a portion of replacement tube 6 NE which had been installed new just before operation under Port Washington conditions was commenced on Mar. 14. To the eye, all of the surface except the band at the top was uniformly reddish brown. Examination under the polarizing microscope revealed that the surface of the black band was the familiar magnetic iron oxide, that the white deposit was iron phosphate similar to that previously observed in a tube from Port Washington, and that the reddish brown coating was chiefly finely divided metallic copper. Both the iron phosphate and the metallic copper could be readily rubbed off with a cloth, leaving the fundamental tightly bonded surface coating of Fe_3O_4 on the steel.

Change in Design of Ash-Screen Tubes. Before the boiler was again placed in service, the burners were swung out from the walls to decrease the diameter of the vortex in the furnace. At the same time, the entire east half of the ash screen was replaced, using tubes 3 instead of 3.5 in. in diameter, bent to give an increase in average slope from about 7.5 to about 12.5 deg. The change in slope is indicated in Fig 27. Replacement tubes of the original design were installed in 6 NW and 3, 6, 7, and 14 SW to allow direct comparison of the effect of tube design during the next operating period.

During the two months from June 30 to Sept. 2, water conditions were held closely the same in the east and west halves of the boiler, again with the low limit of alkalinity set by Port Washington. Toward the end of this period the steam output was progressively increased from a level of 700,000 to a maximum of 1,000,000 lb per hr, the rated capacity, just before the boiler was killed.

During this test period the EX sampling line was still located in tube 3 NE, but this was now of the new design. The representative data for Aug. 16 to Sept. 3 reproduced in Fig. 19 indi-

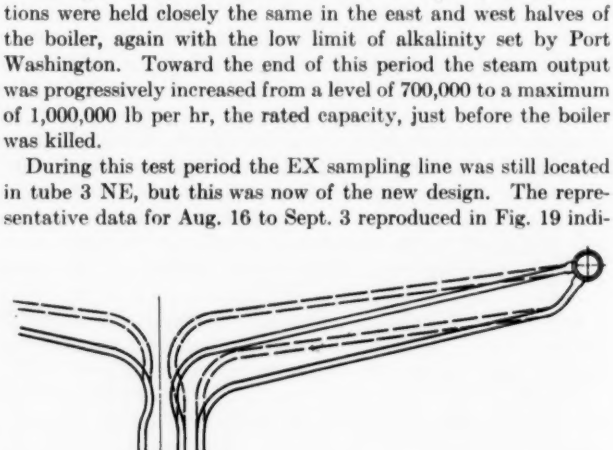

FIG. 27 CHANGE IN DESIGN OF ASH-SCREEN TUBES AT LOGAN STATION

(Broken lines: Original tubes, 3.5-in. diam, 7.5-deg slope. Solid lines: New tubes, 3-in. diam, 12.5-deg slope.)

cate a consistent dilution of the sample by the steam in the top of the tube, but not even at the maximum rating was there steam blanketing such as that shown for the old design of screen tube on Jan. 21 and 22 and on Apr. 15. This promise of better performance of the new tubes was substantiated when the boiler was inspected on Sept. 4. While all of the tubes of the old design in the west end showed the characteristic black band along the top, frequently edged and spotted with the white deposit of iron phosphate, the tubes of the new design in the east end were practically unmarked.

That the marks in the tubes in the west end were not merely carried over from previous operation was proved by the appearance of the replacement tubes of the old design. Thus 6 and 7 SW, new at the beginning of the test period, could not be distinguished from 8 SW, which had been in the boiler since it was erected.

While the appearance of the tubes of the old design attested continued steam blanketing, the actual attack during the two months under Port Washington conditions had been slight relative to that previously developed during the shorter early periods of operation with more alkaline boiler water. Reflecting the shift in the angle of the burners, tubes 8 to 10 SW lost more metal than those toward the corner or toward the center of the screen, and the maximum decrease of 0.05 in. in wall thickness occurred in tube 10 SW, 6 ft from the side-wall header.

Of the tubes of the new design in the east half of the screen, 12 SE was the only one to show a dark band along the top. This band, about 0.5 in. wide at its mid-point, extended from about 3 to about 6 ft from the side-wall header. The corresponding tube on the other side, 12 NE, showed a few discontinuous spots along the top. Measurement indicated an apparent maximum loss of 0.03 in. in wall thickness at one point in 12 SE and no loss greater than the uncertainty in measurement in 12 NE.

Effect of Increased Alkalinity on Tubes of New Design. The evidence now clearly indicated that the attack on the old design of tube had been greatly retarded by decreasing the alkalinity of the boiler water but that the fundamental cause of the attack, steam blanketing of the tops of the tubes, had been almost completely eliminated by the change in design. The next question was whether the new design would actually stand up when boiler-water alkalinity was again raised to the original operating level.

During the shutdown from Sept. 2 to 6, the deflector plates in the secondary-air passages of the upper burners were adjusted. Contrary to expectations, the change caused the flame to sweep down through the screen tubes during the period from Sept. 6 to 23. The plates were then changed back, restoring normal flame conditions during the operating period from Sept. 26 to Oct. 7. While the alkalinity of the boiler water was allowed to reach a B reading of 3 on one day during these two periods, it was not until shortly after the boiler again went on the line on Oct. 10, producing steam at a rate of about 840,000 lb per hr, that the alkalinity was progressively raised as indicated in Fig. 25. A B reading of 5.3, corresponding to a nominal concentration of 70 ppm of NaOH, was reached on Oct. 19 and held the following day. On Oct. 21 tube 17 NW, of the old design, located at the center of the furnace, developed a leak along the top which necessitated taking the boiler off the line.

Measurement of the screen tubes showed that while those of the old design in the NW quarter had lost quite generally about 0.15 in. of metal, with less severe attack indicated in the SW quarter, there had been no measurable attack on the tubes of the new design in either the NE or SE quarters. Complete replacement of the tubes in the west end with those of the new design was the result. This was carried out during a shutdown from Nov. 24 to Dec. 6, 1938. Further operation will be watched with no little interest.

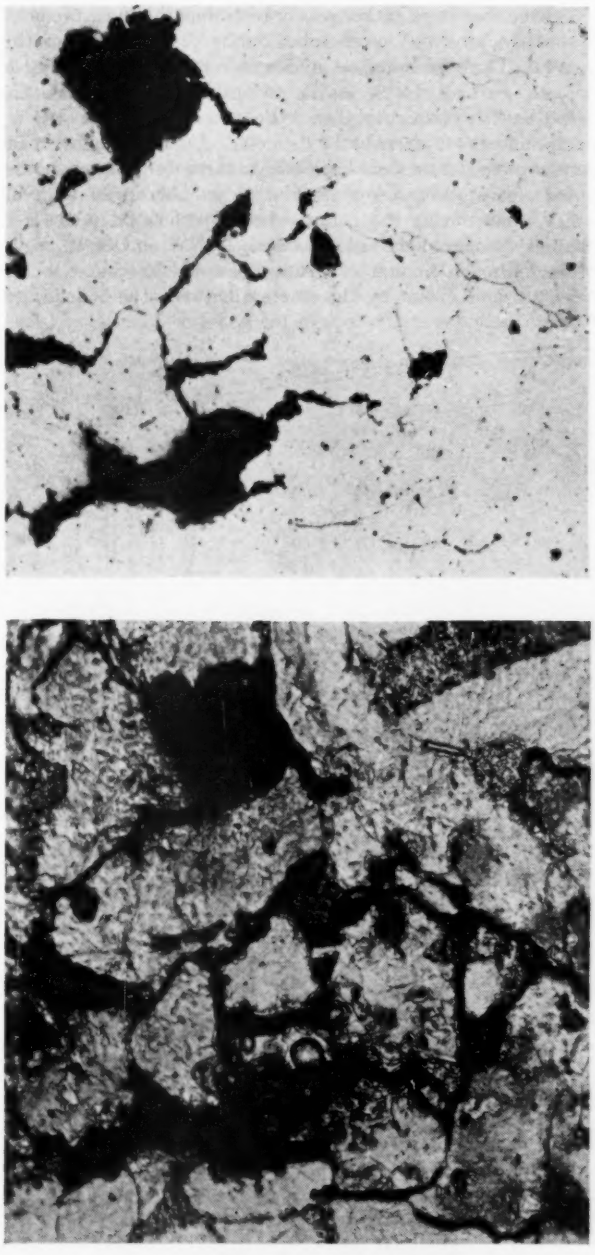

FIG. 28 STRUCTURE OF TOP OF TUBE 17 NW FROM LOGAN STATION, ×500

(Top: Unetched. Bottom: Etched with 4 per cent nital.)

Metallographic Examination of Failed Tube. Under the microscope, specimens from the area of failure in tube 17 NW revealed not only a structure indicative of excessive overheating, but also intergranular cracks developing from the internal surface. As may be seen from Fig. 28, the finer cracks in the unetched condition appeared only as faint lines but etching developed these into relatively broad black bands which seemed to follow the boundaries of the original grains.

Hydrogen Evolution as a Warning Signal. Theoretically the hydrogen content of the steam from a boiler should be a measure of the amount of boiler metal oxidized by reaction with the water. Actually the hydrogen measurements made on the steam from each end of the boiler at Logan Station daily since March 15,

1938 have correlated rather poorly with the other measurements of the attack on the screen tubes during the various operating periods. Thus the apparent hydrogen content was observed to increase markedly with steam output during one operating period at low alkalinity, but little attack was indicated by measurements of internal tube diameter. Likewise the hydrogen content of the steam went higher for a longer time during another period of operation at low alkalinity when there was negligible attack, than during the period when experimental increase in alkalinity produced the failure of tube 17 NW on Oct. 21.

The hydrogen content of the steam would, of course, be affected to some extent by the reaction between the boiler water

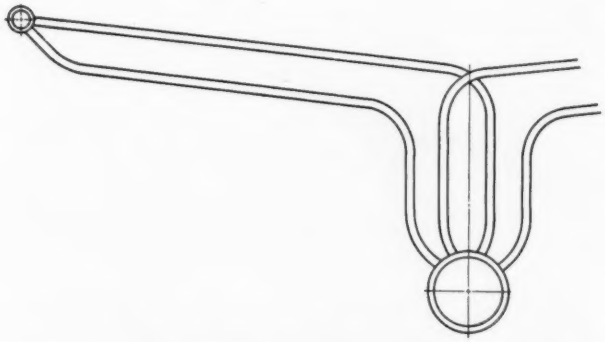

FIG. 29 ELEVATION OF ASH-SCREEN TUBES IN BOILER 5 AT ROUGE PLANT
(Tube diameter, 3 in.; slope, 7 deg.)

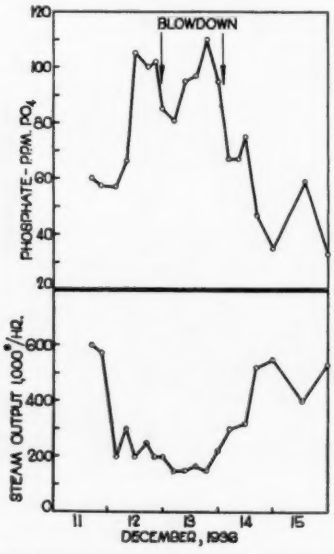

FIG. 30 INVERSE RELATION BETWEEN PHOSPHATE CONCENTRATION AND STEAM OUTPUT DUE TO "HIDING OUT"

and any excess of the ferrous sulphate used as an oxygen scavenger. However, 1 lb of iron combined in the form of ferrous sulphate would produce only 61 liters of hydrogen, as against 244 liters from 1 lb of metallic iron.[9]

[9] These values are based upon the equations:

$$3FeSO_4 + 6NaOH \rightarrow 3FeO \cdot H_2O + 3Na_2SO_4$$
$$3FeO \cdot H_2O \rightarrow Fe_3O_4 + 2H_2O + H_2$$
$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2$$

The reactions of iron and of ferrous hydroxide with water to form Fe_3O_4 and H_2 have been observed experimentally by E. Berl and F. van Taack, *Archiv. für Wärmewirtschaft*, vol. 9, 1928, pp. 165–169.

Ford Motor Company

Power Plant No. 1 of the Rouge plant of the Ford Motor Company contains three 1350-psi dry-bottom boilers, which have experienced no difficulty with internal attack along the tops of the ash-screen tubes. Boilers 1 and 3, each with a rated output of 700,000 lb of steam per hr, have been in operation since 1931, and boiler 5, rated at 800,000 continuous, 900,000 for 2 hr, and actually operated on test at 1,040,000 lb per hr, went into service July 15, 1936.

Boiler 5 is in many respects similar to the Logan boiler. However, the screen tubes are 3 in., while the original tubes at Logan were 3.5 in. in diameter. The ash screen, which has a slope of approximately 7 deg, is shown in elevation in Fig. 29.

Initially the superheat on boiler 5 tended to run from 30 to 40 F too low and adjustment of the burners upward was necessary to attain 900 F. No such adjustment was necessary on the earlier boilers 1 and 3.

Boiler-Water Conditions. In boiler 5, as well as in the older high-pressure boilers at the Rouge plant, the water conditioning has always been carefully controlled. Only infrequently does the boiler water show concentrations which are outside of the control limits of from 10 to 20 ppm of OH and from 60 to 80 ppm of PO_4.

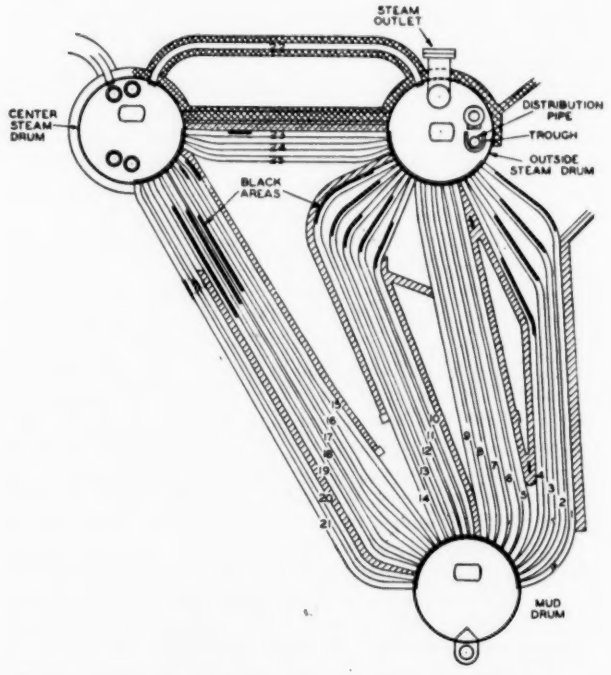

FIG. 31 LOCATION OF BLACK AREAS IN TUBES OF NO. 2 BOILER AT BEACON STREET
(Tubes 1 to 16 were inspected with a mirror. The lower ends of tubes 10 to 14 could not be seen because of bends. Tubes 17, 18, and 19 were removed and opened for examination.)

Although inspection has consistently shown all three high-pressure boilers to be free of attack in the ash-screen tubes, the boiler-water analyses show definite evidence of hiding out of phosphate during normal operation followed by its return to solution on reduction of load during the night or over a week end. The results of a test on boiler 5 are shown in Fig. 30.

This case has been included as representative of the considerable number of boilers in which no serious difficulty has yet been encountered, even though steam blanketing apparently is present.

Generating Tubes in a Bent-Tube Boiler

Beacon Street Heating Plant

The cracking of tubes in the double-set bent-tube boilers in the Beacon Street Heating Plant of The Detroit Edison Company has been reported previously (13), but is discussed here with some additional information. When the first two of these boilers went into service in September, 1926, they were the largest in the world with respect to heating surface. It was soon found, however, that the desired output of 435,000 lb of steam per hr from each boiler could not be reached without excessive carry-over. After trial of mechanical separators had failed to produce sufficiently dry steam, it was found by experiment that lowering the working water level achieved the desired result. Accordingly, during the summer of 1928, the water columns on each boiler were moved down 13 in. from their original location at the center line of the 54-in. drums.

For nearly eight years the boilers operated without difficulty. During inspections black areas were noted on the upper internal surfaces of many of the tubes, but little importance was attached to this condition until a No. 19 tube in boiler 2 developed a leak in February, 1936. When this was removed and sectioned, a thin, velvety-black coating of magnetic iron oxide was found on the high side, extending over a distance from 3 to 7 ft downward from the center drum, and in this area were many circumferential cracks. The tube wall had not been thinned, nor was it bulged.

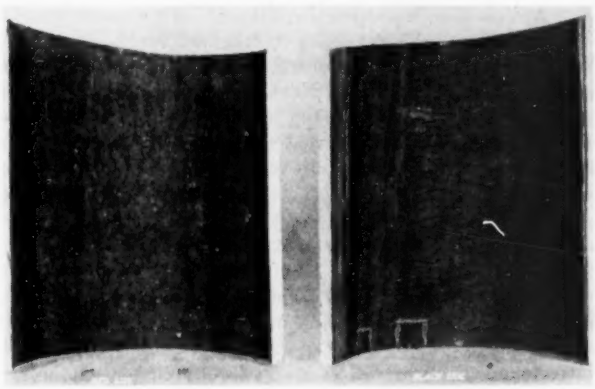

Fig. 32 Cracking as a Result of Steam Blanketing in a Bent-Tube Boiler at Beacon Street Heating Plant

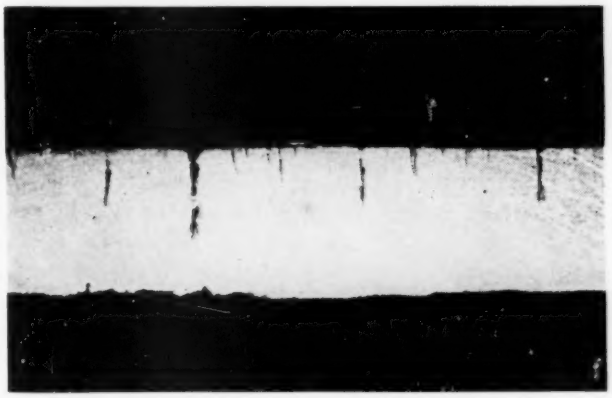

Fig. 33 Cracks Developed From Internal Surface of Boiler Tube at Beacon Street Heating Plant

Fig. 34 Decarburized Region Adjacent to Crack, ×500

However, along this portion of its length the tube was warped about 3 in. out of line, due to an apparent shortening of the black side.

Subsequent detailed examination revealed black areas as indicated in Fig. 31, in every case on the high side of the tube and in most of the tubes across the boiler. The No. 21 and No. 20 tubes, in front of the first baffle and closest to the furnace, were notably unaffected. The No. 19 tubes, however, not only showed well-defined black areas, but the majority were cracked in the same manner as the first tube removed. Fig. 32 shows the typical appearance of the undamaged front half and badly cracked rear half of one of these tubes.

Inspection revealed that boiler 1, and also boilers 4 and 5 installed respectively in 1929 and 1927, all showed black areas similar in appearance and location to those in boiler 2, but no cracks were apparent on visual examination of specimen tubes. A rough bending test caused the development of obvious cracks in the black areas but not in the normal areas of tubes from boiler 1. No cracks were revealed by this test in specimens from boilers 4 and 5.

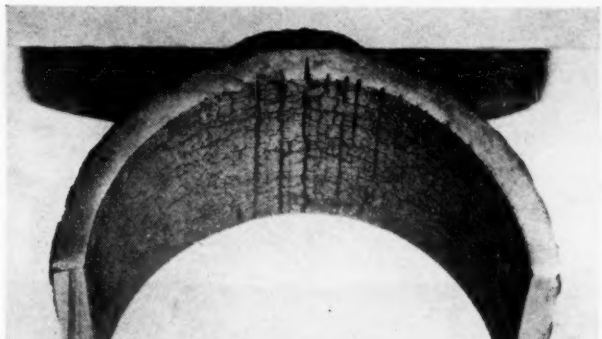

FIG. 35 LONGITUDINAL AND TRANSVERSE CRACKS IN TOP OF STEAM-CIRCULATING TUBE FROM 600-LB BOILER AT PIEDMONT PLANT

The typical character of the cracks is illustrated in Fig. 33. Microscopic examination showed them to be transcrystalline and revealed that the tube metal had been locally overheated. It was noted, moreover, that the inside surfaces of the cracks and the inside surface of the tube adjacent to the cracks were almost completely decarburized, as may be seen in Fig. 34.

Further evidence concerning the cause of the cracking was supplied by operating tests with thermocouples attached to tubes in the areas where the black-oxide coating had developed. It was found that, at the water level which had been employed, areas on tubes 15, 16, 17, 18, and 19 remained continuously at temperatures of from 600 to 1200 F, but that when the water level in the drum was raised, normal temperatures of from 360 to 460 F resulted. Phenomenally rapid and extreme changes in temperature were observed. Thus, on many occasions, raising or lowering the water level in the gage glass only $^1/_2$ in. produced a change of nearly 800 F in less than 1 min at some points on the high side of the tubes.

Overheating due to steam blanketing was recognized as the immediate cause of the difficulty. From the temperature studies, it was decided that the water level must be raised 9 in. toward the original level to establish adequate circulation through the tubes which had been affected. This again raised the problem of wet steam, which was solved by installing special baffles in the center steam drum and adding 184 new steam circulators between the center and the outside drums in each boiler.

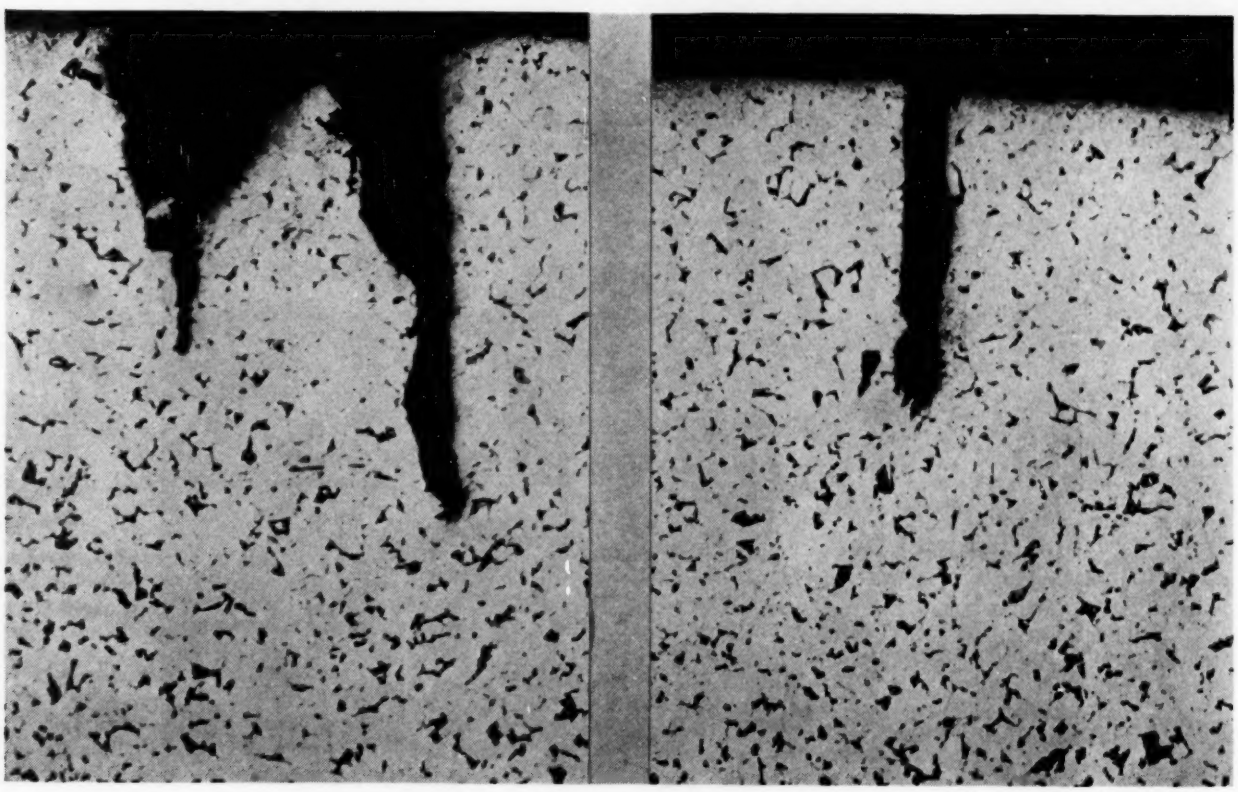

FIG. 36 CHARACTER OF CRACKS IN TOP OF STEAM-CIRCULATING TUBE

Cracking of Steam Circulators in a Bent-Tube Boiler

West Virginia Pulp and Paper Company

Boilers 22 and 23 in the Piedmont Plant of the West Virginia Pulp and Paper Company are 600-psi three-drum bent-tube units, which went into service respectively in December, 1934, and May, 1938. Cracking of steam-circulating tubes in each of these boilers has posed an interesting problem.

The first cracking in boiler 22 was observed in the spring of 1937, and all of the trouble developed in the second row of tubes from the top, at or close to the bend adjacent to the steam drum. Failure occurred first in the third and fourth tubes from one side and then in the fourth and fifth tubes from the other side. Efforts were made to continue these in service by welding up the first cracks observed but when further cracking led to the removal of tubes it was discovered that the internal surfaces were literally disintegrated. Fig. 35 shows the network of longitudinal and transverse cracks on the upper half of one of the tubes after pickling in acid to dissolve the thin coating of calcium phosphate present when it was removed from the boiler.

Under the microscope the tube wall had the typical appearance shown in Fig. 36, suggesting that the trouble was due to stress corrosion. The steel showed no signs of spheroidization.

By segregating the discharge from the wall tubes into the intermediate drum so that it was forced to pass out through the top row of circulators to the steam drum, conditions in the second row of circulators in boiler 22 were materially improved. This arrangement was accordingly installed in boiler 23. This did not prevent the development of the same type of cracking, which first became evident during the fall of 1938. In boiler 23, however, the failures occurred in the third instead of the second row from the top, and black oxide was evident on the ceilings of the tubes in the five lower rows.

A number of changes have been made to increase the ratio of water to steam in the circulating tubes. The third row of tubes, in which the cracks had developed, was removed and the holes were blanked; discharge from the upper waterwalls was divided between the top two rows; discharge from the lower waterwalls formerly entering the mud drum was routed into tubes delivering directly to the steam drum; and the baffling in the gas passage through the vertical tubes between the steam and mud drums was changed in an effort to increase the rate of downward flow of water through the tubes. While further modifications may be necessary for a final solution of the problem, recent operation indicates that the condition is much improved if not entirely cured.

The Relation Between Low pH, Pitting, and Stress Corrosion

Operation with little or no caustic alkalinity has proved effective in minimizing the attack of excessively concentrated boiler water on the tops of steam-blanketed tubes, as indicated in the preceding discussions of Port Washington and Logan Stations. While it is known that boilers fed with condensate containing consistently little dissolved oxygen may operate for years at a relatively low pH level with no difficulty from pitting or stress corrosion, nevertheless the experiences of a number of plants suggest that low alkalinity may contribute to these types of attack. As examples, the histories of Colfax Station of Duquesne Light Company and of Edgar Station of Boston Edison Company may be cited.

Pitting and Stress Corrosion at Colfax Station

At the time the first unit of seven 265-psi straight-tube cross-drum boilers was installed in Colfax Station of Duquesne Light Company in 1920, operation with pure distilled water was considered the ultimate answer to the then almost universal problem of boiler scale. With the exception of a few weeks during 1924, when soda ash was fed to the head tanks, and of some tests with sodium silicate on individual boilers, the plant was operated without chemical treatment until November, 1929. In the meantime a second unit of seven boilers had been added in 1922, a third unit of five in 1924 and 1925, and a fourth unit of three in 1927. While the design changed in detail from unit to unit, the general arrangement of the heat-absorbing surface is indicated in Fig. 37, which shows a boiler of the third unit. Boilers of the first two units were stoker-fired, while those of the third and fourth units were fired with pulverized coal.

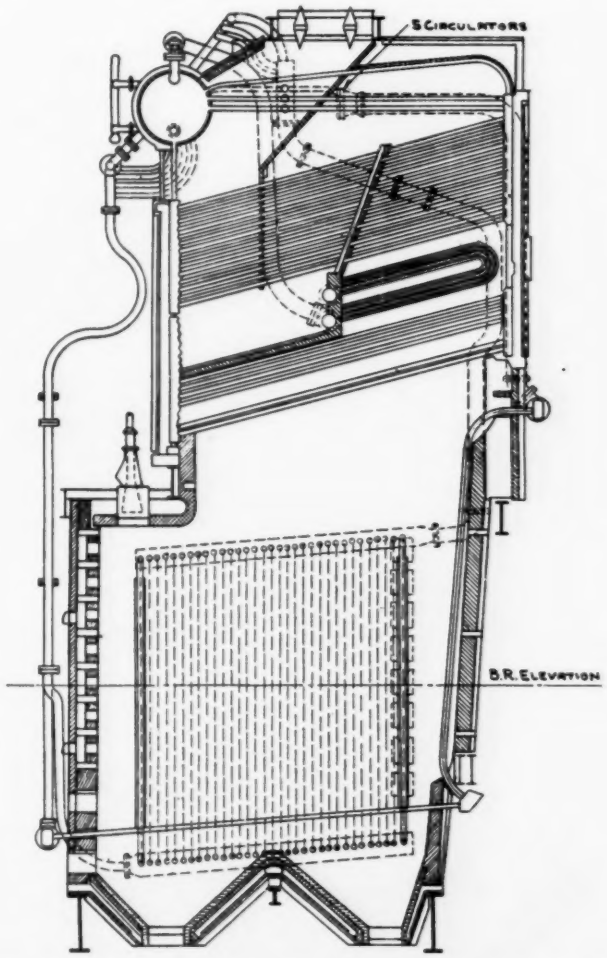

Fig. 37 Cross Section of Third-Unit Boiler at Colfax Station

Efforts to Reduce Oxygen Content of Feedwater. According to the information available when Colfax Station was designed, serious corrosion was not anticipated if the oxygen content of the feedwater was kept below 0.5 ml per liter. In retrospect, it is not surprising that this amount of oxygen introduced into boiler water at a low pH should have caused noticeable corrosion during the early operation of the plant. This led to the practice of covering the surfaces of the drums with a special paint. In 1923 and 1924 pitting of the tubes in the boilers of the first unit was recognized as a problem, and oxygen as a primary factor. Painting of the generating tubes, started late in 1925, proved ineffective.

A small deaerator installed to treat the 2 per cent make-up from the evaporators and auxiliary supplies went into service

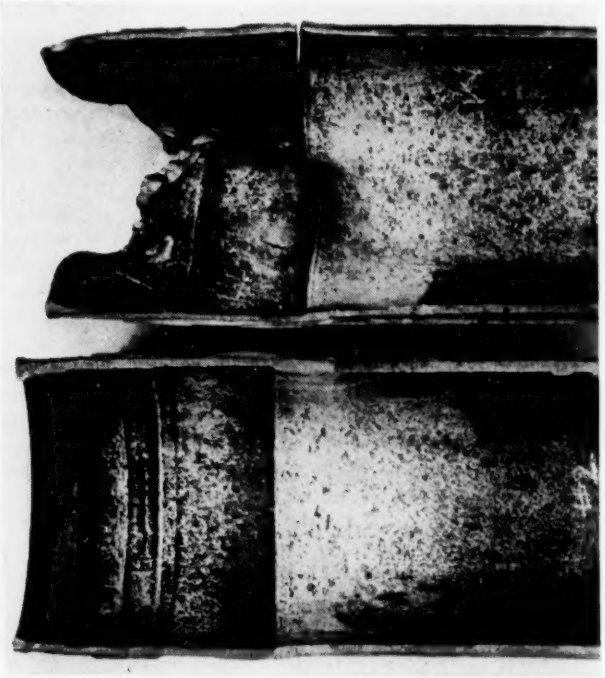

FIG. 38*b* INTERNAL VIEWS OF CRACKED NIPPLE

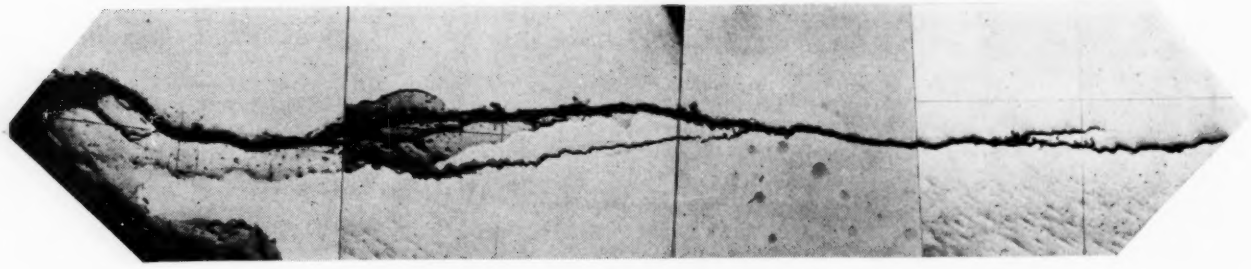

FIG. 40 TYPICAL CRACK IN HEADER, ×20

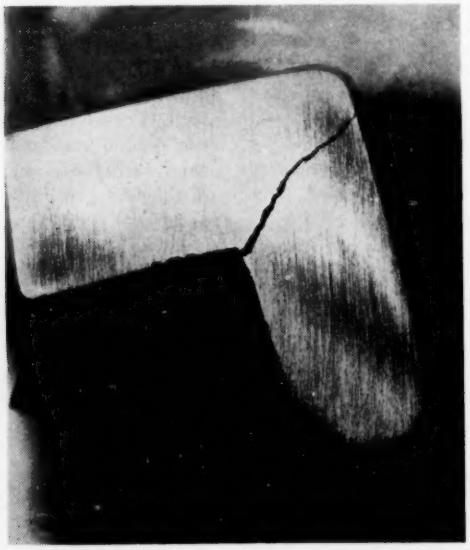

FIG. 39 STRESS-CORROSION CRACK IN CORNER OF HEADER

in April, 1924, and in September, 1925, closed heaters were substituted for the barometric condensers which had served as feedwater heaters, while possible sources of air leakage into the system were closely checked. As a result, the oxygen content of the feed was reduced from 0.5 to a maximum of 0.2 ml per liter (14) during full-load operation of the first and second units. A second deaerator was installed in 1927 with the fourth unit of boilers. In 1930 the small deaerator installed in 1924 was replaced by a larger one to deaerate surge return to the condensate system.

Cracking Due to Stress Corrosion. Not only did pitting continue in spite of these efforts, but nipples in the downtake headers and the headers themselves began to crack with increasing frequency as a result of what would now be called stress corrosion, which may have been developing for years. Figs. 38 and 39 illustrate typical cracking in a nipple and a header, respectively. The character of the cracks in the headers is shown by the photomicrograph of Fig. 40. All cracks developed from the internal surface.

Beginning in 1928, as a precautionary measure, all of the downtake nipples on the boilers at Colfax Station, except those in the newly installed fourth unit, were replaced with particular care to minimize deformation during rolling in.

In the boilers of the first and second units, which were equipped with umbrella-type feed nozzles in the drums, the cracking had occurred chiefly in the nipples in the downtake headers immediately below these nozzles. Boilers in the third and fourth units, equipped with perforated feed pipes extending the length of the drum below the water level, developed cracking of the nipples more at random. It was found however that the oxygen content of the boiler water was lower in the first and second units, where the entering feedwater was partially deaerated by spraying through the steam space,[10] than in the other units. The combined advantages of deaeration and distribution were secured in the boilers of the first two units by substitution of troughs for the feed nozzles during the period from May, 1929, to November, 1930.

Chemical Conditioning of Boiler Water. It should be remembered that during all of these efforts to reduce the oxygen content of the feedwater and to distribute the feed, the water in the boilers contained only what dissolved substances might be introduced by evaporator carry-over or condenser leakage, so that the pH inevitably remained low, ranging between 7 and 9. In November, 1929, however, after some tests on a single boiler, the feed of trisodium phosphate to all boilers was started for the combined purposes of preventing the formation of a thin but dense scale on the heat-transfer surfaces, and of minimizing corrosion. While control on the basis of maintaining from 25 to 50 ppm of PO_4 in the boiler water did eliminate scale, the average pH of the water in the boilers was increased only to about 8.8, and corrosion and cracking continued, although to a decreased extent.

In June, 1932, the trisodium phosphate was supplemented by caustic soda to maintain between 17 and 34 ppm of OH in the boiler water. Installation of steam seals on the surge tanks the following March reduced the dissolved oxygen in the feedwater to the range from 0.02 to 0.05 ml per liter, as determined by the standard Winkler procedure, and the feed of sodium sulphite was commenced in May, 1933. No failures due to cracking have occurred since 1933.

At the time the feed of sodium sulphite was started, corrosion was occurring primarily at the uptake ends of the tubes in the lower deck and chiefly on the lower half of the tubes. In the stoker-fired boilers of the first two units, the treatment with sodium sulphite substantially stopped this corrosion which, however, persisted in the pulverized-fuel boilers operated at somewhat higher ratings. It was found, as a result of a series of tests begun during the latter part of 1935, that ferrous hydroxide effectively inhibited this type of corrosion. As a result, it has been progressively substituted for sodium sulphite on all pulverized-fuel boilers. The reason for the improved results with ferrous hydroxide in these boilers is not known. During the last two years, there has been practically no indication of active corrosion at Colfax Station, although occasional failures of previously pitted tubes have occurred.

Summary of Replacements Due to Corrosion. Condensed in Table 7 is a record of replacements of generating tubes, steam circulators, and headers on account of internal corrosion. Many of the tube replacements were made before actual failure, particularly those in the third unit in 1930 and 1932. Not included in the table are a considerable number of tubes removed primarily for observation in the early years of the station, and the complete replacement of all downtake nipples in the first three units, which was started in 1928.

A number of interesting features are apparent in Table 7. Thus 10 out of 11 cases of header cracking occurred in the first unit, with the remaining one in the third unit. Cracking of nipples was distributed chiefly between the first and third units, with 16 in the former, 14 in the latter, and only 4 in the second unit.

The third unit has undergone by far the most extensive replace-

[10] The oxygen survey given in (14) indicated only from 0.04 to 0.06 ml of oxygen per liter in the boiler water at various locations when the entering feedwater contained 0.2, and the saturated steam 0.24 ml per liter.

ment of tubes due to corrosion, with 367 out of a total of 465 generating tubes, and 262 out of a total of 273 steam circulators. The general replacement of the latter in 1930 in all the boilers of the third unit may have been due chiefly to overheating produced by secondary combustion in the upper part of the furnace adjacent to these necessarily steam-blanketed tubes. This view is substantiated by analyses which show that the top halves of the tubes were coated primarily with iron oxide, while the deposit on the lower halves comprised typical scale-forming constituents.

The experience at Colfax Station might be summarized briefly by the statement that, after reduction of dissolved oxygen in the feedwater and maintenance of higher alkalinities and oxygen-scavenging chemicals in the boiler water, pitting and stress corrosion have apparently been stopped.

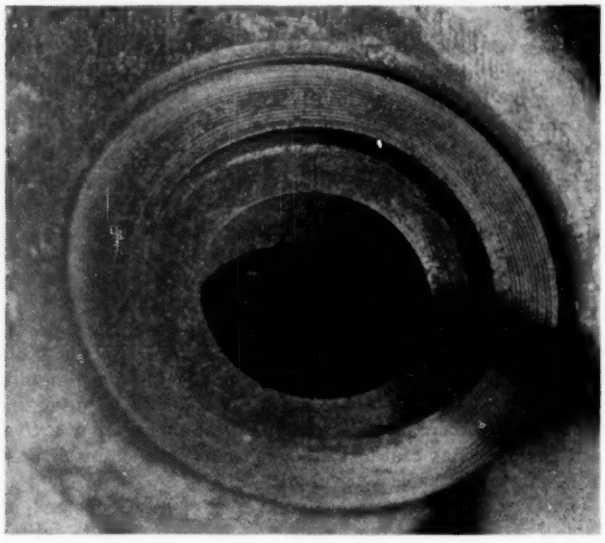

FIG. 41 CRACKS IN WATER COLUMN AT LOWER CONNECTION, BOILER 6, EDGAR STATION

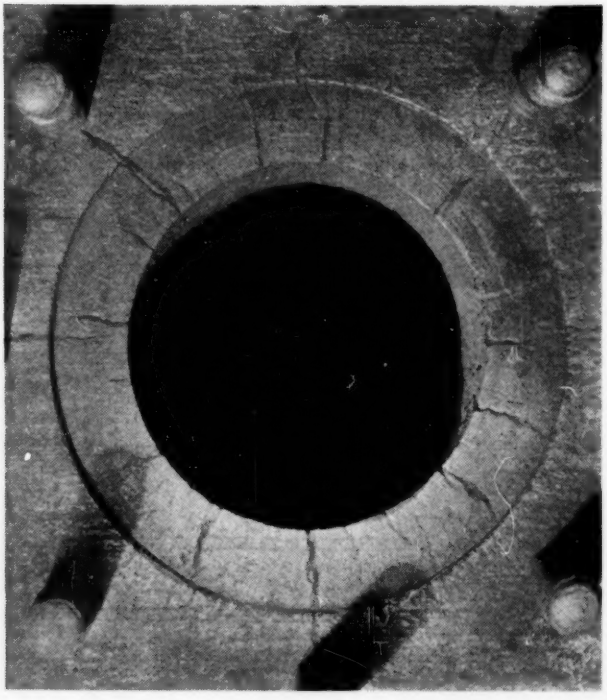

FIG. 42 CRACKS IN DRUM AT FEED-LINE CONNECTION, BOILER 5, EDGAR STATION

STRESS CORROSION AT EDGAR STATION

In Edgar Station of Boston Edison Company there are five high-pressure boilers. No. 3, installed in 1925 to operate at 1200 psi, was one of the pioneer units in this pressure range. Boilers 5 to 8, designed for 1400 psi, went into service successively from 1927 to 1929.

Late in 1935, it was found that the water columns on boiler 6 were cracked at the bottom companion joint, as indicated in Fig. 41. The same condition was then observed on boiler 5. In no case, however, were any cracks found in the corresponding joints at the upper end of the water columns.

The following year, cracks were discovered in boiler 3 in the cutouts for the feedwater connections, where the drum itself formed part of the feed line. Later inspections showed similar

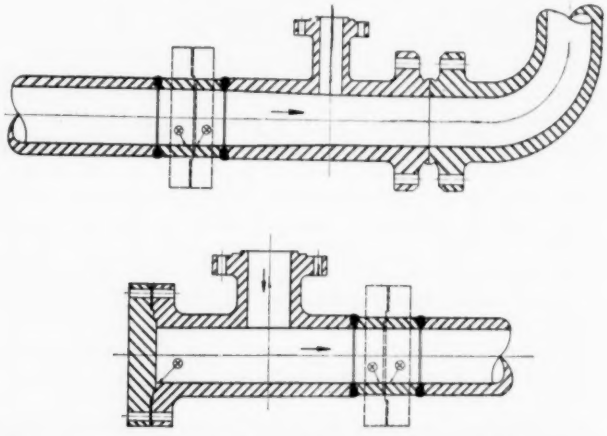

FIG. 43 LOCATION OF CRACKS AT BOTTOM OF FLANGED CONNECTIONS AT ENDS OF SUPERHEATER INLET AND OUTLET HEADERS, BOILER 5, EDGAR STATION

cracking in boiler 5, both in the drum at the feedwater connections and in the flanged joints of the superheater headers, and in boiler 6, in the Van Stone laps of the supply and riser tubes to the waterwalls.

The most serious condition was that in the drum of boiler 5. Fig. 42 shows how the cracks had developed to the stud circle on the inside surface. This boiler was removed from service in February, 1938, for rebuilding. The details of the inspection made at this time and of the changes made to obviate further cracking have been given by White (15).

Both repeated stress and contact with water at a low pH seemed to be important factors in the development of the cracks in the various locations. The feedwater to the drum, comprising condensate and evaporated make-up, was substantially neutral, with a pH between 6.9 and 7.2, and a temperature between 250 and 350 F. As a result of the intermittent introduction of feedwater by the automatic regulator, the temperature in the wall of the hole in the drum must have varied repeatedly between this range and the temperature of the water in the drum, about 585 F, presumably setting up localized thermal stresses in the steel.

On both the inlet and the outlet headers of the superheaters, tees are connected by flanged companion joints, as indicated in Fig. 43. Cracks were found in these joints at the bottom only, where a definite water line showed that condensate had col-

lected at various intervals. No cracks were found in the side outlets of the tees, which were in a position to drain readily, or in the Sargol joint on the outlet fitting.

In the water columns, normal condensation kept the bottom connections in contact with water which showed pH values as low as 7.3 when samples were withdrawn slowly to avoid flow of water from the drum back into the column.

The only cracking where water at a higher pH may have been in contact with steel was in the Van Stone laps on the supply and riser tubes to the waterwalls of boiler 6. Since the supply tubes take off from the drum, it might be expected that boiler water with a pH of 11 or higher would pass through them. Short-circuiting of feedwater down the supply tubes is, however, possible. No means are available for checking the actual pH of the water in this circuit.

The concentration of dissolved oxygen which may have contributed to the stress corrosion is not known. Although mechanical deaeration eliminated oxygen from the feedwater to the point where it could not be detected in the standard Winkler test, some trouble with pitting was encountered prior to the adoption of sodium sulphite as a chemical scavenger during September, 1932.

Interpretation of Evidence

By piecing together evidence from the various case histories a reasonably complete picture of steam blanketing and its effects may be sketched. The most direct proof of the development of a steam blanket in a slightly inclined tube is afforded by the experiments at Logan in which substantially pure steam issued from a special sampling line located with its intake at the top of one of the original ash-screen tubes, Fig. 19. The overheating which must result from high heat input to a blanketed tube was observed by means of thermocouples at San Antonio and at Beacon Street, and was indicated by the microstructure of the steel at South Amboy (Fig. 5) and at Logan (Fig. 23). The hiding out measured at San Antonio (Fig. 7) and Rouge (Fig. 30) may reasonably be ascribed to localized evaporation on the ceiling or at the water line along the sides of steam-blanketed tubes.[11]

Grooving and Cracking of Tubes

Grooving such as occurred at South Amboy (Fig. 4), Port Washington (Fig. 15), and Logan (Fig. 20) is believed by the authors to develop where a relatively constant condition of steam blanketing causes excessive localized concentration of a normally alkaline boiler water along the ceiling of a highly overheated tube. Cracking such as was experienced at Beacon Street (Fig. 32) and at Piedmont (Fig. 35), on the other hand, is attributed to repeated quenching of overheated steel by intermittent contact with boiler water.

It is interesting to note that grooving occurred in the high-pressure boilers at Mannheim, Germany, in 1929 (16). The published photographs show tube walls thinned in the same manner as those illustrated in the present paper.

An early case of cracking of upper-row tubes near the uptake headers occurred in 1925 at Hell Gate Station of the United Electric Light and Power Company. The study of tube temperatures and the application of cores to prevent overheating has been briefly described elsewhere (17).

Effect of Boiler-Water Composition

Maintenance of low controlled alkalinity characteristic of the best contemporary operation did not prevent failures of steam-blanketed tubes at South Amboy, San Antonio, Springdale, Waterside, Rivesville, Port Washington, Logan, Beacon Street, or Piedmont. Increasing the concentration of sodium hydroxide aggravated the trouble at South Amboy (Fig. 6) and at Port Washington (Fig. 17), while substantial elimination of this substance from the boiler water at Port Washington and at Logan minimized grooving (Figs. 17 and 25).

On the other hand, Rouge is representative of many plants which have experienced no difficulty when operating with normal low concentrations of sodium hydroxide in the boiler water, while stress-corrosion cracking has apparently been promoted by the absence of this constituent at certain localities in the boilers at Edgar and during the earlier operation at Colfax.

Formation of an iron phosphate, which takes place only to an insignificant extent in boilers operated with definite though low concentrations of sodium hydroxide, apparently is promoted by elimination of this caustic alkalinity. Both at Port Washington (Fig. 18) and at Logan (Fig. 26) considerable amounts of a white iron phosphate were found admixed with black Fe_3O_4 on the tube surfaces and exposed along the steam-blanketed strips on the tube ceilings. The authors believe this to be merely a casual result, with no particular significance as far as prevention of attack is concerned.

Effect of Tube Slope

The influence of tube slope is shown most clearly by the fact that the drop-leg tubes at South Amboy failed frequently, and always along the top of the nearly horizontal section, while the straight inclined tubes with which they alternated were practically free from trouble except as they were cut externally by leaks from the drop-leg tubes. At Logan the increase in slope of the ash-screen tubes was accompanied by a decrease in diameter; to what extent the resulting improvement may have been due to possible increase in velocity of flow can scarcely be guessed, but the writers believe that this effect was less important than the increased slope.

Effect of Circulation

So little is known about the rate at which water actually circulates through individual tubes that little can be done to evaluate the influence of this factor. The attempt at Logan to double the velocity in the tubes at the corners of the ash screen failed to produce any marked improvement, and the modifications with respect to flow at San Antonio apparently had no great effect.

In straight-tube sectional-header boilers in general, the circulation appears to be downward through the upper row or rows of tubes (7, 8). In most cases, any damage from the resultant steam blanketing is confined to the tops of the tubes near the uptake header, as at San Antonio, and at Springdale before insertion of cores. The location of the failures on the bottom of the tubes at Waterside is difficult to explain, unless it is assumed that at times little water was passing through them. The attack on the bottom of the cored tubes at Springdale suggests the same condition.

With respect to ash-screen tubes, even if the rate of flow were greatly increased, as by forced circulation, steam blanketing might still occur. In this connection, the authors have had the privilege of examining a specimen of studded tube from a forced-circulation once-through boiler which showed pits on the internal surface precisely under the studs on the portion of the wall toward the combustion chamber. Apparently the studs had served as channels for localized high heat input to the tube wall.

Effect of Rate of Heat Input

Heat absorption sufficient to develop steam blanketing in a specific tube may not actually cause any serious damage to the steel. Progressive increase in heat transmission must, however, increase tube temperature and localized concentration of boiler

[11] Hiding out is also indicated in the control reports of a number of other boilers of contemporary design.

water, thus accelerating attack. Unfortunately, there is little basis for determining the maximum rate at which heat may be safely absorbed by a steam-blanketed tube.

The experimentation at San Antonio revealed that as long as the temperature of the tube wall did not exceed 800 F, oxidation was slow. The practical solution of the problem at this plant, it will be recalled, was baffling of the gas flow to shift the zone of heat absorption away from the upper ends of the tubes.

Swinging the burners out slightly from the walls at Logan moved the region of most severe attack from the sides toward the center of the ash screen. Adjustments of this sort may have played a critical part in determining whether other plants would or would not encounter trouble as a result of steam blanketing. For example, the shift of the burners upward on boiler 5 at Rouge in order to achieve the desired superheat may have helped to obviate the failure of ash-screen tubes.

The three 1300-psi boilers at Lakeside Station of Wisconsin Electric Power Company represent the pioneer application of ash screens in the United States. What the actual heat transmission to the tubes in these screens may be is not known, but the fact that no failures have occurred in spite of probable steam blanketing suggests a lower input to these tubes than to those in more recent installations of similar type. It is interesting to note from the discussion by Anderson (18) that some development of black oxide took place at Lakeside at particular points in both the boiler and fin tubes where the heat transfer was the highest.

Stopping the failure of floor tubes at Rivesville by increasing the thickness of the floor insulation is perhaps the most direct example of the effect of rate of heat input on the damage to steam-blanketed tubes.

Intergranular Cracking

While in the tubes at Beacon Street and at Piedmont which were presumably subjected to repeated quenching, the cracks were characteristic of stress corrosion (Figs. 33 and 36), the intergranular cracks observed first at Waterside (Fig. 13) and later at Logan (Fig. 28) suggest the possibility of embrittlement by sodium hydroxide or by hydrogen. However, intergranular cracks produced in low-carbon steel during long-time creep tests at 1000 F in air by White, Clark, and Wilson (19) and cracks developed in Armco iron at 1100 F in air as well as in hydrogen by Thielemann and Parker (20) are similar to those in Fig. 13. The latter authors attributed the intergranular character of the cracks in their experiments, which also included low-carbon and alloy steels, primarily to long-continued load above the equicohesive temperature, and expressed the belief that intergranular cracking preceded intergranular oxidation rather than resulting from it. The similarity of prolonged overheating of a tube in a boiler to a creep test under low stress is obvious. Whether or not intergranular corrosion by the boiler water, analogous to that which sometimes develops in riveted seams, was a factor in the formation of the cracks at Waterside and at Logan, excessively high temperature seems to have been the fundamental cause.

Significance of Metallic Copper

Metallic copper present in deposits of magnetic iron oxide has sometimes been regarded as the principal cause of the process which produced the oxide (21). The authors believe, however, that the copper is merely an incidental product of the fundamental reaction of steel with boiler water, and if supplied to the boiler by attack on condensers, valves, pumps, or other auxiliary equipment, will be found chiefly wherever stress, steam blanketing, or other influence accelerates reaction between the water and the steel.

Black Oxide and Hydrogen as Warning Signals

Steam blanketing leaves its distinctive mark in a tube before the conditions produced by it become dangerous. This will usually appear as a dark band along the top of a tube, sometimes dull and sooty, sometimes scintillating with the light reflected from the faces of small but well-formed crystals of Fe_3O_4. The presence of such a band or area does not necessarily mean immediate danger, but it should be considered as a warning signal. When loose, powdery Fe_3O_4, which may be admixed with metallic copper, is found in any appreciable amount either adhering to tube surfaces or lying in tubes or headers, the condition should be regarded as serious.

Hydrogen in steam has been used as a measure of the attack on tubes under superheating conditions by Fellows (22) and more recently by Potter, Solberg, and Hawkins (23). As a measure of the over-all attack in the boiler it proved useful at Port Washington but yielded rather unreliable results at Logan. While the technique of accurate determination of the hydrogen content of a representative sample of steam is not simple, this type of measurement applied to saturated steam should tell whether or not any serious oxidation of steel by boiler water is taking place.

Definition of the Problem

Difficulties caused by steam blanketing in various types of boilers of four different manufacturers in nine plants have been described in this paper. The intention has not been to raise a great alarm, but to bring what seems to be a general problem clearly into focus, so that it may be discussed and solved to the advantage of both the manufacturer and the purchaser of contemporary high-capacity boilers.

How can the difficulties resulting from steam-blanketing of slightly inclined tubes in high-pressure boilers best be prevented? One answer would be to eliminate the steam blanketing by eliminating the slightly inclined tubes; another, to minimize steam blanketing by controlling heat input or improving circulation; and still a third, to modify the composition of the boiler water so that the rate of attack, even on overheated steel, would be insignificant.

A boiler without slightly inclined tubes is a problem for the designer. Where a boiler is already in service, extensive changes may be justifiable neither from the mechanical nor from the economic viewpoint. It may be possible, however, to redistribute heat absorption or improve circulation sufficiently to minimize the damage from steam blanketing, even though the latter may still persist.

To reduce the heat input over any appreciable fraction of the heat-absorbing surface of a boiler apparently runs counter to the current trend toward smaller furnace volume and higher heat release. The question may well be asked, however, whether a small increment in the initial cost of a boiler guaranteed for a specific output of steam might not save both the manufacturer and the purchaser several times this amount in money and in the money equivalent of the time during which the boiler is unavailable for service due to necessary modifications.

Over against the factor of design, which fundamentally determines whether steam blanketing will or will not occur in a boiler, and if so, to what extent the blanketed areas will be heated above normal temperature levels, must be set the factor of boiler-water conditions. By eliminating sodium hydroxide from a boiler water and operating only with the alkalinity contributed by phosphate, the wasting away of metal in steam-blanketed tubes may be greatly reduced, although attack will still continue at a slow rate. Control of the pH of the boiler water can scarcely, however, be expected to reduce the temperature of the overheated tube wall which, if quenched repeatedly by water striking it, may ultimately crack. Operation with zero caustic alka-

linity seems less a solution to the problem of steam blanketing than an expedient which, in competent hands, will allow operation until the necessary fundamental changes can be made.

The writers believe that the real solution of the difficulties described in this paper lies in the prevention of steam blanketing in tubes subjected to high heat input, or conversely, limitation of the heat input to tubes which are likely to develop a steam blanket. Once this is accomplished, the question of what alkalinity should be maintained in the boiler water is no longer conditioned by what must be done to save overheated steel from attack by excessive local concentration of the boiler water, but instead by what will give maximum protection to the boiler as a whole.

Discussion

J. B. Romer.[12] The authors have presented considerable data that they have gathered on the question of high-temperature corrosion of steel by steam and the effect of boiler-water conditioning, particularly along the lines reported by M. K. Drewry (12) on this general problem.

Their paper may be summed up to the effect, that overheated tubes, irrespective of angle, in contact with steam corroded severely and that with the possible exception of a special treatment involving excess ferrous iron, there is no known feedwater treatment which adequately takes care of this situation.

The writer is in agreement with this summation and under these conditions the answer must lie in adequately taking care of this situation through the medium of design.

[12] The Babcock & Wilcox Co., Barberton, Ohio.

The microstructures as presented by the authors indicate that the nonoxidized metal, at the point of corrosion, had been at temperatures well above 1000 F and quoting from the authors:

> Correlation of the temperature measurements with the observed condition of the tubes showed that the deposit of black oxide had accumulated only in those tubes which had exceeded 800 F during the operating period. Measurement of the internal diameter revealed that there had been little actual loss of metal from the tubes.

These two items place the oxidation limit, of steel in steam, at or above 1000 F.

Straub in his paper[13] indicates that in laboratory tests the limit may be as low as 750 F—this when certain chemistry is adhered to. That control of the chemistry controls the extent of the oxidation is not only extremely interesting but it is also valuable information.

We should not lose sight of the effect of sodium sulphate. Straub shows that a decided decrease in the hydrogen generated and in the amount of corrosion observed follows as the result of an increased content of sodium sulphate.

This is quite significant and it is also unexpected that this particular problem should show up the advantage of the old caustic-soda antidote, sodium sulphate.

While the writer agrees that the answer to the formation of black magnetic oxide of iron in certain tubes at temperatures above about 950 to 1000 F is not one of proper water treatment, he wishes to point out that the feedwater chemist cannot dodge his two major problems:

1 To produce scale-free water at maximum operating temperatures by such methods that will

2 Produce water which will not damage the material of the boiler.

He should not raise the bugaboo that "lack of circulation is the cause of certain types of scale."

While there may be evidence indicating or pointing in the direction that certain types of scale form under these conditions of "dryness" there are other equally if not more definite indications that this dryness is the result of the formation of a type of sludge the porosity of which is insufficient to permit water to reach and cool the tube wall adequately, and further that this sludge formation may and does occur in the presence of ample circulation.

The second job, namely, to produce water that will not damage the material of the boiler generally involves controlling the pH. Experiences over a long period of time indicate that water having a low pH is excessively reactive toward iron and steel and unless this reactivity can be satisfied without using up or depleting the excess soluble ferrous ions then the boiler metal may suffer from some form of corrosion or corrosion fatigue.

In connection with the hiding out of soluble solids the writer would like to inquire as to a condition frequently encountered in modern boiler-water-conditioning practice. In many instances it is well known that the feedwater contains both calcium and magnesium apparently as carbonates or bicarbonates. Within the boiler these are treated with phosphate for the purpose of changing the calcium salts from a form of relatively low solubility to a more stable material supposedly of the sludge type. The blowdown from such units, even when the concentration of soluble salts is normal, is often crystal clear. Under these circumstances, what becomes of the sludge which is being formed in the boiler?

Another question which is quite pertinent to this problem is: Can dry areas be produced by water conditioning? In a number of instances sludge has accumulated in areas as shown in Fig. 1 and resulted in starvation of certain sections, thereby producing dry areas.

Among the case histories quoted by the authors are four with which the writer is familiar, namely, South Amboy, Rivesville, Edgar, and Colfax. At the present time it is considered that the first two of these have been satisfactorily taken care of by suitable changes in design. The third has been taken care of by changes in design which simultaneously involve changes in pH and the fourth case has been taken care of by changes in the pH alone.

The authors raise the question as to the possible secondary dangers as the result of maintaining low pH and point out the experiences at both Colfax and Edgar in this connection. Although the latter case may be of the stress-corrosion type, it is well known that low pH lowers the stress which may be applied to a pressure vessel to a marked degree, that many failures of boiler metal parts in the past have been directly due to low pH of the boiler waters, and that proper correcting of this value has eliminated the trouble.

Authors' Closure

That the reader does not always get out of a paper what the writer tried to put into it is illustrated by the remarks of Mr. Romer. His discussion implies that tube slope is not a factor in steam blanketing, and that oxidation of the ceiling of a steam-blanketed tube may possibly be avoided by maintaining excess ferrous iron in the boiler water. Without wishing to seem dogmatic, the authors again call attention to the improvement in conditions at South Amboy and at Logan following an increase in tube slope, and to the fact that the use of ferrous hydroxide at Colfax minimized only ordinary corrosion due to dissolved oxygen, rather than the oxidation due to steam blanketing, which was the chief concern of the paper.

Professor Straub and Mr. Nelson, in their paper[13] presented on the same program as that of the authors, concluded from laboratory studies of steam-blanketing that:

1 "This type of corrosion occurs only in partially dry areas.

2 "If the metal temperature is below 750 F, sodium hydroxide appears to be the active constituent in the boiler water causing the corrosion.

3 "If the metal temperature is below 750 F, the corrosion may be controlled by modifying the boiler water as follows: (*a*) reducing the causticity to zero, and (*b*) adding other salts, such as sulphate, silicate, etc.

4 "If the metal temperature is above 750 F, corrosion takes place in the absence of sodium hydroxide and chemical treatments effective at the lower temperature are no longer protective."

Unless one is willing to grant or to guarantee that the ceiling of a steam-blanketed tube will fail to exceed 750 F or some temperature not far above this, there is little basis either in the laboratory tests of Straub and Nelson or the operating experiences cited in the present paper for assuming that ferrous hydroxide or sodium sulphate or anything else added to the boiler water would prevent damage to the steel.

As the writers noted in the second sentence of the paper, neither the insulating effect of scale nor the acceleration of ordinary corrosion by dissolved oxygen are factors in the type of damage which is the chief subject of the paper. In most of the cases described, the amount of sludge found on the boiler surfaces was literally microscopic, and in no case was it sufficient to be a factor in the major problem. The authors hope, therefore, that, without evading any responsibility, they may postpone to some more appropriate forum a response to Mr. Romer's comments and questions relative to scale and sludge.

Deflection of Helical Springs Under Transverse Loadings

By W. E. BURDICK,[1] F. S. CHAPLIN,[2] AND W. L. SHEPPARD[3]

This paper presents an analytical approach to the problem of the transverse deflection of a helical closely coiled spring under the action of a force perpendicular to its axis and an end moment. Supporting test data are included to substantiate the formulas within established limits. Expressions for the stresses under this loading in combination with an axial force are derived for the critical points on the spring.

THE USE of helical closely coiled spring suspensions for vibrating masses has not only necessitated a careful consideration of the characteristics of the spring under normal axial loading but in addition, where a thrust acts in a direction perpendicular to the axis of the helix, equal regard should be given to the properties of the coil under transverse loadings. This condition is evident in the case of those reciprocating mechanisms where an unbalanced force lies in the horizontal plane; also, it exists in certain types of vehicular suspensions in which a helical spring is utilized to take lateral or fore-and-aft reactions in addition to gravity loadings. The latter application is best exemplified in certain recently constructed types of railway-car trucks incorporating this particular capacity of a helical spring to cushion loads in more than one plane.

It is the authors' intention to present herein an analytical approach to the problem of a helical spring with one end resting on a rigid foundation and the other subjected to a transverse loading alone or in combination with an end moment. The investigation includes a derivation of the relationship for the resulting transverse deflection at the free end and attendant stresses under such a condition. Comparison will be made with actual test results made with a wide variety of spring sizes and loadings to demonstrate the validity of the expression for deflection and establish the approximate range of application. The stress derivations are dependent on the ability of the stock itself to follow Hooke's law of proportionality for a material in bending and torsion, with appropriate factors for stress concentration due to curvature and may be accepted with no more reservations than are accorded the present approved method of investigation for the axial loading condition.

The only specific information available on this subject which the authors were able to find was a paper by Marty.[4] In this case, the investigation was mainly concerned with a uniformly distributed transverse load over the length of the spring as occurs under centrifugal loading. This author expressed an effective flexural and torsional rigidity of a helical spring analogous to a beam as a function of certain of its dimensions, and stated the relationship for stress and deflection but without derivations or supporting test data. Timoshenko[5] has evaluated the equivalent column characteristics of a helical spring as an axially loaded member for purposes of determining its stability.

Nomenclature

The nomenclature used in this paper is as follows:

- h = height of helix
- ϕ = slope of end coil
- D = diameter of helix
- R = radius of helix
- d = bar diameter
- P = axial loading
- L = transverse loading
- M_0 = end moment on coil
- n = effective number of coils = $\left(\frac{\text{solid spring height}}{d} - 1\right)$
- f = pitch of helix = (h/n)
- θ = angular coordinate of any point on the helix
- M_t = torsional moment on any cross section of the bar
- J = polar moment of inertia of this section
- τ_t = shear stress on this section due to M_t
- M_x = bending moment on this section about the axis perpendicular to the axis of the helix
- I_x = moment of inertia about this axis
- σ_x = bending stress on this section due to M_x
- M_y = bending moment on this section about the axis parallel to the axis of the helix
- I_y = moment of inertia about this axis
- σ_y = bending stress on this section due to M_y
- S_x = shear load on this section perpendicular to axis of helix
- S_y = shear load on this section parallel to axis of helix
- Q = axial load on this section
- τ = shear stress
- E = modulus of elasticity in tension and compression
- G = modulus of elasticity in torsion
- Δ = vertical deflection of coil
- δ = transverse deflection of coil
- V = total strain energy
- C_v = vertical spring constant
- C_l = transverse spring constant

Deflection

Any analysis covering the exact deflection of a helical spring necessarily involves consideration of that portion of the deflection introduced by the end coils. Such an analysis introduces complex quantities, and for simplification only that portion of the helix will be considered which involves the full bar diameter.

Consider a helical spring with initially parallel ends supported on a rigid foundation, as shown in Fig. 1*a*. Assume the helix to extend along the center line of the bar from the first full diameter of the bar on one end to the corresponding point on the other end. This gives a helix height equal to the full distance

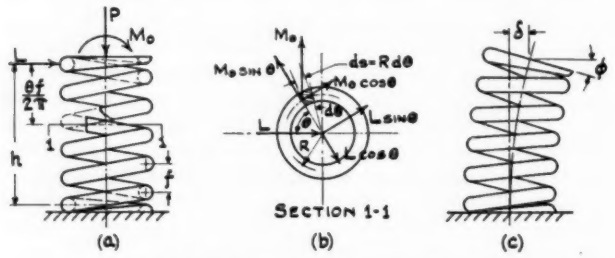

Fig. 1 Helical Spring With Initially Parallel End Supported on a Rigid Foundation

between coil ends less one bar diameter. Therefore, the number of turns in the helix n will be one less than the solid spring height divided by the bar diameter. Assume the spring to be initially loaded axially with P and consider the effect of superimposing a lateral load L and a moment M_0. Let L intersect the helix axis and lie in a horizontal plane containing the highest point on the helix. Let the transverse end couple M_0 have its vector perpendicular to the plane containing the helix axis and L. Since L is independent of P, only the deflections due to L and M_0 will be considered. The transverse deflection resulting from the application of P will be considered in the Appendix. The helix is developed by the continuous function $R\theta$ and the pitch f. The origin of θ will be taken at its coincidence with L.

The general equation for the strain energy[6] is expressed as

$$V = \frac{1}{2}\int_0^s \left(\frac{M_x^2}{EI_x} + \frac{M_y^2}{EI_y} + \frac{M_t^2}{GJ} + \frac{KS_y^2}{AG} + \frac{KS_x^2}{AG} + \frac{Q^2}{AE}\right) ds \quad \ldots\ldots [1]$$

This form of strain-energy equation neglects the effect due to curvature, but is sufficiently accurate for a first approximation.

In order to maintain the linear relationships required by the Castigliano theorem the influence of the couple $P\delta$ due to deflection is also disregarded. Since the strain energy of direct shear and compression is relatively small, only that portion of the energy equation dealing with bending and torsion will be considered. The slope and deflection may be expressed by

$$\delta = \frac{\partial V}{\partial L} \quad \text{and} \quad \phi = \frac{\partial V}{\partial M_0}$$

Hence, from Equation [1]

$$\delta = \int_0^s \left(\frac{M_x}{EI_x}\frac{\partial M_x}{\partial L} + \frac{M_y}{EI_y}\frac{\partial M_y}{\partial L} + \frac{M_t}{GJ}\frac{\partial M_t}{\partial L}\right) ds \quad \ldots. [2]$$

$$\phi = \int_0^s \left(\frac{M_x}{EI_x}\frac{\partial M_x}{\partial M_0} + \frac{M_y}{EI_y}\frac{\partial M_y}{\partial M_0} + \frac{M_t}{GJ}\frac{\partial M_t}{\partial M_0}\right) ds \ldots\ldots [3]$$

[6] "Strength of Materials," by S. Timoshenko, D. Van Nostrand Co., Inc., New York, N. Y., 1930, pp. 318–336.

For closely coiled springs, the pitch angle is small, and with sufficient accuracy, the reactions due to L and M_0 on any section with coordinate θ may be designated as follows:

1 A bending moment M_x in the vertical plane

$$M_x = L\frac{\theta f}{2\pi}\sin\theta + M_0\sin\theta \ldots\ldots [4a]$$

2 A bending moment M_y in the horizontal plane

$$M_y = LR\sin\theta \ldots\ldots [4b]$$

3 A torsional moment M_t

$$M_t = L\frac{\theta f}{2\pi}\cos\theta + M_0\cos\theta \ldots\ldots [4c]$$

In addition, there are the following reactions which have been disregarded as influencing deflections:

A direct horizontal shear

$$S_x = L\cos\theta \ldots\ldots [4d]$$

A direct compressive load

$$Q = L\sin\theta \ldots\ldots [4e]$$

The partial derivatives of Equations [4*a*], [4*b*], and [4*c*] with respect to L and M_0 are

$$\frac{\partial M_x}{\partial L} = \frac{\theta f}{2\pi}\sin\theta; \quad \frac{\partial M_y}{\partial L} = R\sin\theta; \quad \frac{\partial M_t}{\partial L} = \frac{\theta f}{2\pi}\cos\theta;$$

$$\frac{\partial M_x}{\partial M_0} = \sin\theta; \quad \frac{\partial M_y}{\partial M_0} = 0; \quad \frac{\partial M_t}{\partial M_0} = \cos\theta$$

Since $ds = Rd\theta$, Equations [2] and [3], with n = number of turns and $s = 2\pi nR$, become

$$\delta = \int_0^{2\pi n}\left(\frac{Lf^2}{4\pi^2 EI_x}\theta^2\sin^2\theta + \frac{M_0 f}{2\pi EI_x}\theta\sin^2\theta + \frac{LR^2}{EI_y}\sin^2\theta + \frac{Lf^2}{4\pi^2 GJ}\theta^2\cos^2\theta + \frac{M_0 f}{2\pi GJ}\theta\cos^2\theta\right) Rd\theta \ldots\ldots [4]$$

$$\phi = \int_0^{2\pi n}\left(\frac{Lf}{2\pi EI_x}\theta\sin^2\theta + \frac{M_0}{EI_x}\sin^2\theta + \frac{Lf}{2\pi GJ}\theta\cos^2\theta + \frac{M_0}{GJ}\cos^2\theta\right) Rd\theta \ldots\ldots [5]$$

The integration of Equations [4] and [5] with simplifying approximations, is shown in the appendix.

Hence with $f = (h/n)$

$$\delta = Rh\pi n\left(\frac{Lh}{3} + \frac{M_0}{2}\right)\left(\frac{1}{EI_x} + \frac{1}{GJ}\right) + \frac{LR^3\pi n}{EI_y} \ldots. [6]$$

$$\phi = R\pi n\left(\frac{Lh}{2} + M_0\right)\left(\frac{1}{EI_x} + \frac{1}{GJ}\right) \ldots\ldots [7]$$

Expressing M_0 in terms of ϕ and L from Equation [7], and substituting in Equation [6], the deflection is

$$\delta = \frac{LRh^2\pi n}{12}\left(\frac{1}{GJ} + \frac{1}{EI_x}\right) + \frac{LR^3\pi n}{EI_y} + \frac{\phi h}{2} \ldots\ldots [8]$$

In the case where the ends of the spring remain parallel after deflection ($\phi = 0$), and noting that from symmetry $M_0 = -Lh/2$, both Equations [6] and [8] become

$$\delta = \frac{LRh^2\pi n}{12}\left(\frac{1}{GJ} + \frac{1}{EI_x}\right) + \frac{LR^3\pi n}{EI_y} \ldots\ldots [9]$$

For a round bar steel spring with $E = 29{,}500{,}000$ lb per sq in., and $G = 11{,}500{,}000$ lb per sq in., the general Equations [6] and [8] for the lateral deflection become

$$\delta = \frac{Dn}{10^6 d^4}(0.825h^2L + 1.238M_0h + 0.271D^2L) \quad [10]$$

and

$$\delta = \frac{LDn}{10^6 d^4}(0.271D^2 + 0.206h^2) + \frac{\phi h}{2} \quad [11]$$

and for a spring whose ends remain parallel after deflection

$$\delta = \frac{LDn}{10^6 d^4}(0.271D^2 + 0.206h^2) \quad [12]$$

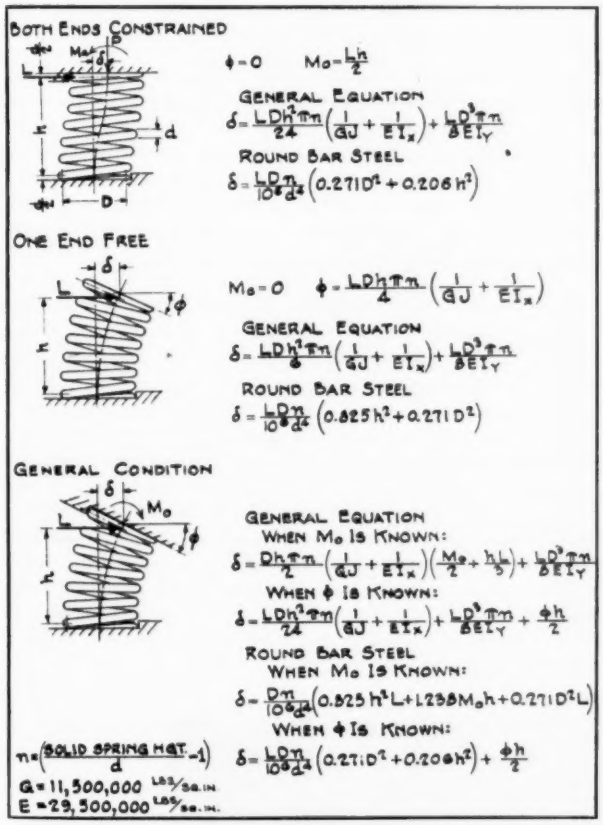

FIG. 2 TRANSVERSE-DEFLECTION FORMULAS FOR CLOSELY COILED HELICAL SPRINGS

The transverse-deflection formulas are shown with illustrative diagrams in Fig. 2.

STRESSES

The maximum stresses imposed by the loading described previously will now be discussed. As in the case of the deflections, the small influence of the helix angle has been neglected. The maximum shear stress under axial loading, including Wahl's[7] concentration factor, is given by the formula

$$\tau = \frac{16PR}{\pi d^3}\left(\frac{4c-1}{4c-4} + \frac{0.615}{c}\right) \quad [13]$$

where $c = D/d$.

[7] "Stresses in Heavy Closely Coiled Helical Springs," by A. M. Wahl, Trans. A.S.M.E., vol. 51, 1929, paper APM-51-17, pp. 185–200.

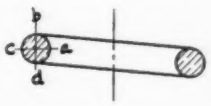

FIG. 3

This stress occurs on the inside of the coil as shown at a in Fig. 3, and is constant for all values of θ. The portion $\frac{16PR}{\pi d^3}\left(\frac{0.615}{c}\right)$ is due to direct shear P and will not be affected by the transverse loading. The remainder, $\frac{16PR}{\pi d^3}\left(\frac{4c-1}{4c-4}\right)$ is due to the torque PR and will be increased by any augment in the torque due to L and M_0. The expression for torque, that is Equation [4c], with the addition of PR is

$$M_t = \left(\frac{L\theta f}{2\pi} + M_0\right)\cos\theta + PR \quad [14]$$

It is obviously a maximum when the expression $[(L\theta f/2\pi) + M_0]$ is a maximum and $\cos\theta = \pm 1$. Also $[(L\theta f/2\pi) + M_0]$ will be maximum when θ is either 0 or a maximum, depending on the relative values and signs of L and M_0.

Thus, the maximum shear stress will occur on the inside of the coil in the plane containing L and P, shown in Fig. 1. Its magnitude will be

$$\tau = \left[\left(\frac{L\theta f}{2\pi} + M_0\right)_{\max} + PR\right]\frac{16}{\pi d^3}\left(\frac{4c-1}{4c-4}\right) + \frac{16PR}{\pi d^3}\left(\frac{0.615}{c}\right) \quad [15]$$

Disregarding the direct horizontal shear and compressive load due to L given by Equations [4d] and [4e], there remain the bending stresses due to M_x and M_y. An examination of the expressions for these moments shows every term to contain $\sin\theta$ and they are accordingly zero for the points already investigated. The moments M_x and M_y attain their maximum values when $\sin\theta = \pm 1$, i.e., at that section of the coil intersected by a plane which includes the axis of the helix and lies at right angles to (the direction of) L.

Thus, $M_x = [(L\theta f/2\pi) + M_0]\sin\theta$ and reaches a maximum value a quarter turn from the maximum for M_t. The moment $M_y = LR\sin\theta$ and is likewise a maximum twice every turn. Where M_x and M_y are maximum, M_t has the value of PR.

The maximum stress due to M_x occurs at the extreme fibers of the bar section at points b and d shown in Fig. 3. At these points the torsional and bending stresses are not increased by any stress concentration.

Therefore, at b the stresses will be

$$\tau_t = \frac{16PR}{\pi d^3} \quad [16]$$

$$\sigma_x = \frac{32[(L\theta f/2\pi) + M_0]}{\pi d^3} \quad [17]$$

The maximum principal stress

$$\sigma_{\max} = \frac{16}{\pi d^3}\left[\left(\frac{L\theta f}{2\pi} + M_0\right) + \sqrt{(PR)^2 + \left(\frac{L\theta f}{2\pi} + M_0\right)^2}\right] \quad [18]$$

and the maximum shear stress

$$\tau_{\max} = \frac{16}{\pi d^3}\sqrt{(PR)^2 + \left(\frac{L\theta f}{2\pi} + M_0\right)^2} \quad [19]$$

The maximum stress due to M_y occurs at the inside of the bar at a shown in Fig. 3, where it combines with a torsional shear.

At a, the stresses will be

$$\tau = \frac{16PRk}{\pi d^3} \quad [20]$$

where $k = \left(\frac{4c-1}{4c-4} + \frac{0.615}{c}\right)$, and

$$\sigma_y = \frac{32LRq}{\pi d^3} \quad [21]$$

From the curved-beam theory, $q = (4c-1)/(4c-4)$. The maximum principal stress

$$\sigma_{max} = \frac{16}{\pi d^3}\left[LRq + \sqrt{(PRk)^2 + (LRq)^2}\right] \quad [22]$$

and the maximum shear stress

$$\tau_{max} = \frac{16}{\pi d^3}\sqrt{(PRk)^2 + (LRq)^2} \quad [23]$$

In general it will be found for springs of normal proportions, that the maximum shear stress will be more critical than the maximum direct stress. Therefore, the critical stress will occur on the inside of the coil where M_t is a maximum at which point it will have the value

$$\tau = \left[\left(\frac{L\theta f}{2\pi} + M_0\right)_{max} + PR\right]\frac{16}{\pi d^3}\left(\frac{4c-1}{4c-4}\right) + \frac{16PR}{\pi d^3}\left(\frac{0.615}{c}\right) \quad [15]$$

It will be noted that the maximum moment occurs on the end coil. Obviously, if this coil were tapered, the maximum moment would occur on a reduced section and some provision may be necessary for its protection.

Discussion of Other Contributing Factors

As previously mentioned, Timoshenko[6] has discussed the stability of helical springs under axial loading. It is obvious that the addition of a transverse load will decrease the axial critical load. A complete investigation and discussion of stability was considered to be beyond the scope of this paper.

TABLE 1 CHARACTERISTICS OF SPRINGS TESTED

10	0.752	0.123	2.801	1.455	96	6.12

The precise equation, including the effect of the helix angle, expressing a relationship for transverse deflection is shown in the Appendix. Numerical calculations on two springs, whose helix angle was approximately 5 deg, indicated an error of less than 0.5 per cent.

Description of Test Procedure

In order to demonstrate the validity of the foregoing formulas, tests were conducted on several sets of helical springs to determine the transverse-load-deflection rates. While the original tests were conducted on large springs of the railway type, the procedure was cumbersome due to the magnitude of the vertical loads required. Accordingly, to facilitate experimental work, subsequent tests were conducted on small springs, accurately coiled and with the ends ground. These springs were furnished by the Railway Steel Spring Company.

The pertinent characteristics of all springs tested for lateral deflection properties in conjunction with this paper are shown in Table 1. It will be noted that the experimental springs covered a wide range of ratios of height to diameter, and the spring indexes varied from 4.5 to 6. The experimental apparatus was essentially the same for both the large and small coils, employing in each case four identical helical springs with ground ends seated at the four corners of a rectangular base plate and surmounted by a similar plate on which the vertical load was placed. The assembled coils were then loaded transversely by a turnbuckle and tension rod in series with a load-measuring device lying in a horizontal plane and affixed, one end to a rigid foundation and the other to some point on the top plate according to whether pure translation or combined translation and rotation was to be applied to the top plate.

Fig. 4 Apparatus Used for Testing High-Capacity Springs

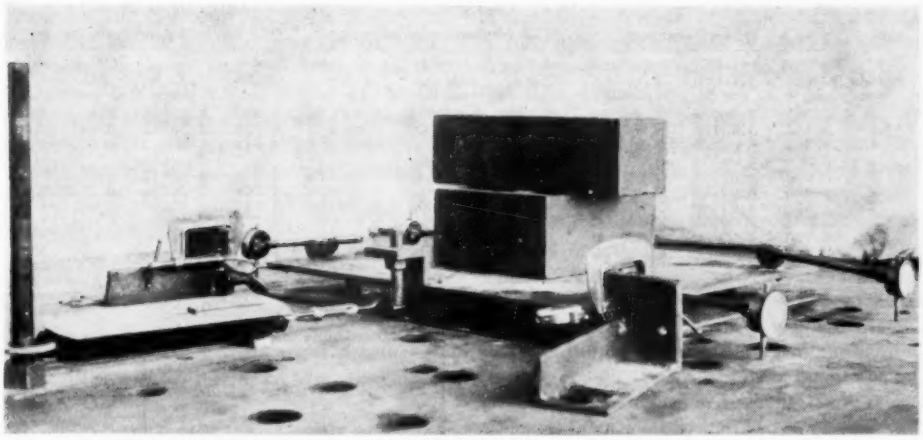

FIG. 5 APPARATUS FOR TESTING SMALL SPRINGS

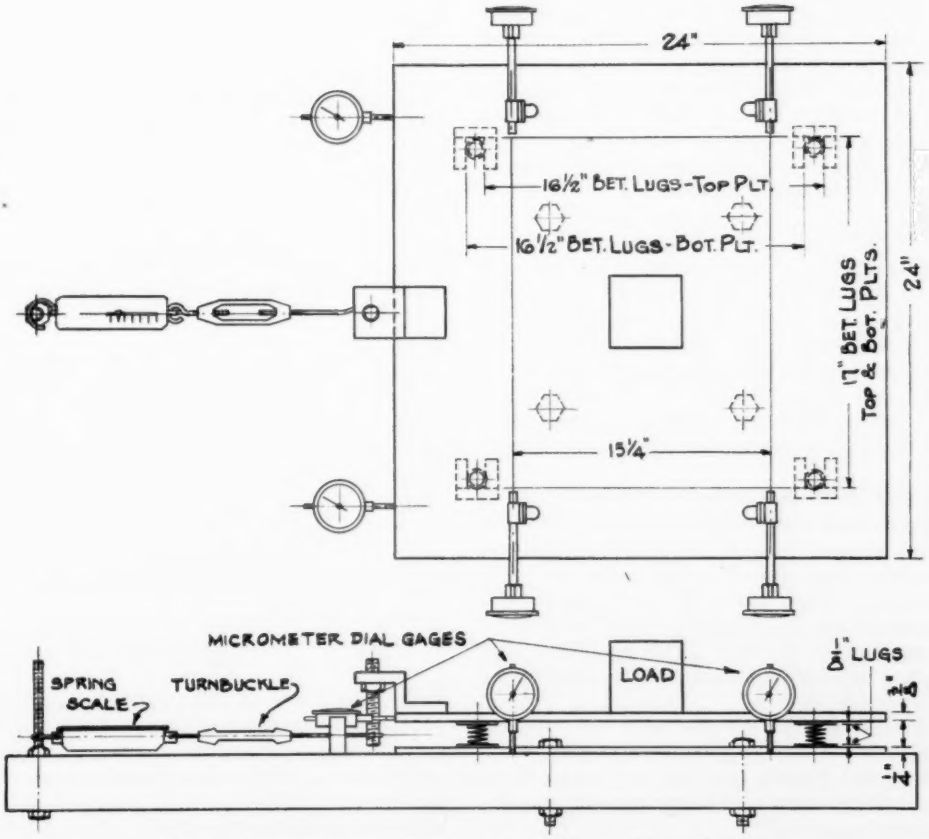

FIG. 6 ARRANGEMENT OF APPARATUS FOR TESTING SMALL SPRINGS

In the case of the large testing apparatus, which is shown in Fig. 4 the springs were retained at both extremities by set bolts tapped in an annular ring welded to each plate around the spring seat and abutting the end coil at the quarter-circle points. A slotted lug was provided at the midpoint of the underside of the top plate, which afforded an opportunity for varying the height of transverse-load application.

As shown in Figs. 5 and 6, the small springs were retained in their position by cleats of the same thickness as the bar diameter of the spring; the cleats were welded to the plates on such a side of the coil as to prevent horizontal movement of the ends under transverse loading. An auxiliary cleat was welded at right angles to this, thus forming an angle which thereby nested the end coil on two points of its circumference. An adjustable threaded rod affixed to the front edge of the top plate, in this case, provided a means of varying the height of transverse load application.

On both apparatus the amount of transverse load was determined by mounting a calibrated ring gage or accurate spring scale, according to the magnitude of the loads, in tandem with the turnbuckle. Micrometer dials or, wherever necessary, surface gages, were used to observe all necessary deflections. Lateral deflections were taken on either side of the center line of the

top plate to insure an average value of this reading, while vertical deflections were taken at the four corners of the assembly to determine the change in spring heights between the front and rear sets of springs under rotational loading.

All springs were tested for transverse deflections under gravity loadings of about 25, 50, and 75 per cent of their axial capacity, except in those few cases where the instability of the coil prevented it. Springs Nos. 1, 2, and 3 were transversely loaded at the level of the top plate. It was then recognized that the slope ϕ contributed an appreciable increment to the deflection. Therefore, springs Nos. 4 to 10, inclusive, were loaded at the height of the point of contraflexure of the springs for the purpose of eliminating the end slope. Sufficient increments of transverse load were applied to establish the true rate of transverse deflection, although for obvious reasons the loading was not pursued to the point of instability of the spring. Upon release of the lateral load, no appreciable lag was observed.

Discussion of Test Results

Examination of the results, as shown in Table 2 indicates good agreement between the actual and the calculated values for a majority of the springs tested. However, a discrepancy exists in the case of certain springs. The approximations occurring in the formula are discussed elsewhere in this paper, together with their effect on the exact evaluation of δ. It will suffice at this point to consider wherein the actual conditions of testing depart from the original assumptions, and to what degree they influence the results obtained.

In order to simulate the general method of a helical-spring installation involving no rigid attachment of the end coils to their base, the testing arrangement made no provision for a constraining moment other than that offered by the loaded plate. In addition, the transverse loading was applied at whatever point of tangency happened to be established between the end coil and the restraining cleat (or set bolt). This procedure, while duplicating practical application, upset certain premises on which the theory was established.

(*a*) The end moment M_0 acted not only upon that portion of the spring contained in the helix proper, but also over the diminishing section of the tapered end coil, thus producing a finite deflection for this portion of the spring which was disregarded in the general equation.

(*b*) Likewise, the transverse loading L, unless the spring possessed exactly n plus $1/2$ coils (where n is a whole number) acted at a point within the tapered region of the end coil, and thereby added its component of transverse deflection in excess of the calculated value.

The magnitude of the error in the calculated value as the axial loading progressed from 25 to 75 per cent capacity was increased or decreased according to which of two effects was prevalent. (1) When the spring was well within the limits of stability under load, the decrease in M_0 as the working height diminished meant a corresponding decrease in its distorting effect on the end coil as just described in paragraph (*a*). (2) If the spring approached an unstable condition as the gravity load increased,

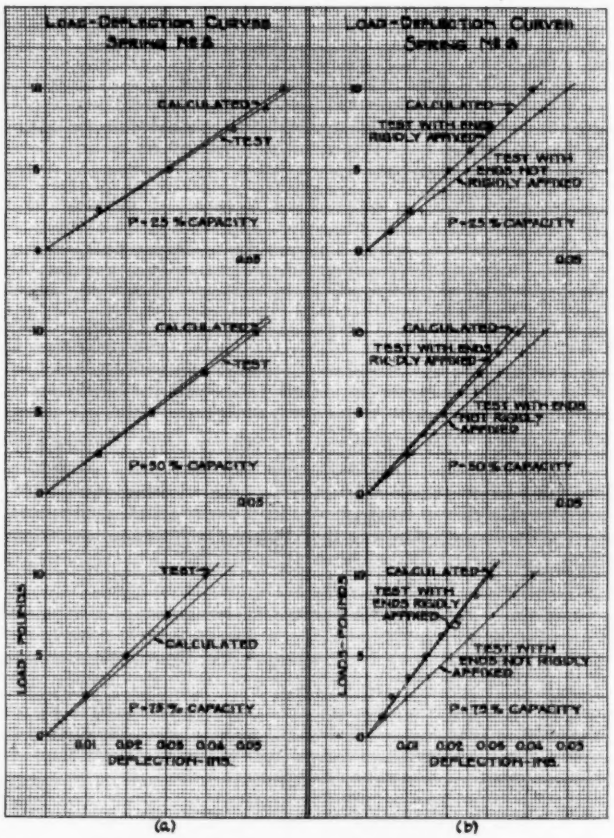

Fig. 7 Transverse-Deflection Characteristics of Two Representative Springs

a given transverse loading produced a greater deflection than would occur for the same transverse loading in combination with a smaller axial-load application.

The actual transverse-deflection characteristics of a representative spring (i.e., spring no. 8) is shown in Fig. 7*a* with the calculated curve for the extent of the test. Similar characteristics for spring No. 6 is shown in Fig. 7*b*. This latter spring was subsequently affixed rigidly to steel base plates at its extreme coil faces and almost perfect agreement with the calculated values was obtained. Examination of the actual plotted points in Figs. 7*a* and 7*b* indicates that there is no measurable deviation from the straight line. This apparently indicates that the omission of the influence of the couple $P\delta$ is justified.

Conclusions

A plot of the ratio of actual to calculated deflection versus the ratio of working height to the mean diameter D, on the basis of the actual tests, is shown in Fig. 8.

As previously noted, the springs were chosen to give a wide

variation of the latter ratio in order to establish the range of application of these formulas. It appears from the results of these tests that the equations may be used with reasonable accuracy when this ratio is less than 1.5. For the majority of engineering applications of compression springs subjected to transverse loadings, this ratio will not be exceeded. With springs in excess of this ratio there is the possible danger of approaching the limit of stability.

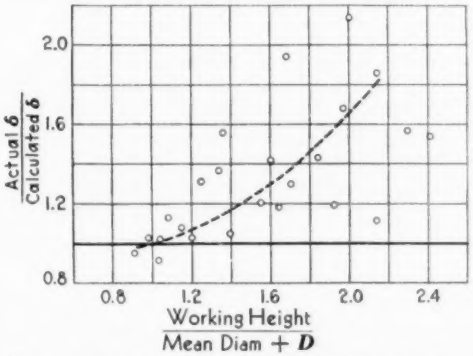

FIG. 8 RATIO OF ACTUAL TRANSVERSE DEFLECTION TO CALCULATED TRANSVERSE DEFLECTION VERSUS THE RATIO OF WORKING HEIGHT TO MEAN DIAMETER OF SPRINGS

The extent to which the instability and end-coil conditions weaken the validity of the expressions, can only be qualitatively appraised at this time.

Since the scope of this paper was to establish the expression for lateral deflection within the stable limits and did not consider the influence of the end coil, it is hoped that this research effort will furnish the impetus for further investigation into the subject.

Appendix

The integrals involved in Equations [4] and [5] are as follows:

$$\int_0^{2\pi n} \theta^2 \sin^2\theta d\theta = \left[\frac{\theta^3}{6} - \frac{\theta^2}{4}\sin 2\theta - \frac{\theta}{4}\cos 2\theta + \frac{1}{8}\sin 2\theta\right]_0^{2\pi n} \approx \frac{4\pi^3 n^3}{3} \quad [24a]$$

$$\int_0^{2\pi n} \theta \sin^2\theta d\theta = \left[\frac{\theta^2}{4} - \frac{\theta}{4}\sin 2\theta - \frac{1}{8}\cos 2\theta\right]_0^{2\pi n} \approx \pi^2 n^2 \quad [24b]$$

$$\int_0^{2\pi n} \sin^2\theta d\theta = \left[\frac{\theta}{2} - \frac{1}{4}\sin 2\theta\right]_0^{2\pi n} \approx \pi n \quad [24c]$$

$$\int_0^{2\pi n} \theta^2 \cos^2\theta d\theta = \left[\frac{\theta^3}{6} + \frac{\theta^2}{4}\sin 2\theta + \frac{\theta}{4}\cos 2\theta - \frac{1}{8}\sin 2\theta\right]_0^{2\pi n} \approx \frac{4\pi^3 n^3}{3} \quad [24d]$$

$$\int_0^{2\pi n} \theta \cos^2\theta d\theta = \left[\frac{\theta^2}{4} + \frac{\theta}{4}\sin 2\theta + \frac{1}{8}\cos 2\theta\right]_0^{2\pi n} \approx \pi^2 n^2 \quad [24e]$$

$$\int_0^{2\pi n} \cos^2\theta d\theta = \left[\frac{\theta}{2} + \frac{1}{4}\sin 2\theta\right]_0^{2\pi n} \approx \pi n \quad [24f]$$

In evaluating the foregoing integrals, only the first terms in the brackets have been retained. It will be seen that the balance of the terms diminish rapidly from the first and the evaluation of their maxima was found to affect the calculated deflection less than 1 per cent with n between 3 and 4. With larger values of n the error decreases.

The foregoing analysis deals only with the deflection and slope, resulting from the application of a lateral force and end couple, to a spring initially loaded with an axial force. It is to be noted that the axial force itself may produce a lateral deflection and slope, and by the reciprocal theorem the lateral force and moment may produce a vertical deflection. The following investigation will disclose this effect.

Referring to Fig. 1, let P, only, act on the spring, and apply a dummy load $L = 0$. The only coupling between the two, neglecting the helix angle, lies in the moment M_t, or

$$M_t = PR + \frac{L\theta f}{2\pi}\cos\theta \quad \text{and} \quad \frac{dM_t}{dL} = \frac{\theta f}{2\pi}\cos\theta$$

Hence

$$\delta_P = \int_0^{2\pi n} \frac{PR^2 f}{2\pi GJ}\theta\cos\theta d\theta$$

$$\delta_P = \frac{PR^2 h}{2\pi GJn}\left[2\pi n \sin 2\pi n + \cos 2\pi n - 1\right] \quad [25]$$

It will be seen that when n is a whole number the value of the bracket (and hence the deflection) is zero. At other values of n the deflection is expressed as follows:

n = whole number plus:	δ_p equals:
1/4 turn	$\frac{PR^2h}{GJ}\left(1 - \frac{1}{2\pi n}\right)$
1/2 turn	$-\frac{PR^2h}{GJ}\left(\frac{1}{\pi n}\right)$
3/4 turn	$-\frac{PR^2h}{GJ}\left(1 + \frac{1}{2\pi n}\right)$

To determine the end slope induced by P, the dummy moment $M_0 = 0$ may be applied, from which it will be found that

$$\phi_{Pe} = \frac{PR^2}{GJ}\sin 2\pi n \quad [26]$$

Similarly the vertical deflection induced by the application of L and M_0 will be found to be

$$\Delta_L = \frac{LR^2 h}{2\pi GJn}\left[2\pi n \sin 2\pi n + \cos 2\pi n - 1\right] \quad [27]$$

$$\Delta_{M_0} = \frac{M_0 R^2}{GJ}\sin 2\pi n \quad [28]$$

An evaluation of these reciprocal relationships involves an end-coil analysis to disclose the total effective number of turns so that the equations of the form $(An \sin Bn)$ and $(An \cos Bn)$ may be determined accurately. This is also true for a precise evaluation of the sinusoidal terms in Equations [24a] to [24f], inclusive. Such an analysis lies beyond the scope of this paper.

It is sufficient, however, to point out that with multiple-spring suspensions, it is possible to dispose the various coils so that their lateral deflection components may counteract.

The point has been raised regarding the lateral deflection under the action of axial loading, inasmuch as it indicates a field of profitable investigation in its bearing on the stable limits of spring loading.

The derivation of the transverse deflection in the body of the paper disregarded the helix angle. Including the effect of the helix angle [$\alpha = \tan^{-1}(f/\pi d)$] gives the following moments:

$$M_x = L\frac{\theta f}{2\pi}\sin\theta + M_0\sin\theta$$

$$M_y = \left(L\frac{\theta f}{2\pi}\cos\theta + M_0\cos\theta\right)\sin\alpha + LR\sin\theta\cos\alpha$$

and

$$M_t = \left(L\frac{\theta f}{2\pi}\cos\theta + M_0\cos\theta\right)\cos\alpha - LR\sin\theta\sin\alpha$$

Also

$$ds = \frac{Rd\theta}{\cos\alpha}$$

By rewriting Equations [4] and [5] and proceeding as in the previous case, the more exact expression for Equation [9] becomes

$$\delta = \frac{LRh^2\pi n}{12}\left(\frac{\cos\alpha}{GJ} + \frac{1}{EI_x\cos\alpha}\right) + \frac{LR^3\pi n}{EI_y}\cos\alpha - \frac{LR^2h}{2}\left(\frac{1}{GJ} + \frac{1}{EI_y}\right)\sin\alpha \quad [29]$$

for the deflection of a spring whose ends remain parallel.

ACKNOWLEDGMENTS

The authors acknowledge the cooperation of the following men:

R. Ebenbach, of the E. G. Budd Manufacturing Company, who assisted in conducting the tests.

E. G. Hallquist, vice-president of General Steel Castings Corporation, who placed the facilities of this plant at the authors' disposal for conducting the tests on the large springs.

E. Schmidt, of the E. G. Budd Manufacturing Company, who made possible the tests on the small springs. The latter were furnished through the kindness of T. R. Weber, Railway Steel Spring Division, American Locomotive Company.

The authors are grateful to R. Eksergian, of the E. G. Budd Manufacturing Company, for his personal assistance and contributions in the preparation of this paper.

Discussion

E. T. P. NEUBAUER.[8] In this paper valuable data are presented on the problem of spring mountings for the isolation of machinery vibration. In order effectively to isolate the vibration of heavy machinery it is necessary to have the critical or resonance frequency of all the various degrees of freedom well below the operating frequency of the machine. This requires a knowledge of the transverse deflection of springs as well as the longitudinal.

A. M. WAHL.[9] The authors have contributed interesting test data which, in conjunction with the analytical work, should be of considerable interest to spring designers.

The writer notes that in deriving the formula for lateral deflection, as mentioned in the paper, the authors have neglected the effect on the axial load. This would be in such a direction as to increase the deflection above the calculated value using the formulas given. Since most of the test deflections were higher than the calculated (in some cases twice as high), it is suggested that a part at least of the discrepancy between calculated and test deflections may be accounted for by the fact that this effect was neglected.

A formula to take into account the increased lateral deflection due to presence of an axial load on a spring laterally loaded (with both ends constrained) has been derived by E. Rausch.[10] This lateral deflection is

$$\delta_{max} = \alpha\delta_n$$

where δ_n = nominal deflection, figured by neglecting the axial load (this is given by Equation [12] of the paper, which agrees with the formula derived previously by Rausch).

The term α is a factor greater than unity which takes into account the increased deflection due to the axial load

$$\alpha = \frac{1 - \dfrac{\frac{\delta_1}{h}}{\left(2.6 + \frac{\delta_1}{h}\right)\left(1 + 0.77\frac{h^2}{D^2}\right)}}{1 - \dfrac{\delta_1}{2.6\,h}\left(1 + K\dfrac{h^2}{D^2} - \dfrac{\frac{\delta_1}{h}}{2.6 + \frac{\delta_1}{h}}\right)} \quad [30]$$

where

$$K = \frac{0.83 + 0.77\frac{h^2}{D^2}}{1 + 0.77\frac{h^2}{D^2}} \times 0.93$$

where

δ_1 = deflection under the axial load
h = working height of spring
D = mean diameter

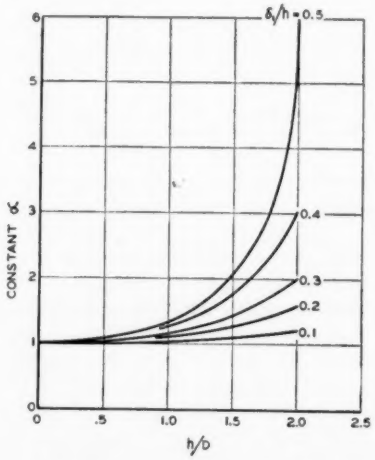

FIG. 9 CURVE FOR FINDING α

Curves given by Rausch for the application of this formula indicate that, where the ratio of working height h to mean diameter D is between 1 and 2, the factor α may be as high as 3,

[8] Machine Designer, York Ice Machinery Corp., York, Pa. Jun. A.S.M.E.

[9] Research Engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. Mem. A.S.M.E.

[10] "Die Steifigkeit von Schraubenfedern senkrecht zur Federachse," by E. Rausch, *Zeit. V.D.I.*, vol. 78, Aug. 11, 1934, p. 964.

where the axial deflection δ_1 due to the axial load is around 40 per cent of the working height. This effect decreases as the axial load decreases. The constant, α, is plotted in Fig. 9 (given by Rausch) for various ratios of δ_1/h (for ease in calculation). Of course, as indicated by the authors, the question of stability must also be considered.

It would be of interest if this formula could be applied to the springs tested by the authors to see whether or not better agreement could be had between test and calculated results.

Authors' Closure

The authors wish to thank Mr. Wahl for calling their attention to the paper by Professor Rausch, which was overlooked in preparation of this paper. Professor Rausch's original abstract[11] is quite complete and the authors are gratified to note that his formula based on both ends constrained parallel agrees with Equation [12], although obtained through a different mathematical approach.

Equation [30] for the correction factor α was given by Professor Rausch in collaboration with Dr. A. Röver and appeared in a supplement[10] to the original paper. However, there was no proof or derivation given and the authors were therefore unable to check it. For this reason the authors thought it advisable to derive a correction factor which was based on the properties of a column.

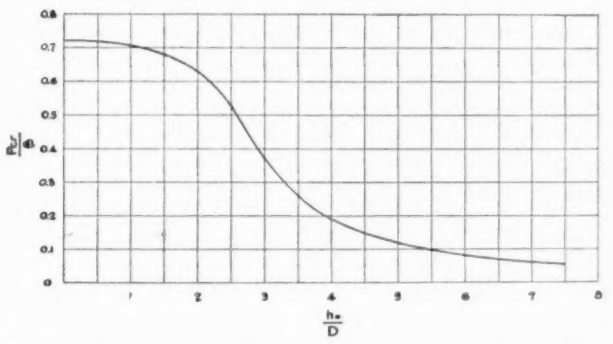

Fig. 10 Curve Showing Ratio of Critical Load to Compressive Rigidity Versus Ratio of Free-Spring Height to Mean Diameter

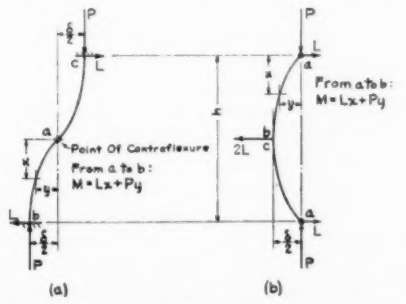

Fig. 11 Showing Similarity Between Column With Ends Constrained Parallel and Pin-Ended Column

It is true that the axial load influences the transverse deflection of the spring. The magnitude of this influence depends on the ratio of the imposed axial load to the critical load at which buckling of the spring occurs (without regard to transverse forces).

The buckling resistance of helical springs has been reviewed by Dr. Timoshenko.[5] For pin-ended connections the critical axial load may be obtained from the curve shown in Fig. 10 which is reproduced from Timoshenko's review,[5] using the values of G and E given previously in this paper. The compressive rigidity β may be found from

$$\beta = \frac{GIh_0}{\pi n R^3} = C_v h_0 \quad [31]$$

where h_0 = free spring height of helix.

From Fig. 11 it will be noted that the deflection curve of a column with parallel ends free to move laterally satisfies the conditions for a pin-ended column, since the bending moment acting on each half of the column (a) is duplicated on each half of the curve (b). It will be recognized that the curve, Fig. 11(a) represents the axis of the deflected spring.

The deflection for a pin-ended column, Fig. 11(b), transversely loaded at the center line has been derived by Dr. Timoshenko[12] and is expressed as

$$\delta = \delta_0 \lambda \quad [32]$$

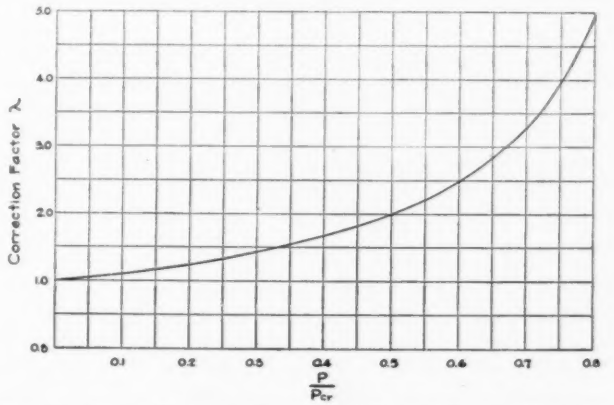

Fig. 12 Curve Showing Correction Factor Versus Ratio of Axial Load to Critical Load

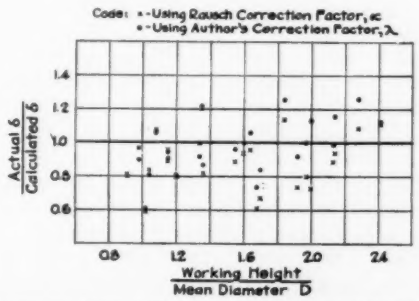

Fig. 13 Ratio of Actual Transverse Deflection to Corrected Calculated Transverse Deflection Versus Ratio of Working Height to Mean Height of Springs

where

$\lambda = \dfrac{3(\tan u - u)}{u^3}$ and δ_0 = deflection due to the transverse load acting alone.

$$u = \frac{\pi}{2}\sqrt{\frac{P}{P_{cr}}} \quad [33]$$

Fig. 12 illustrates the correction factor λ expressed as a function of $\dfrac{P}{P_{cr}}$. To find the correction factor it is only necessary to deter-

[11] "Die Steifigkeit von Schraubenfedern senkrecht zur Federachse," by E. Rausch, *Zeit. V.D.I.*, vol. 78, March 24, 1934, p. 388.

[12] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Company, Inc., New York, N. Y., 1936, p. 4.

mine the critical load P_{cr} from Fig. 10, from which the ratio $\frac{P}{P_{cr}}$ may be obtained. The correction factor may then be determined directly from Fig. 12.

Examination of Equation [9] shows that the first term represents the portion of the deflection due to the action of bending moments, while the second term represents the portion due to shear forces alone. Since only the former is affected by the column action, Equations [9] and [12] may be written with the correction factor λ as

$$\delta = \lambda \frac{LRh^2\pi n}{12}\left(\frac{1}{GJ} + \frac{1}{EI_x}\right) + \frac{LR^2\pi n}{EIy} \quad \ldots\ldots [9a]$$

$$\delta = \frac{LDn}{10^6\, d^4}(0.271D^2 + 0.206h^2\lambda) \quad \ldots\ldots [12a]$$

The authors have recalculated the deflection ratios of the experimental springs based both on the Rausch correction factor and on the factor λ obtained as just outlined. Fig. 13 illustrates the results plotted similarly to Fig. 8. It will be noted that a much better agreement is obtained when the correction factors are applied; the majority of the calculating values agreeing within 20 per cent of the actual.

A treatment of the correction factors applied to the general case of a spring the ends of which do not remain parallel is too complex to be treated here.

Studies in Boundary Lubrication

Variables Influencing the Coefficient of Static Friction Between Clean and Lubricated Metal Surfaces

By W. E. CAMPBELL,[1] SUMMIT, N. J.

A thorough survey has been made of the literature on static-friction measurement. It is shown that there are large discrepancies among the results of different investigators and it is concluded that the differences are largely due to lack of control of experimental technique. A complete bibliography is presented.

An experimental study of several of the more important variables influencing static friction is described. The variables studied are the effect of load, vibration, and cleanliness of the surfaces. An inclined-plane and a horizontal-plate apparatus are used. It is concluded that the method of cleaning the surfaces is the factor which has the greatest influence upon the results and it is shown that invisible films which may be deposited upon the surfaces during the cleaning process can exert large effects upon static-friction measurements.

A method of cleaning is described which involves polishing the surfaces with moist abrasive. This method yields high and reproducible values for static friction between unlubricated surfaces. It is shown that sulphide and oxide films on steel, copper, and brass produce a lowering in static friction and that the amount of lowering depends upon the thickness of the film.

A comparison is made between the static and the kinetic values obtained on several bearing metals lubricated with typical oils. It is shown that the static values are in general considerably higher than the kinetic values, and it is concluded that the differences which are observed are due in large part to viscosity effects in the kinetic measurements.

An analysis of static-friction measurements on typical lubricating oils leads to the conclusion that moisture and corrosion effects are responsible for many of the phenomena observed. It is concluded that static-friction measurements do not lend themselves to routine testing of oils, but that they can be used to considerable advantage for studying single variables influencing boundary lubrication.

DURING the last few years increasing attention has been given to a study of the factors which govern lubrication in the region where loads and speeds are such that the film of oil separating the rubbing surfaces is no longer continuous. Under these conditions the coefficient of friction for constant operating conditions is no longer a simple linear function of the viscosity (1).[2] The composite effect of the new variables entering into the problem when operation takes place under incomplete film or boundary conditions has been assigned the vague term "oiliness," but no really satisfactory definition has been proposed, nor has much attempt been made to study the separate variables in a quantitative manner. A comprehensive review of the results and findings of investigators of oiliness is given in a paper by Herschel (2), which includes descriptions of testing machines commonly employed. More recently a complete discussion of the subject of boundary lubrication, containing a list of the various factors which may contribute to oiliness, has been given by Hersey (3). In general the important factors may be summarized as follows:

1 The adsorptive force operating at the metal-liquid interface, which may vary with the nature of the metal and of the liquid.

2 The structure of the molecules adsorbed at the interface.

3 Solid films formed on the surface during operation, such as adsorbed graphite films, or oxide, sulphide, and chloride films formed by chemical action between lubricant and metal.

4 The structure of the bearing surfaces.

5 The increase, with increasing pressure, of the viscosity of the lubricant.

A large number of oiliness investigations have been carried out using kinetic-friction measurements, and have been concerned primarily with the development of a machine for routine rating of oils. Kinetic measurements, though they have the advantage that they may be made under conditions closely approximating those obtaining in service (28), yield results complicated by viscosity effects (26). The static-friction method, on the other hand, has the advantage of giving results which are independent of viscosity (4, 5, 10*b*). It involves the use of simple apparatus and lends itself much better to the study of very small quantities of pure compounds under controlled atmospheric conditions.

The present investigation was originally undertaken with the object of studying the effect of molecular structure on boundary lubrication, and the static-friction method appeared to be the most suitable choice for such a study. Difficulties were encountered in the early stages in reproducing the measurements of earlier workers, and reference to the literature indicated considerable discrepancies among the data of different observers using similar methods. It was therefore found necessary to make a detailed study of the variables entering into static-friction measurements, which will be described in the experimental section of this paper.

Rayleigh (6) appears to have been the first to use static-friction measurements for studying boundary lubrication effects. He estimated that the thickness of the films between the surfaces was 1000A or less, and observed that lubrication by these films could not be treated hydrodynamically. Shortly afterward Langmuir (7) showed that static friction between glass surfaces could be lowered from a value between 1.1 and 1.7 to 0.10 by a monomolecular film of a fatty acid transferred to the glass from a water surface. Deeley (4) and Hyde (8) were able to show marked differences between lubricating oils which correlated with their efficiencies as judged by practical experience, and by the Lanchester worm-gear testing machine. Hardy and his collaborators (10) have carried out studies of a high degree of accuracy on a large number of pure organic compounds, and have obtained ex-

TABLE 1 VARIABILITY OF RESULTS OBTAINED BY DIFFERENT OBSERVERS FOR THE COEFFICIENT OF STATIC FRICTION BETWEEN METAL SURFACES

Observer	Brass-brass, μ	Steel-steel, μ
Rennie (14)	0.175	0.146
Jacob (15)	0.07	..
Hardy (10)	..	0.82
Tomlinson (16)	0.63	0.41
Deeley (4)	..	0.17

ceedingly reproducible results which indicate relations of astonishing simplicity between coefficient of friction and molecular weight for members of a given homologous series. Woog (11), Wilharm (12), Wilson and Barnard (5), and more recently Rhodes and his coworkers (13), have demonstrated the value of static-friction measurements between lubricated surfaces for the analysis of oiliness phenomena.

It is to be expected that the measurement of a property such as static friction, which is controlled largely by interfacial forces, would be profoundly influenced by very small variations in the state of the surfaces. A study of the literature bears this out, and indicates that the attainment of reproducible and significant static-friction measurements requires the development of an elaborate and time-consuming experimental technique. There is considerable difference of opinion, however, regarding the extent of control necessary for any given experimental variable, such as preparation of surface, control of temperature, and purity of atmosphere.

Some idea of the spread of comparable data in the literature can be seen from Table 1, in which are given results for dry static friction between similar metal combinations obtained by several independent workers.

The lack of agreement is probably due in large measure to the presence of different amounts of grease or other films on the surfaces. That Deeley's surfaces were contaminated is indicated by the fact that the friction rose when the surfaces were breathed upon, an effect of moisture on friction which is characteristic of greasy surfaces, but which Hardy (10*a*), and the present author have found to be absent for clean surfaces. Deeley also gives figures showing a continuous drop in friction coefficient with load for clean plane surfaces, which is contrary to the law of solid friction, but which is in agreement with results obtained by Hardy and Bircumshaw (10*h*) for thin invisible films of lubricants on steel.

In view of the variability of the results for dry friction, it is not surprising that those for lubricated surfaces are in poor agreement. Coordination of results of different investigators is further complicated by the fact that most of the work reported covers a wide variety of loads, and is concerned for the most part with commercial lubricating oils of indefinite compositions from widely different sources.

Only one group of investigators (10) has made a thorough study of the variables entering into measurements of static friction. In their early papers it is claimed that reproducible values can be obtained only by using highly purified chemical compounds and by carrying out the measurements in a very pure dry atmosphere. Woog (11), Deeley (4), and Hyde (8), however, have published data indicating a high degree of precision on surfaces lubricated with commercial lubricating oils and exposed to laboratory atmospheric conditions.

Woog (11) lays stress on the sensitivity of measurements to vibration and to minute irregularities in the surfaces. Wilharm (12) also found elaborate precautions necessary to minimize vibration effects, but other investigators (5, 17) appear to have obtained reproducible values in the presence of considerable vibration from a driving motor. There is fairly general agreement regarding the necessity for highly polished surfaces, but there is also evidence that the coefficient of friction is independent of the roughness of the surfaces (10*a*).

No work has been done on the possible effect of invisible films of oxide and sulphide which may be present on the surfaces before application of lubricant, although it is well known that such films form during and immediately after the polishing process (18), and Dow (19) has shown that oxide films on brass produce a friction-lowering effect.

There is some difference of opinion regarding the effect of load. Deeley (20), in describing the technique to be employed in using his machine, assumes that the coefficient of friction is independent of the load, but other workers (17*a*, 17*b*), using the same machine, have published data indicating a decrease in the static coefficient of friction up to a limiting load of from 50 to 100 psi, when it becomes constant. Other publications (10*h*, 21) confirm this latter finding and indicate that the coefficient of friction is constant with increasing load for a spherical slider on a plane surface. Hardy and Bircumshaw (10*h*) explain the friction results they observe for small loads and plane surfaces, where the friction is considerably higher than it is above the limiting load, as being due to orientation of molecules by attractive forces at the metal-liquid interface. They consider that these orientation effects extend to a distance of the order of 7μ from the surfaces. The work of Bulkley (22) and of Bastow and Bowden (23) indicates that the length of such oriented chains cannot exceed 0.01μ.

The effect of temperature on the static coefficient of friction appears to be rather complicated. The majority of observers assume no temperature effect over the range of temperatures from 20 to 35 C. This assumption has been clearly demonstrated for pure organic lubricants (10*d*), but seems less certain for commercial lubricating oils in the light of more recent work (10*j*, 10*k*, 13*b*), which shows that the coefficient of static friction may remain constant, decrease, or increase according to the nature of the adsorbable components in the oil.

Hardy (10*g*) has found that if μ_{a-a} and μ_{b-b} are the coefficients of dry friction for metal a against metal a and metal b against metal b, respectively, then the coefficient of static friction between metal a and metal b will be $(\mu_{a-a} + \mu_{b-b})/2$ and that the same law holds true for lubricated surfaces. Tomlinson (16) has confirmed this law, which Hardy calls the mean-value rule, for clean metal surfaces. He finds that it follows by considering friction to be the resultant of the attractive and repulsive forces between atoms, since the former is considerably greater than the latter and a less rapidly decreasing function of the distance between atoms. Similar views are expressed by Shaw (24). However, the data of other observers (8, 13*a*) on static friction between lubricated surfaces show little confirming evidence of such a rule,[3] and it is very uncertain whether it can be generally applied.

Hardy (10*h*) has also noted that large changes in friction may take place with time of contact between lubricated surfaces. The time during which an equilibrium value is approached he calls the latent period, which is always one of falling friction at loads above the limiting load. The length of the latent period is dependent on the molecular structure of the lubricant employed, being large for long-chain molecules having polar groups, such as fatty acids and alcohols, and negligibly small for nonpolar molecules such as straight-chain saturated hydrocarbons. This latent period is considered to be the time of orientation of molecules in the adsorbed layer.

Many of the measurements recorded in the literature have been made with the Deeley machine (20), in which the friction is measured between a stationary three-legged slider and a disk which is started slowly rotating from a position of rest so that both static and kinetic measurements can be made with the same apparatus. Although it is not always clear how the readings are

[3] Rhodes and Allen (13*a*), for example, find that the coefficient of static friction is the same for surfaces of steel, brass, or chromium, lubricated with the same material.

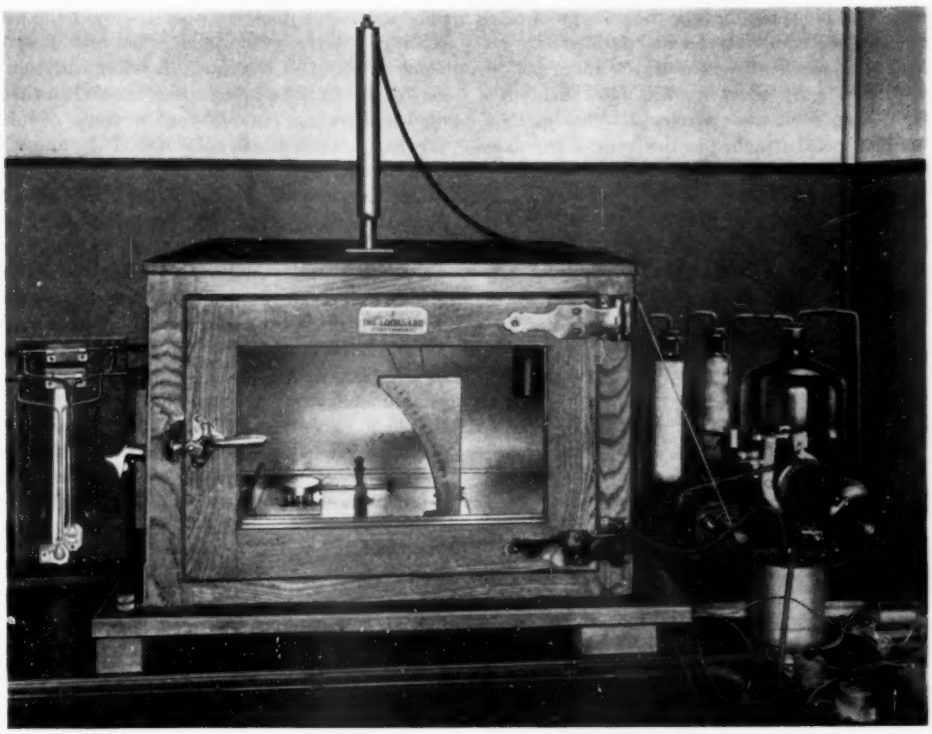

FIG. 1 INCLINED-PLANE APPARATUS

taken, it is likely that most of the values obtained with this machine are kinetic values. Deeley assumes that the static and kinetic coefficients of friction between lubricated surfaces are equal under boundary conditions, and recommends taking the latter value as being more reproducible, and Dover and Helmers (17*c*), using Herschel's modification of Deeley's machine (25), state that their kinetic measurements are independent of viscosity. On the other hand, the results of McKee (1) for a journal-bearing machine, and Bridgeman (26, 27) for a modified Herschel machine, indicate that the coefficient of friction is a function of viscosity practically down to zero speed, and that single measurements of kinetic friction at a given speed cannot be used as a direct measure of oiliness.

On only one point is there fairly complete agreement, and that is that static friction between lubricated surfaces in the boundary region takes place between thin adsorbed films of oriented molecules, although there is considerable difference of opinion, as has already been noted, regarding the thickness of these films. It is also fairly well established that long-chain molecules having a polar group at one end of the chain will be good boundary lubricants, but it is certain that high adsorptive power alone is not a measure of oiliness (5, 10*b*, 11) since substances like water or glycerin, though strongly adsorbed on metals, definitely produce no lowering effect on the static friction between metal surfaces.

EXPERIMENTAL PROCEDURE

Two forms of apparatus, differing mainly in the method of application of a tangential force to a sliding member, were used. The first apparatus, an inclined-plane machine which is essentially the same as that used by Wilson and Barnard (5), is shown in Fig. 1. A polished metal plate, upon which was placed a three-legged slider, rested against a stop on the plane. The plane was tilted by a motor operating through a reducing gear, and when slip occurred between slider and plate, a switch operating a solenoid brake on the motor was thrown, so that the movement of the plane was sharply halted. The fraction of the right angle through which the plane had moved was read to three significant figures by means of a vernier attachment, and the coefficient of friction calculated from this angle. The rate of raising the plane for most of the measurements was 12 cm per min measured at the moving end. This rate was chosen after it had been shown that the static coefficient of friction between lubricated steel surfaces was independent of the rate of raising the plane over the range of speeds from 5 to 20 cm per min. The apparatus was contained inside a metal-lined box through which a current of air, cleaned and dried by passage through sulphuric acid, soda lime, dehydrite, cotton, and glass wool, was passed at a rate of 500 liters per hr. Under these conditions a volume of air equal to that of the box was passed every 15 min and the relative humidity was maintained between 0.1 and 1.0 per cent. The slider was manipulated between readings through a small side door at the left of the box. The box and contents were insulated from vibration by means of layers of sponge rubber and tissue paper. For some of the work slight movement of the slider brought it against a contact attached to the stop on the base plate, closing a relay circuit which operated the solenoid brake on the motor. This method was not always convenient, particularly in certain cases when slip was very slow, and it was found that equally accurate results could be obtained by observing visually the opening of a gap between the back of the slider and a brass disk attached to the base plate.

The second form of apparatus, a horizontal-plate apparatus, which is similar to that used by Hardy, is shown in Fig. 2. The plate carrying the slider was placed upon a brass leveling platform, and the tractive force was applied tangentially by means of a light thread attached to a corner of the slider and passing over a pulley. The load was applied by running water into a light glass bucket attached to the other end of the thread. The plate was prevented from slipping by a step at one end of the leveling platform. The assembly was mounted inside a glass desiccator of 10

liters capacity, bored with holes to admit of the passage of clean dry air during the course of a run. The air was purified as previously described and was passed at a rate of 100 liters per hr. Slip was generally detected by observing the movement of a galvanometer needle when a circuit was closed by contact between a polished strip of metal attached to the front of the slider and a point ground on the end of the feeler of a depth gage set in the wall of the chamber. Successive readings were taken by

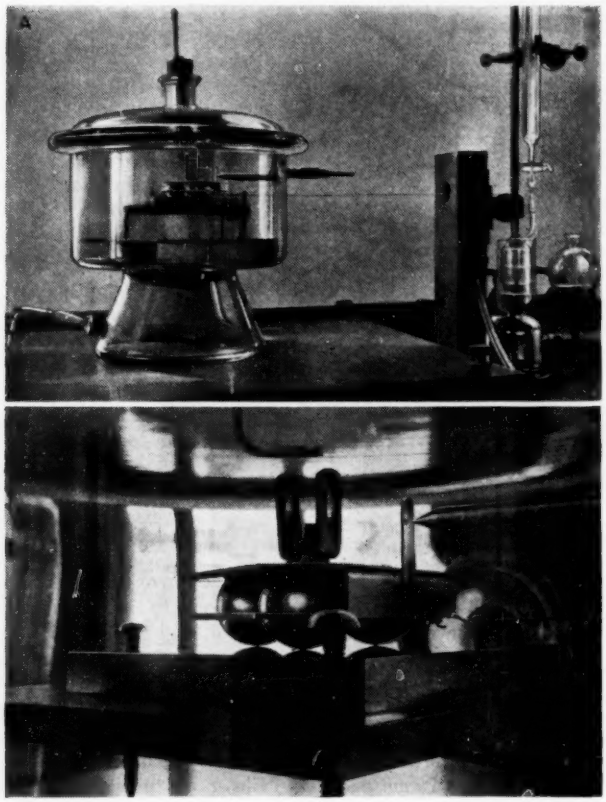

FIG. 2 HORIZONTAL-PLATE APPARATUS

drawing the feeler back 0.010 in. In some cases, however, when experimental conditions were such as to make the electrical contact uncertain, the slip was observed by watching the closing of the gap between the point of the feeler and its shadow on the polished metal strip.

The slider shown in Fig. 1 was the type used in the earlier experiments. The pegs were of speculum metal or steel, and the radius of curvature of their polished ends was 1 in. The mass was 370 g. Sliders of the type shown in Fig. 2 B were generally used. They consisted of three ball bearings at the apexes of a triangle of 2-in. sides, held between two triangular steel plates. By loosening a screw, the balls could be turned so that each of a series of readings could be made on an unscratched surface of the ball if desired. The sliders were of two sizes, fitted with balls of 1 in. and $^1/_2$ in. diam, respectively. Their masses varied from 290 to 300 and 125 to 135 g, respectively. The steel balls were hardened-tool-steel ball bearings and were obtained from the Atlas Ball Company, Philadelphia. The plates were of hardened steel. Two most frequently used were toolmaker's flats obtained from Pratt and Whitney. Others were cut to $3^1/_2 \times 3^1/_2 \times {}^1/_2$ in. from ground flat stock and were hardened, lapped, and polished.

The most important factor to be controlled in order to obtain significant results is the cleanliness of the surfaces. Fatty films only a molecule thick not only can lower the friction between unlubricated surfaces enormously but can lower considerably the value obtained on subsequent flooding with lubricant. The work carried out in these laboratories has shown that the only method of cleaning which removes the last traces of lubricant used in the previous test consists in polishing off the film with moist abrasive on a metallurgical lap.

The data in Table 2 indicate the large effects which an invisible film can produce on the friction between dry and lubricated surfaces. Before each run the surfaces, after solvent treatment, were cleaned by polishing with wet broadcloth sprinkled with magnesium oxide used for metallographic polishing. For the first four runs water was removed from the surfaces, after polishing and scrubbing under water, by rinsing with alcohol and drying in air. For runs 5 to 9 the water was removed by means of a clean linen cloth. Application of a test, to be described later, of the cleanliness of the surfaces, which consisted in the observation of their tendency to be wetted with water, showed that the alcohol-rinsed surfaces were clean, whereas those dried by wiping with the cloth were covered with an invisible contaminating grease film.

TABLE 2 EFFECT OF CLEANING ON COEFFICIENT OF FRICTION BETWEEN SPECULUM METAL AND STEEL

Treatment of surfaces	Run no.	Lubricant	μ	Per cent average deviation from mean
Polished under water, rinsed with alcohol, dried in air	1	None	0.45	3.6
	2	Acto oil	0.28	9.0
	3	S.A.E.-10 automobile oil	0.21	5.9
	4	Acto oil + 1 per cent oleic acid	0.16	3.9
Polished under water, dried with clean cloth	5	None	0.13	11.2
	6	None	0.08	8.4
	7	Acto oil	0.11	5.0
	8	S.A.E.-10 automobile oil	0.10	..
	9	Acto oil + 1 per cent oleic acid	0.16	6.8

It will be observed that the coefficient of friction between the surfaces rinsed with alcohol and dried in air after abrasion (run 1) is more than four times greater than that obtained when the surfaces were dried with a cloth (runs 5 and 6). The effect of the film deposited by the cloth is almost as great for the lubricated surfaces; the results for the two mineral oils are considerably higher when they lubricate the clean steel surfaces (runs 2 and 3) than when they lubricate the cloth-treated surfaces (runs 7 and 8). It will also be noted that the difference between the white Acto oil and the automobile oil is masked by the presence of a contaminating film, and that the effect of addition of oleic acid to the white oil is actually reversed (runs 4 and 9).

The values of the coefficient of friction are the means of ten determinations. It will be observed that the spread of the readings averaged is not lowered by improving the cleaning technique. This was rather disappointing since many published results (4, 10*c*, 11) indicated that static-friction determinations reproducible to three or four significant figures were obtainable.

Although the cleaning method giving the higher values in Table 2 gave more promising results than had been obtained hitherto, the reproducibility of dry values was still rather poor (μ = 0.4 to 0.6 for speculum on steel). After testing various cleaning methods, the following was adopted: The surfaces were first scrubbed with cotton soaked in benzene and acetone, and were then polished on wet broadcloth sprinkled with levigated alumina; the hands of the operator were covered with welt cotton gloves. When the surfaces appeared to be clean they were scrubbed with cotton under running tap water, washed with redistilled ethyl alcohol, and dried by resting the slider or plate on the lip of a glass beaker, cleaned by flaming, set under a bell jar through which was passed a current of clean dry air. The

sliders were harder to clean than the plates, particularly those having balls held between two steel plates, because contaminating material became lodged in crevices and became deposited on the lower surfaces by the alcohol rinse. These sliders were therefore frequently dismantled, the parts cleaned with solvents, reassembled, and extracted with ether in a large Soxhlet-type extractor before the final cleaning by abrasion. All handling of sliders and plates, except during the actual polishing, was done with crucible tongs which had been cleaned by heating to redness. Alcohol was found to be the best solvent to use for removing the water after polishing. In general, absolute alcohol as received left the surfaces clean, but it was found safer to use redistilled alcohol, which was stored in carefully cleaned Pyrex bottles. Other solvents invariably left a film of grease on the surfaces unless they were freshly distilled.

The plates were tested for freedom from grease by wetting with water and draining in a vertical position. When the surface is clean the water will remain in a continuous film until it has become so thin by drainage and evaporation as to show interference colors at the upper edge. A straight line of interference colors will then proceed down the plate. Any drying at the vertical edges should also be preceded by the appearance of interference colors.

It is rather difficult to tell when the surface of a ball is clean by the wetting test, particularly if the radius of curvature is small. The following method has been found the most satisfactory: After rinsing in redistilled alcohol and drying in air, a drop of water is placed on one ball. If the ball is clean, it will wet all over and will be somewhat duller in luster than the two unwetted balls. After about twenty seconds, a circular dry spot, fringed with interference colors, appears near the upper part of the curved surface and spreads fairly rapidly over the ball. If any contamination is present, the water will flash back immediately to the boundary between the ball and the base of the slider, leaving it dry all over.

No method of solvent cleaning alone, such as has been frequently used (5, 13, 20), was found to be satisfactory. Water invariably drew into droplets on steel surfaces cleaned in this manner and the dry coefficient of friction ran between 0.2 and 0.3, for a given slider-plate combination, whereas for surfaces cleaned as previously described, the dry coefficient ran between 0.75 and 0.80.

The necessity for a cleaning technique which provides surfaces free from organic contamination cannot be too strongly emphasized. The work carried out in these laboratories indicates that failure to use adequate cleaning methods is the most important single factor contributing to the lack of uniformity of published results on static friction. Hardy stressed the need for clean metal surfaces in static-friction work as early as 1919. The results of the present work are in full agreement with his findings on this point, and the friction coefficient for steel on steel checks closely his value for steel surfaces cleaned by a similar technique (10*j*).

The plates and sliders were dried for about half an hour after rinsing with alcohol, and were then transferred to the chamber for measurement. Before flooding the surfaces with oil, a few dry-friction measurements were always made as an additional check on the cleanliness of the surfaces. In Table 3 a series of typical results for the coefficient of friction between steel surfaces cleaned in this manner is given. Sliders 6 and 7 were fitted with 1-in-diam balls, and slider 9 with $^1/_2$-in-diam balls. Plates 1 and 5 were toolmaker's flats and plates 6 and 7 were made from ground flat stock. Each of the values given in the table is the mean of at least five readings. The first ten values were obtained using the horizontal-plate apparatus and are picked at random from more than one hundred obtained on surfaces in equilibrium with dry air (relative humidity less than 0.1 per cent) over a 2-year period. Determinations 11 to 14 were obtained using the inclined-plane apparatus in an atmosphere of approximately 1 per cent relative humidity, and determinations 14 to 18 were obtained using the horizontal-plate apparatus in an atmosphere of 70 per cent humidity.

TABLE 3 COEFFICIENT OF STATIC-FRICTION MEASUREMENTS BETWEEN STEEL SURFACES

Determination no.	Normal load, grams	Slider no.	Plate no.	μ	Per cent average deviation from mean
1	295	6	5	0.75	1.4
2	295	6	5	0.82	2.3
3	295	6	6	0.80	1.9
4	295	6	6	0.77	3.4
5	295	6	7	0.75	1.1
6	295	7	5	0.79	3.0
7	295	7	6	0.80	1.3
8	1700	9	5	0.74	2.0
9	133	9	6	0.80	4.1
10	133	9	6	0.82	2.5
11	230	6	1	0.79	1.1
12	470	7	1	0.84	1.7
13	450	7	5	0.80	1.8
14	104	9	5	0.80	1.8
15	295	6	6	0.78	2.0
16	295	6	7	0.74	2.1
17	295	7	6	0.77	3.0
18	295	7	7	0.76	2.5

It will be noticed that over the range of loads tested, the law of friction is obeyed, and that, as would be expected (10*a*), the coefficient of friction is independent of the humidity of the surrounding air.

The grand average of several hundred values obtained over a period of four years for a large number of slider-plate combinations is 0.78, with a maximum deviation of 0.06. For a given slider-plate combination, the maximum deviation is generally of the order of 0.03. This spread is not as low as would be expected from the literature (4, 10*c*, 11), but no higher reproducibility was obtainable, no matter what care was taken.

It had been assumed that the results were independent of temperature. In case temperature effects could account for fluctuations, runs were made at constant temperature with no improvement in reproducibility. It is possible that the extent and nature of irregularities in the surface may be the limiting factor, although no significant difference was observable between the spread of the results obtained on the toolmaker's flat which was optically plane, and of those on the square plates which were flat to only 0.001 in.

The method used for insulating against vibration reduced general building vibration fairly efficiently, but for measurements on the inclined-plane apparatus, an appreciable amount of vibration was transmitted from the motor through the string. In order to determine the effect of this vibration on the reproducibility and on the mean value of the friction readings, runs were made in which readings were taken alternately using the motor lift and a hydraulic lift mounted on top of the chamber. In all, ten readings for each method of lifting the plane were made in a given run, and the means are given (runs 1 and 2 of Table 4). For runs 3 and 4 the chamber and contents were mounted on a vibration-free mounting suspended by steel springs from the ceiling and the hydraulic lift was used.

TABLE 4 EFFECT OF VIBRATION ON COEFFICIENT OF STATIC FRICTION BETWEEN LUBRICATED STEEL SURFACES

Run no.	Surfaces	Method of lifting plane	μ	Per cent average deviation from mean
1	Steel, Acto oil, steel	Motor	0.233	6.5
		Hydraulic	0.262	5.5
2	Steel, oleic acid, steel	Motor	0.102	3.2
		Hydraulic	0.126	5.9
3	Steel, Acto oil, steel	Hydraulic	0.273	10.5
4	Steel, Acto oil, steel	Hydraulic	0.255	6.3

These results indicate that vibration from the motor exercises a small lowering effect on the coefficient of friction. This lowering,

TABLE 5 FRICTION BETWEEN SULPHIDED COPPER SURFACES FOR VARYING FILM THICKNESS

Run no.	Color of film	Equivalent air-film thickness cm × 10^{-5}	μ
1	No film	..	1.17
1	Slightly darkened	1.0	1.07
1	Rose I	1.2	0.91
2	Blue I	1.6	0.88
2	Yellow II	2.8	0.77
2	Purple II	3.9	0.78
2	Blue II	4.3	0.73
2	Blue green II	4.9	0.73
3	Light blue II	4.6	0.78

however, is scarcely greater than experimental error and is negligible for practical purposes. It is also clear from Table 3 that vibration effects were not responsible for the lack of reproducibility in earlier values—in fact the highest spread was found in run 3, which was carried out under practically vibrationless conditions.

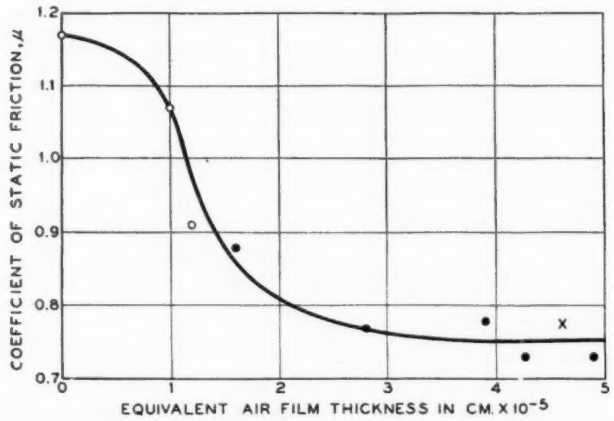

FIG. 3 RELATION BETWEEN COEFFICIENT OF STATIC FRICTION AND THICKNESS OF TARNISH FILM ON COPPER

In the early work there had been indications that the presence of thin tarnish films, such as oxide and sulphide, formed on the surfaces while drying in laboratory air, might be responsible for irregularities in both dry- and lubricated-friction results. Since also the formation of corrosion films plays an important part in the functioning of extreme-pressure lubricants, a series of experiments was carried out to determine the effect of oxide and sulphide films of various thickness on the static friction between steel, brass, and copper surfaces.

The sulphide films were made by immersion of slider and plate for varying times in 0.02 per cent sodium-sulphide solution, and the oxide films were made by heating in air at temperatures from 100 to 500 C.

A preliminary survey indicated that in general the very thin invisible or barely visible films produced little or no effect, but that the friction dropped sharply when a certain limiting thickness of film was reached. For example, the invisible oxide film formed on steel by a 5-min immersion in hot chromic acid and on brass by heating for 1 hr in air at 110 C gave a friction lowering only slightly greater than experimental error, whereas thicker films produced a reduction in friction of the order of 50 per cent. Some results obtained for sulphide films on copper over a wide range of thickness, which illustrate this point clearly, are given in Table 5 and plotted in Fig. 3. The procedure for each run was to dip slider and plate in the sodium-sulphide solution until a given uniform tarnish color was obtained. They were then rinsed with water and alcohol, dried, and used for a friction determination. After testing for cleanliness by the water-wetting test, they were redipped in the sodium-sulphide solution and the friction redetermined. The results given are the means of ten readings. The thickness of the films was not measured directly. It has been shown by Constable (29), however, that the equivalent air-film thickness, which is the thickness of an air film between glass plates giving the same color as the tarnish film under consideration, is directly proportional to the measured thickness. Air-film thicknesses are therefore given in the third column of Table 5 and provide a relative measure of the thickness of the film.

It will be observed that at the pressures used in these experiments (mass of slider = 297 g, diameter of balls = 1 in.)[4] no pronounced drop in friction takes place until the film is thick enough to show well-defined interference colors. The friction then drops sharply to a relatively constant value for thicker films. Similar results were obtained for oxide on copper. The film produced by the action of sodium sulphide on steel appears to be an exception to this behavior in that a sharp drop in friction was measured for an invisible film in this case.

Table 6 gives results for the friction between surfaces of steel, brass, and copper coated by a variety of solid films of thickness large enough that little or no breakdown took place. The unlubricated surfaces reacted clean to the water-wetting test after each set of ten readings, the means of which are given in the table. The results recorded in this table as well as those of Table 5 were obtained using the horizontal-plate apparatus.

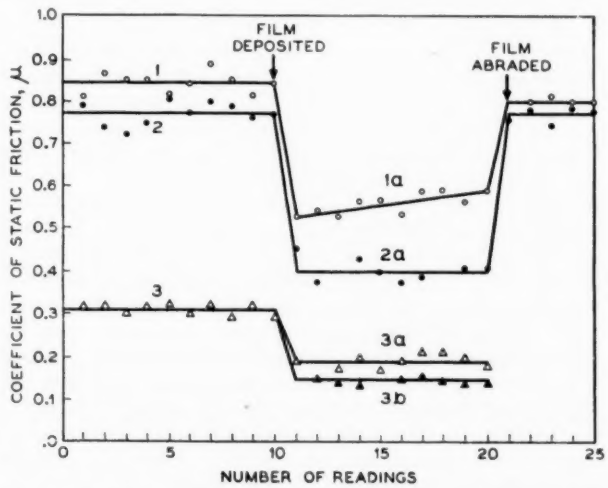

FIG. 4 EFFECT OF SULPHIDE FILMS ON BRASS AND STEEL ON THE COEFFICIENT OF STATIC FRICTION

1	Brass	1a	Sulphided brass
2	Steel	2a	Sulphided steel
3	Steel, Acto oil	3a	Sulphided steel, Acto oil
		3b	Oxidized Steel, Acto oil

TABLE 6 FRICTION-REDUCING EFFECT OF SOLID FILMS ON STEEL, BRASS, AND COPPER

Metal combination	Treatment of surfaces	Static coefficient of friction, μ — Untreated surfaces	Treated surfaces
Steel-steel	Oxide	0.78	0.27
Steel-steel	Sulphide	0.78	0.39
Brass-brass	Sulphide	0.88	0.57
Copper-copper	Sulphide	1.21	0.74
Copper-copper	Oxide	1.21	0.76
Steel-steel	Oleic acid	0.78	0.11
Steel-graphite	Oleic acid	0.21	0.09
Steel-steel	Acto oil	0.78	0.32
Steel-steel	Oxide, Acto oil	0.78	0.19
Steel-steel	Sulphide, Acto oil	0.78	0.16

It will be observed that a substantial drop in friction results from the presence of the solid films.

[4] Assuming Hertzian surfaces the average pressure is of the order of 1.5×10^4 psi.

The values for the lubricated solid films are lower than those for the metals lubricated by the same oil, but the reduction is not as large nor as consistent as that which would follow from application of the empirical rules given by Hardy and his coworkers.

Some of the results of Table 6 are given in more detail in Fig. 4. The figures plotted are those obtained for individual readings and a good idea of the reproducibility of the results in the tables may be gained from a study of the curves. The upward trend in the values for sulphided brass indicates some breakdown of the film on the balls; similar but considerably steeper curves were obtained by Dow (19) for friction as a function of the number of slips for thin layers of oxide on brass. He interprets the rise in friction as due to the abrasive action of thin oxide films. His results, however, are all considerably lower than those obtained in the present work, and it is believed that they may be interpreted as being due to the removal of an oxide film contaminated with a thin layer of fatty material.

The last series of readings for curves 1 and 2 in Fig. 4 were taken after the slider had been rubbed back and forth on the plate to produce three areas of clean but roughened metal surface of approximately 1 sq cm. A spot of clean metal approximately 0.04 sq cm in area was formed on each ball. The readings were taken on these abraded areas. The results are in good agreement with the values obtained for polished surfaces and offer additional evidence that the coefficient of friction is independent of the area of contact and of the roughness of the surfaces (10) for solid friction.

In order to find out to what extent the static-friction method could be used to differentiate among a variety of oils and in order to gain some idea as to how the static and kinetic methods of friction testing would compare, studies were made on a series of commercial lubricants of widely differing chemical properties and viscosities on several different bearing metals, after these same combinations had been measured by the Herschel disk friction machine. The static-friction measurements on the bearing alloys were made using the inclined-plane apparatus, and the kinetic measurements were made by Winslow Herschel in the friction and lubrication section of the U. S. Bureau of Standards. After the kinetic measurements were completed, the $^1/_2$-in. balls were removed from the slider and fitted into an aluminum frame so that they were no longer free to rotate, giving a slider mass of 75 g. The plates were the same disks that had been used for the kinetic-friction measurements. The results for steel were obtained using the slider with 1-in. steel balls described earlier, on the toolmaker's flat, using the horizontal-plate apparatus. The surfaces were completely flooded with oil after cleaning, and the plate was rotated through an angle of about 20 deg after each reading. The slider was pressed in place and agitated gently on the plate before a measurement, which was taken 5 min later. The plane was lifted using the motor.

The composition of the alloys was as follows:

	Per cent		Per cent		Per cent
A.S.T.M. No. 1	tin 91	copper	4.5	antimony	4.5
A.S.T.M. No. 8	lead 80	tin	5	antimony	15
A.S.T.M. No. 1	lead 83	tin	2	antimony	15
Frary metal	lead 96.9	tin	0.18	barium	1.71
	calcium 0.70	mercury	0.33	zinc	0.11

The following oils were tested:

	Viscosity, poises at 30 C
Atlantic spindle oil	0.33
Liberty aero oil	8.92
Castor oil	4.73
Lard oil	0.73
Atlantic spindle oil + 2 per cent oleic acid	0.34

The results of the tests are given in Table 7, and show the means of ten readings in the case of the static measurements. These results are represented in Fig. 5, and are reproducible to ±0.01.

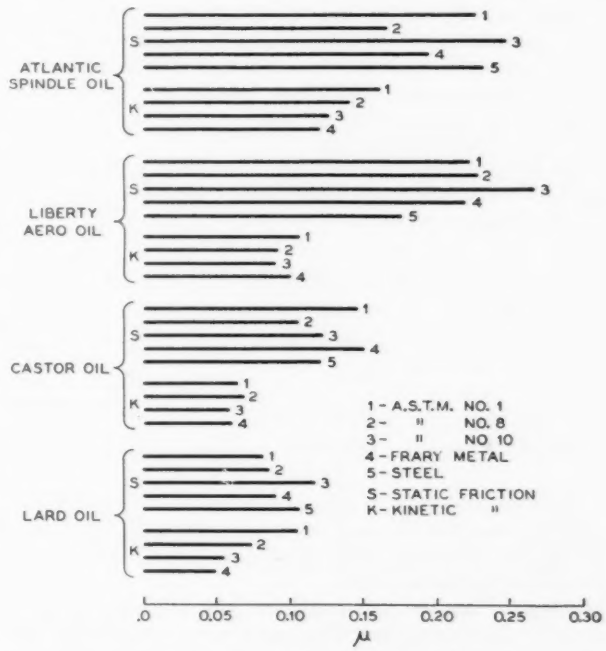

FIG. 5 REPRESENTATION OF COMPARATIVE DATA ON STATIC AND KINETIC FRICTION FOR SEVERAL OILS AND BEARING MATERIALS

It will be noticed that the kinetic values are in general considerably lower than the static values and that for the two mineral oils kinetic values for the low-viscosity Atlantic spindle are higher than those for the high-viscosity Liberty aero, whereas the static values for these two oils are practically the same. These differences are believed to indicate that the kinetic values are influenced by viscosity effects. With one exception, the kinetic values for the two fatty oils are similar. Here, it is believed, corrosion effects enter as an additional complicating factor.

The kinetic values show some tendency to rate the bearing materials in a given order. It would be expected that some similar effect of the bearing material would be apparent in the static values (10*g*, 16), but none is present. Here again corrosion effects may be in part responsible, but it is clear from other measurements made in these laboratories on a variety of materials, under experimental conditions closely approximating those of Hardy, that the quantitative relations describing the effect of the solid surface given by him do not hold generally.

In many of the runs a pronounced downward trend of values, somewhat reminiscent of the latent period mentioned earlier in this paper, was noticed. This latent period (from 1 to 2 hr) was considerably longer than that described by Hardy and Bircumshaw (10*h*), and was noticed for the relatively nonpolar mineral

as well as for the fatty oils, although it tended to be shorter in the latter case. In general the procedure adopted was to continue taking readings until a steady value for two successive means of ten was reached. It was found that the steady value could be reached immediately by rubbing in the lubricant with a linen pad extracted free from friction-lowering impurities, and then rubbing off all but a thin smear of oil. Some evidence was found that this rubbing-in technique gave more reproducible values than the standard method just described, and in one or two cases, where fatty oils were concerned (e.g., lard oil on A.S.T.M. No. 1), a difference greater than experimental error was found between the value obtained by the standard method and the rubbing-in value. This might be due to the presence of a corrosion layer at the interface in the case of the standard value, but the two methods were not investigated in sufficient detail to draw any definite conclusion. It is believed that the downward trend was due in part to the presence of an adsorbed moisture film at the metal-liquid interface. Moisture effects on static-friction measurements have been investigated in considerable detail and will be described in a later paper.

For certain of the runs in Table 7 the effect of an increased load was determined for alternate readings after the steady stage had been reached. The results are given in Table 8.

TABLE 8 EFFECT OF LOAD ON THE COEFFICIENT OF STATIC FRICTION BETWEEN LUBRICATED METAL SURFACES

Lubricant	Metal combination	Load, gr	μ
Atlantic spindle oil	Steel—A.S.T.M. No. 8	75	0.168
		175	0.176
Lard oil	Steel—A.S.T.M. No. 8	75	0.085
		175	0.094
Castor oil	Steel—A.S.T.M. No. 8	75	0.103
		175	0.110
Liberty aero oil	Steel-steel	292	0.22
		717	0.23

These results indicate that under the conditions of test there is a slight increase in the static coefficient with load. The effect, however, is not greater than experimental error and was not investigated in further detail.

Although clear-cut differentiation was obtained among a series of oils, it is clear that the static-friction method is not suitable as a routine test for oiliness. At best it can only give information regarding the state of surfaces at the beginning of motion, and the elaborate precautions required to obtain consistent results provide a further limitation on its use. However, when proper precautions are observed, it provides a useful supplement to other oiliness-testing methods, and can be used to good effect as a research tool for fundamental investigations of the factors operating at the solid-liquid interface in boundary lubrication.

The writer wishes to express his thanks to E. A. Thurber and to H. V. Wadlow for their assistance in obtaining many of the experimental results.

Stresses in Helical Compression Springs—Present Status of the Problem

By C. T. EDGERTON,[1] NEW YORK, N. Y.

Since Dr. Röver, in 1913, first formulated the modern theory of the stress distribution in a helical spring, including the effect of bar curvature, pitch angle, direct-shear stress, etc., a number of investigators have treated the problem. Wahl, Göhner, Adams, Vogt, Perkins, and Keysor have all presented interesting analyses. Most of these vary somewhat in the detailed method of treatment, but they all arrive at substantially the same result, in terms of the maximum fiber stress in the section. Wahl, in a notable series of experiments, demonstrated that these maximum stresses postulated by the theory are actually present in the spring.

Thus it would appear that we have a satisfactory working theory. But practical spring men feel that there must be something wrong; the theory, when applied to certain standard spring designs with very satisfactory service records, predict stresses which seem far too high to be compatible with good endurance in service. This feeling is supported by the results of a few endurance tests, which indicate rather clearly that the maximum stresses predicted by the theory, though undoubtedly present, do not correctly index the actual endurance.

In the author's opinion, all the evidence points to the conclusion that the problem of design stresses in helical springs is not one for the mathematician, but must be worked out in the laboratories, by actual experiment.

IT WAS as long ago as 1913 that Röver published an article (1)[2] in which was announced, for the first time, a first approximation to the modern theory of the stress in helical springs. Up to that time the Reuleaux formula (2) had been the universal standard; it assumed that the only stress present was pure torsion. Röver's theory recognized not only the torsional stress, but also the direct-shear stress, the bending stress due to the pitch angle, and the variation in torsional stress from point to point of the section, due to the curvature of the bar.

Röver developed his theory in three steps. He first worked out an approximate correction factor for the maximum value of the stress augment due to the bar curvature, plus the direct-shear stress; the pitch angle was taken as zero. He then amplified this correction factor to include the bending stress due to the pitch angle. Both of these formulas are approximate, and both are based on the assumption that the center of torsional rotation coincides with the geometrical axis of the bar. This is incorrect, as the shear moments over the section would not be in statical equilibrium. The center of torsion is displaced a small amount toward the spring axis.

Röver's third step was to develop a more exact but very complicated solution, based on elastic theory, for a particular value of the spring index. This development is therefore of value only as a check on his approximate formula. The latter gives a result differing by only 1 per cent from the more exact solution, for the numerical case examined.

Considering the importance of Röver's theory, it is surprising that it attracted so little attention. It seems to have been practically unnoticed for 15 years, when Wahl made his experiments at the Westinghouse laboratories (3).

This research of Wahl's was magnificently simple in conception and execution. He mounted a half coil of a spring in a testing machine, in such a way that the stress distribution accurately simulated that in the body coils of a complete helical spring, and measured the strains at the innermost helical element (the locus of maximum stress); then reduced these strains to corresponding shear stresses. He also took measurements at the outermost element (locus of minimum stress) and checked these with measurements on the outermost element of complete springs. Due to space limitations, it was impossible to check the complete springs at the innermost element.

Supplementing his experimental work, Wahl announced a revised stress formula. It takes into account the stress differentials due to bar curvature and to direct shear, but not the pitch angle. The correction for bar curvature recognizes the displacement of the center of torsion from the geometrical center of the bar, in accordance with curved-bar theory. Therefore Wahl's formula is presumably more accurate than Röver's first approximation. As to the experimental results, Wahl did not report any numerical figures; however, he did show a graphical plot of his results, together with the theoretical curve for the test springs based on his formula. He ran the tests on two specimens, and as the theoretical stress was a few per cent greater than the experimental result on one, and a few per cent less on the other, we can consider that he got substantial agreement.

Another interesting contribution to the subject was that of Adams (4), who developed an extremely complicated set of equations for the torsional stress. However, it is difficult to appraise accurately the value of Adams' work. The author himself states that "the results derived in the.....analysis are rigorous." But the analysis is not given in full; in an editorial footnote it is stated that the integrations are very difficult and lengthy, and cannot be reproduced, but that they have been examined and checked. Adams gives his final result (a correction factor for the stress augment due to bar curvature) in three separate equations. Then he arbitrarily inserts in the equation another correction factor, representing the effect of direct-shear and bending stresses, and he names certain values for this factor, for various index values. He says he has "shown (this) elsewhere." His formula for displacement of the axis of torsion gives about the same numerical value as the form used by Wahl, for an index of 4. His final correction factors agree closely with Wahl's for very small and rather large index values; however, for intermediate values there is a difference of several per cent. Thus Adams was

able to check Wahl's experimental results to about 1.25 per cent; Wahl's test springs were of index 3.

The next contribution we find is that of Göhner. In 1930 and 1931 Göhner published three articles developing the pure theory of the stress distribution in helical springs. In March, 1932, he published a fourth article (5) in which he announced a series of simplified formulas based on his earlier work and in convenient form for practical spring calculations. The stress formula is stated in four different forms, each successive form being a further simplification.

In the year following Göhner's work, Vogt (6) made some ingenious simplifications of the equations developed by Röver as his second step; as explained before, this step includes the corrections for bar curvature, direct shear, and pitch angle. There-

fore Vogt's equations, like Röver's, involve the error of taking the center of torsion at the geometrical axis of the bar.

Vogt makes the interesting suggestion that the stress equation be stated in terms of tensional stress instead of torsional, and in his own paper his equations are so stated. Probably something could be said on both sides of this question, but a discussion of the subject does not come within the scope of the present paper.

At the December, 1933, meeting of the A.S.M.E., Professor H. C. Perkins of Cornell University presented a paper (7) in which he developed a very interesting set of equations. Perkins followed the method used by Röver in his accurate solution for a particular index value; but, he generalized the loading on the spring to cover a combination of an axial force and an axial couple, and he generalized his solution to cover any numerical value of index.

In the following year, Professor Perkins gave us a second paper, in which he gave stress equations for the case of an eccentrically loaded helical spring.

It is necessary to mention one other name. At the A.S.M.E. meeting in December, 1934, Keysor (8) gave us a discussion of the problem from a new standpoint. All the previous investigators had discussed a condition in which the stress distribution was the same in every section of the bar. Keysor, in considering the problem of the number of inactive coils, decided that any assumptions as to axial loading were not justified, and investigated the general case of a helical spring of standard end conformation compressed between two parallel plates. He found that the effective loading was in general nonaxial, the eccentricity varying with the spring index, the number of total coils, and the number of fractional coils. For certain combinations of these variables the eccentricity becomes zero.

While the Bibliography given with this paper is by no means complete, it probably covers the more important contributions to the subject. Now it will be interesting to look at the various formulas that have been mentioned, and compare the results they give.

In Table 1 are listed the formulas, their authors, the stress components accounted for by each, and the numerical value of the correction factor from each formula for an index value of 4. For ready comparison, all the formulas are reduced to a standard form, consisting of the Reuleaux formula times a correction factor, and a common notation is employed. The latter is

S_b = maximum tension or compression stress (bending plus direct tension or compression)
S_t = maximum shear stress (torsion plus direct shear)
S_s = maximum combined stress, in terms of shear stress
d = diameter of spring bar
M = mean diameter of helix
P = applied load, compressing the spring
c = spring index = M/d
ϕ = pitch angle.

In order to calculate the numerical values of the correction factors, it is necessary, where the formulas involve the pitch angle ϕ, to assign a particular value therefor. As the fiber stress is a maximum when the spring is completely compressed or solid, and this solid stress is usually the starting point for design calculations, it seems logical to use as typical the value of the pitch angle when the spring is solid. This value is

$$\phi = \tan^{-1} d/\pi M = \tan^{-1} 1/\pi c \quad \ldots\ldots [1]$$

Listed first in Table 1 is the Reuleaux formula, which probably needs no introduction to engineers. It is the well-known

$$S = \frac{8PM}{\pi d^3} \quad \ldots\ldots [2]$$

in which only pure torsional stress is considered.

Next come the several Röver formulas. It is easy to see how Röver arrived at his first and simplest form. Neglecting the pitch angle and the displacement of the axis of torsion, he assumed that the stress augment at any point on the periphery of the bar varied inversely as its distance from the cylindrical axis; its maximum value, at the innermost point of the periphery, was

$$S = S_0 \frac{M/2}{(M-d)/2} \quad \ldots\ldots [3]$$

where S_0 is the mean stress as given by the Reuleaux formula. The fractional term obviously reduces to the first term in the Röver equation $c/(c-1)$. For the direct shear at the innermost point on the cross section, Röver wrote $(P/2)/(\pi d^2/4)$, which, when the term $8PM/\pi d^3$ is factored out, becomes the second term in his correction factor, that is, $^1/_4c$.

Röver then modifies his formula to give effect to the influence of the pitch angle. Space will not permit a detailed description of the method used. The two formulas developed, for torsion-shear and bending-tension stresses, respectively, are

$$S_t = \frac{8PM}{\pi d^3}\left(\frac{c}{c-\cos^2\phi} + \frac{1+\sin^2\phi}{4c}\right)\cos\phi \quad \ldots\ldots [4]$$

$$S_b = \frac{16PM}{\pi d^3}\left(\frac{c}{c-\cos^2\phi} + \frac{\sin^2\phi}{4c}\right)\sin\phi \quad \ldots\ldots [5]$$

Röver then combines these in the classic form (taking Poisson's ratio as $m = 3^1/_3$)

$$S_s = 0.35S_b + 0.65\sqrt{(S_b^2 + 4S_t^2)} \quad \ldots\ldots [6]$$

Substituting the two values, and rewriting in terms of torsion-shear stress, we obtain the third Röver formula given in Table 1.

This formula can be rigidly transformed into the fourth form. The latter can be further simplified very greatly, with only very minor losses in accuracy. However, a discussion of these does not lie within the scope of this paper.

Reference to the last column in Table 1 shows that for index 4 the value of the correction coefficient has been increased about 4 per cent by including the effect of the pitch angle.

Going now to Wahl's formula, this is quite widely known and used, and a full description of the derivation is readily available; therefore, only a brief statement is necessary here. Wahl used for the displacement of the axis of rotation the well-known approximation $d^2/8M$. He then found that the Röver factor for torsional stress augment, that is, $c/(c-1)$, must be multiplied by another factor

$$\frac{(d/2) - (d^2/8M)}{d/2}$$

and becomes

$$\left(\frac{c}{c-1}\right)\left[\frac{(d/2)-(d^2/8M)}{d/2}\right] = \left(\frac{c}{c-1}\right)\left(1-\frac{1}{4c}\right) = \frac{4c-1}{4c-4} \quad \ldots\ldots [7]$$

For the direct-shear stress at the innermost point of the cross section, Wahl used the expression $1.23P/(\pi d^2/4)$, and his complete correction factor becomes

$$\frac{4c-1}{4c-4} + \frac{0.615}{c}$$

It may be noted that the first term of Wahl's correction factor yields considerably lower numerical values than Röver's and the second term gives higher values. The two values for the complete expressions, as shown in Table 1 differ by less than 1 per cent for $c = 4$.

Wahl made no allowance for the pitch angle, stating that "it can be shown that a change in slope from zero to 10 deg does not change the maximum shear stress more than a few per cent."

It is impossible to discuss Adams' formulas in detail for the reasons already given. A glance at Table 1 will reveal their complex character. As one of the terms in the final equation is an arbitrary constant, it was necessary to read off the representative numerical value of the correction factor, for index 4, from Adams' graphic chart. As the latter was too small to serve this purpose properly, the tabulated value is only approximate.

Göhner's equations are very interesting. In their simplified forms they are quite easy to manipulate, and calculations for several index values show that for "solid" pitch angles the error in these simplified forms is trifling. This is illustrated by the two values given in Table 1.

Next we come to Vogt's equations. In his simplification of the Röver formulas, Vogt wrote the equation for combined stress

$$S_c = \pm 0.36 S_b + 0.64 \sqrt{(S_b^2 + 4 S_t^2)} \quad [8]$$

with the double sign for the first term, and he said that the plus sign applied to extension springs and the minus sign to compression springs.

This procedure seems to be quite correct. In a compression spring, the bending component acts to bend the bar inward (in the direction of the curvature), and the resultant stress at the innermost fiber of the section is compressive. Also the $P \sin \phi$ component of the direct load is obviously a compressive force. According to the authorities, for combined torsion and compression stresses the equation must be written with a minus sign for the first term.

Röver ignored this distinction; in combining his own formulas he wrote the result as in Table 1. Therefore, while Vogt's extension-spring formula agrees with Röver's, his compression-spring formula gives a value about 10 per cent lower. Apparently Adams missed this point also. Göhner did not give a combined form for his own equations; in working out the values given in Table 1 Vogt's practice was followed.

Perkins' equations are quite interesting, as their accuracy is probably of a very high order. As already stated, Perkins followed Röver's method, except that he generalized it to cover any value of the index, instead of one particular value. He found that a "secondary shear stress" accompanies the bending, opposing the stress in torsion. However, its magnitude is very small.

The final equations for torsion-shear and bending-tension stresses are each stated in several successive steps, like those of Adams; however, Perkins' equations can be combined quite readily into the forms given in Table 1. Consolidation of these two into a single equation for the combined stress would yield a rather complicated expression, which is therefore omitted; for an index value of 4 the combined stress coefficient is 1.320, substantially the same as given by the Göhner and Vogt formulas.

Perkins' equations gave effect to an axial couple as well as an axial force; but in order to make his formulas comparative with the others in Table 1, the terms involving the axial couple have been omitted.

Finally, we have Keysor's paper, dealing primarily with stress augments due to the eccentricity of the effective loading. Keysor's complete analysis is not available at the present writing, and in any event there would be no comparison between his formula and those already dealt with. Keysor used Adams' correction coefficient for bar curvature, direct shear, etc., inserting a symbol in his formula to represent them.

But it should be carefully noted that Keysor's analysis predicts a stress augment, due to eccentricity of loading alone, of as much as 28 per cent in certain designs (springs of very few total coils), and that in the outside coil of the standard A.A.R. freight-car bolster spring this augment is about 8 per cent, superimposed on the stress augments already discussed. Some experimental tests have been made, and a more elaborate research is now in progress, the results from which so far seem to confirm Keysor's theory.

From the comparisons given in Table 1, we might reasonably conclude that we have a very satisfactory theory covering our stress problem. Now let us look for a moment at the practical aspect. In the ten years since Wahl published the results of his research, these results have become quite generally known to spring engineers and designers. While they are coming more and more into use, many practical spring men still regard them with a certain amount of skepticism. It is necessary to inquire into the reasons for this attitude.

What these practical men tell us is, briefly, that our correction factors, when applied to certain widely used spring designs, indicate stresses that look rather absurd. Consider, as an example, the outer coil unit of the standard A.A.R. freight-car bolster spring. Literally millions of these springs are riding American freight cars today. The maximum fiber stress at solid height, by the Reuleaux formula, is about 92,000 lb per sq in. The correction coefficient from Wahl's formula, less about $4\frac{1}{4}$ per cent for the effect of the pitch angle, is about 1.4, making the maximum stress 129,000 lb per sq in. If Keysor's theory be correct, we must now add to this about 8 per cent for load eccentricity, and we arrive at a stress of about 140,000 lb per sq in. in torsion. This is well above the usual yield strength of the material.

It is true that these springs rarely or never go solid in service, but they will frequently come close to it. Yet, if made under reasonably good manufacturing conditions, they will give reasonably good service. There are other spring designs in common use, in which stress conditions are more extreme.

The A.S.M.E. Special Research Committee on Mechanical Springs felt that this practical argument merited some investigation. Here we must distinguish carefully between the intrinsic correctness of the Röver-Wahl theory, and its practical application to spring design. There is no doubt that the maximum stresses predicted by the theory are actually present in the spring; Wahl's experimental work proved that beyond any reasonable doubt. The real question is: Are these the critical stresses which index the life of the spring in service, or in an endurance test? Only the test itself can furnish the answer to this question.

Accordingly the Committee arranged, in connection with its extensive fatigue-test program at Wright Field, to have two groups of springs made up from the same rolling and heat of steel, and otherwise alike in every respect except as to the spring index and related dimensions; one group was of index 5 and the other of index 3. The answer we want is a formula for maximum fiber stress, which, when applied to the results of the fatigue tests, will indicate the same endurance limit for both groups.

The test results are shown graphically in Fig. 1. Datum points for the individual runs are plotted in duplicate, with stresses calculated from the Reuleaux formula and alternatively with the Wahl correction factor. Probable S–N curves are plotted for each of the groups, likewise in duplicate. These curves were calculated from the test data by statistical methods, based on the assumption that the S–N curve for ferrous metals is of the form

$$(N - a)(S - b) = k \quad [9]$$

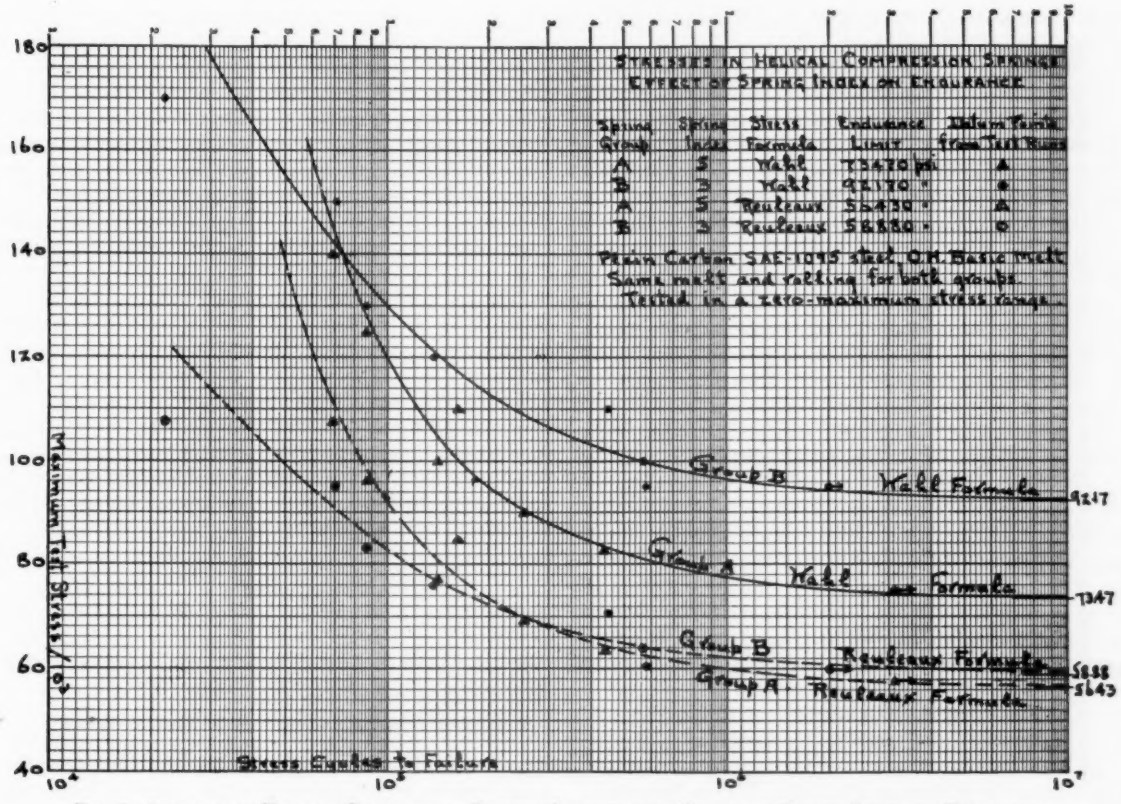

FIG. 1 STRESSES IN HELICAL COMPRESSION SPRINGS SHOWING THE EFFECT OF SPRING INDEX ON ENDURANCE

and that the value of b can be interpreted as the endurance limit. The correlation between the test data and the curves as plotted is quite good for both groups.

A study of Fig. 1 discloses a rather puzzling state of affairs. The two Wahl curves intersect at a rather high stress. Springs in this and higher stress regions are given a quite severe "cold setting" in manufacture, and a possible interpretation of the results might be that under these conditions the springs are very sensitive to local stress augments, and perhaps that they are being subjected to augments not provided for in the Wahl correction factor, such as eccentricity of loading and distortion occasioned by the cold setting; there are several possibilities. As the stress is reduced the two Wahl graphs diverge rapidly, and give predicted endurance limits of 92,170 lb per sq in. for group B (index 3) and 73,470 lb per sq in. for group A (index 5).

For the Reuleaux curves the situation is reversed. They are far apart at high stresses, converge rapidly as the stress is reduced, and the endurance limits are 58,880 and 56,430 lb per sq in., respectively. The apparent conclusion is that for moderately stressed springs local stress augments have little or no effect on endurance. This does not seem quite reasonable, but we can find nothing wrong with the test procedure and data. Further tests along the same lines are projected.

We then got F. P. Zimmerli interested in the problem, and he ran some tests on cold-wound wire springs of different index values. The results are given in Table 2, with an attempt at an analysis thereof.

TABLE 2 TEST RESULTS ON COLD-WOUND WIRE SPRINGS

Spring	Index	Wahl correction factor	Endurance limit, Wahl formula	Endurance limit, Reuleaux	Revised correction factor	Revised endurance limit
A	3.5	1.476	100×10^3	67.75×10^3	1.262	85.50×10^3
B	4.55	1.346	94×10^3	69.84×10^3	1.190	83.11×10^3
C	7.00	1.213	93×10^3	76.67×10^3	1.117	85.64×10^3
D	9.10	1.161	91×10^3	78.38×10^3	1.089	85.36×10^3
E	11.90	1.121	90×10^3	80.29×10^3	1.067	85.67×10^3

The revised correction factors in Table 2 are coefficients, the decimal portions of which have been reduced by a fixed percentage from those of the corresponding Wahl factors. The fixed percentage was established by cut and try, the object being to arrive at a set of revised endurance limits for the various springs which would show a minimum systematic deviation from a mean. The percentage arrived at was 45 per cent. So we might state, as a hypothesis for discussion, that the effective maximum fiber stress in a helical spring is obtained by using a correction factor, the decimal portion of which is 55 per cent of the decimal portion of the Wahl factor.

Mr. Wahl calls this 55 per cent the "sensitivity index," and he attacks the problem along a line of argument, quite different from the foregoing, in a paper[3] being presented coincidentally with this one. He has given a good deal of time and thought to the subject, and what he has to say will be more pertinent than any theory the present writer is able to offer at the moment.

But at least it seems obvious that our theory of stress in helical compression springs, despite the great amount of work that has been done on it and the very consistent results of the mathematicians, will have to be drastically modified to check with what we find in the experimental laboratory, and in actual spring service.

Here the author pauses, somewhat perplexed even to suggest a promising line of attack. Consider for a moment the intricate stress pattern in a helical spring. It includes:

Pure torsional stress.
Direct shear stress.
Bending stress.
Direct tensile or compressive stress.

[3] "Analysis of Effect of Wire Curvature on Allowable Stresses in Helical Springs," by A. M. Wahl, *Journal of Applied Mechanics*, Trans. A.S.M.E., vol. 61, 1939, p. A-25.

A stress increment or decrement, nonsymmetrical with the bar axis, due to curvature of the bar.

A stress increment or decrement, nonsymmetrical with respect to the cylindrical axis, due to eccentricity of the effective loading.

In springs which have been cold-set, entrapped stresses, of which little is known.

Possibly some kind of stress augment about two turns from the tip of the bar. Endurance-test failures show a tendency to localize in this region. This augment may be related to the load eccentricity.

At the Committee meeting last December, Dr. A. W. deForest remarked to the author that in view of the complex stresses present in a helical spring, it seemed hopeless to expect to solve them. Perhaps the best answer is that we can reasonably expect to find a definite consistency in the stress pattern. The proportions of a helical spring can only vary in a very limited number of ways, therefore, our stress pattern should only vary in a correspondingly limited number of ways. This means that while we may never attain to full understanding of the absolute stresses present, we should be able to find out a great deal about the relative stresses.

Stated in this form, the problem is no longer one for the mathematicians; it becomes definitely the problem of the research engineer. The function of this paper is to describe the problem, rather than to suggest solutions. However, the author has for some time been convinced that we must look primarily to the experimental laboratory for our code of design for helical springs.

Discussion

A. M. WAHL.[4] From Table 1 of the author's paper, it would appear that a value of the coefficient of 1.326 (for a spring of index 4) would be obtained by using Göhner's formula, while by using the writer's formula a coefficient of 1.404 is found, the difference between these values being about 6 per cent. However, it should be mentioned that this difference is based on the use of the maximum-strain theory in combining the shear-stress component S_t with the bending stress S_b, the use of this theory being originally suggested by Röver (1)[5] and later used by Vogt (6). If the stress components S_b and S_t had been combined according to the shear-energy (von Mises-Hencky) theory, this difference would have been only about $1^1/_2$ per cent. There are considerable fatigue test data on spring steels which tend to support the shear-energy theory rather than the maximum-strain theory. Moore and Kommers[6] report a ratio between the endurance limit in reversed torsion and that in reversed bending of 0.52 for a 1.2 per cent carbon steel, heat-treated; for a 0.93 per cent carbon steel, heat-treated, a value of 0.53; and a value of 0.50 and 0.56 for quenched and drawn chrome-nickel steels, the average for a large number of alloy steels being 0.58. Also Ludwik[7] reports a ratio of 0.575 between the torsion and bending endurance limits for a chrome-nickel steel. These values are all quite close to the value of 0.577 predicted on the basis of the shear-energy theory, and are considerably different from the value of 0.77 predicted on the basis of the maximum-strain theory. Dr. Koerber, director of the K. W. Institute for Eisenforschung in Germany, in a lecture before the Fifth International Congress for Applied Mechanics also stated that the shear-energy theory appears to yield the best results when compared with the results of fatigue tests on steels made at their laboratories. For these reasons, there seems to be at present a distinct trend toward the use of this theory by engineers interested in strength of materials.

Using the shear-energy theory as a basis, it may be shown that the equivalent stress is given by

$$S_s = S_t \sqrt{1 + \frac{S_b^2}{3S_t^2}} \qquad [10]$$

where S_b and S_t have the same meanings as given in the author's paper and S_s is the equivalent torsion stress.

Using this formula, taking a pitch angle $\phi = \tan^{-1} \frac{1}{\pi c}$ as was done by the author, and calculating S_b and S_t from Göhner's Equations [3] and [4] given in Table 1 of the author's paper, the value of the coefficient for $c = 4$ becomes 1.384. This differs by about 1.5 per cent with the writer's value of 1.404, obtained by neglecting the pitch angle.

Another theory which is quite widely used in industry is the maximum-shear theory, according to which the ratio between the torsion and bending endurance limits should be 0.50 (which is somewhat below the average values obtained by tests). On the basis of this theory the equivalent stress is

$$S_s = S_t \sqrt{1 + \frac{S_b^2}{4S_t^2}} \qquad [11]$$

Using Göhner's Equation [4] of Table 1 as before for calculating S_b and S_t, a coefficient of 1.383 is found for a spring of index 4, which is practically the same as that obtained previously by using the shear-energy theory.

These examples show that if either the maximum-shear or shear-energy theories is taken as a basis, the simple formula previously proposed by the writer, in which the pitch angle was neglected, will give results for most practical springs within less than 2 per cent, as compared with those obtained by Göhner's equations, the derivation of which is based on the more exact methods of the theory of elasticity. For these reasons, it is the writer's opinion that for the present at least the simpler formula may be used with sufficient accuracy for practical work.

Since, at present, no theory for combining the various stress components present in a helical spring can be regarded as definitely established experimentally, it would seem logical to compare individually the stress components figured from the different formulas. The most important component in helical springs is the shear stress due to the axial load. Using Göhner's formula

[4] of Table 1, for $c = 4$ and $\phi = \tan^{-1}\frac{1}{\pi c}$, the stress S_s becomes $\frac{8PM}{\pi d^3} \times 1.379$. Compared with the writer's value of 1.404 this is a difference of less than 2 per cent. Even smaller differences will be found for larger indexes. As far as the bending stresses S_b are concerned, there is little question about these since they may be figured by well-known theory. The formulas given by Göhner in Table 1 for S_b may be shown to be in close agreement with the results calculated by ordinary curved-bar theory,[8] taking the moment equal to $\frac{PM}{2}$ sin ϕ and adding on the direct stress due to the compression component of the axial load.

These examples indicate that, if elastic conditions are assumed, the formulas available will yield stresses in helical springs which are very close to the actual values. However, in most cases, when compressing the spring solid (as is usually the case during manufacture), the peak stress as given by the formula exceeds the proportional limit or even the yield point in torsion. In such cases yielding occurs and the actual maximum stress is less than the calculated. When the load is released, a residual stress of opposite sign is set up, so that when the load comes on again the peak stress is reduced by the amount of this residual stress.

Referring to the freight-car bolster springs cited by the author as an example, the stress of 140,000 lb per sq in., mentioned would not actually exist when the spring is compressed solid. Instead, yielding of the material would take place at localized regions near the inside of the coil so that the peak stress would not appreciably exceed the yield point. Then too, in usual service as mentioned by the author, the springs are subjected to relatively few cycles of the solid stress, although they may be subject to a great many cycles of a smaller stress. In the writer's opinion there is a definite need for fatigue-test data for cases where there are relatively few cycles of a maximum stress, but in between these cycles a relatively large number of cycles of a moderate stress takes place. When such data are available, the performance of these freight-car springs mentioned may be explained on a rational basis.

The results of the tests carried out on the springs at Wright Field seem rather surprising, since they indicate that neither the stress augment due to curvature nor to direct shear has any effect on the endurance limit. This result may be due to a combination of several factors, including: (*a*) The eccentricity of loading in the two sets of springs of different indexes may have been different and this may tend to mask the effect of bar curvature; (*b*) the material may not be fully sensitive to stress-concentration effects; (*c*) the effect of heat-treatment may be different in the springs of smaller index. In this connection, mention should be made that the sensitivity effect of 55 per cent discussed by the author is not the same as the sensitivity index of that used in the writer's concurrent paper (3).[9] In this paper "sensitivity index" is defined as

$$q = \frac{K_f - 1}{K_c - 1} \quad [12]$$

where K_f = actual fatigue-strength reduction factor and K_c = theoretical stress-concentration factor due only to curvature. The definition given by Equation [12] is in line with that used by research workers on fatigue of metals in this country and in Germany. Using the methods developed in paper (3), the results of Zimmerli's tests (mentioned by the author) may be explained, using a sensitivity index of 1 (defined in this manner). This means that the full sensitivity of the material to stress-concentration effects due to curvature are assumed in figuring the variable component of the stress, the static component being calculated by neglecting stress-concentration effects due to curvature.

The writer fully agrees with the author that a great many more laboratory tests must be carried out before a satisfactory code of design for helical springs will be available. However, it is his belief that analytical work carried out in conjunction with the fatigue tests will be of value in correlating and explaining the experimental results.

Author's Closure

The author notes with pleasure Dr. Wahl's extensive discussion. The point made by Dr. Wahl in connection with the use of the maximum-strain theory is probably well taken. Had the author the task of preparing this paper again, he would probably refrain from any attempt to combine the bending- and shearing-stress components into a single formula, except perhaps in the cases of Röver and Vogt, who themselves suggested combined forms. Apparently the correct theory for combined stresses is still a matter of controversy. In any event, it is of no great importance as related to the subject under discussion. Comparison among the various stress formulas can just as well be made on the basis of shear-stress components only. Dr. Wahl seems to feel the same way about it.

Coming now to the discussion of actual test results, it is the author's belief that Dr. Wahl's argument rather begs the question. The statement made in the paper was not that the stress of 140,000 lb per sq in. was actually present in the standard A.A.R. bolster spring, but that this was the stress predicted by the formulas. Obviously, if this stress is beyond the elastic range of the material, plastic deformation will occur, and the figured stress will not be attained. The author does not believe that Dr. Wahl will contend for a moment that such a condition would not have a detrimental effect on the life of the spring. Indeed, there is very satisfactory evidence from the Wright Field tests that the spring endurance is affected to a marked extent by the amount of "cold setting" in initial tests.

The situation with regard to this problem urgently calls for further experimental work. Assuming that the tests at Wright Field can be continued (regarding which there is some doubt), plans are now being made to run some more tests on the effect of spring index on endurance, in the near future.

[9] The effect of sensitivity is treated in the author's bibliographical reference (3).

Discussion

Chlorination of Condenser Cooling Water[1]

H. K. Aldinger.[2] The author's treatise on chlorination of condenser cooling water presents a very interesting and valuable engineering problem. While this article confines itself principally to the chlorination of circulating water for steam condensers, it should be equally interesting to anyone using process water for other purposes, such as bleacheries, chemical plants, food-product plants, and breweries.

In discussing the author's treatise, the writer takes the liberty to depart somewhat from the main issue, that is, chlorination of cooling water for condensers, because he believes that the slime control in water is of equal importance for any other industrial purpose.

Most operating engineers of power and other plants have to deal more or less with slime and scale-forming conditions in such units as condenser tubes, boilers, air washers, tanks, and pipes. In the case of condenser tubes, as the author states, the economic losses due to slime and scale formation are more pronounced in low-temperature heat exchangers than in high-temperature exchangers.

While chlorination of circulating water in large plants may be of decided advantage, it is doubtful whether it would pay for itself in small plants where a condenser can be cleaned easily over week-end shutdowns, unless the slime and scale formation becomes excessive and retards considerably the heat transfer. Such a condition would occur mostly in the spring and summer months, and where the loss in vacuum would amount to 1 in. or more; however, the warmer circulating water in summertime in itself would reduce the vacuum somewhat. Of course, slime conditions in condenser tubes exist mostly with such plants where they take cooling water from rivers, lakes, or open ponds. It hardly occurs where the cooling water is recirculated through a cooling tower and the make-up water is obtained either from deep-well or city-water supply, as is the case with many small plants.

From the writer's observations, slime conditions are caused by algae in the water. Algae in turn are caused only when vegetable matter or pollen is deposited on or into the water, and have sufficient time to disintegrate under the influence of air and sunlight; they are, of course, most annoying in spring and summer months. Pure cellulose, such as wood and cotton fibers, are the best propagators for the development of algae. However, pollen from grass and other plants furnish their share.

These algae troubles are not nearly as bad in condensers as they are where open water from such sources as ponds and reservoirs is used for processing work, as for instance in bleacheries, food-product plants, and chemical plants. Even filtering will not entirely eliminate these algae, and their propagation is very rapid. The writer's studies have been made with water used mostly for finishing cotton products (bleachery); however, it makes very little difference whether reservoir water is used in bleacheries or in a condenser, slime conditions will occur as long as it is infested with algae. While the writer does not claim to have found a cure for such slime formation, he made some experiments for its prevention by exterminating algae with chemicals other than chlorine.

Of course, in using river, lake, or pond water, the algae are carried in with the water to the plant. It would not be practical to cover a lake or pond in order to prevent vegetable matters or any cellulose from entering the water. On the other hand, a reservoir or tank could be covered, provided that algae are not brought in from outside sources with the water entering the reservoir.

The writer does not intend to discuss the histology of cells. There are many books written on it, and a short and comprehensive treatise on algae can be found in Van Nostrand's Scientific Encyclopedia.[3]

Algae are generally referred to in industrial plants as reservoir or pond scum or waterbloom. They can be found in varied forms in stagnant and putrid water, especially in large reservoirs, ditches, ponds, tanks, and open wells where much vegetation exists and around cotton mills where flying lint and organic dust can easily settle on the water. Algae are classified under the group of Thallophyta.

In the case of algae, the pigment enclosing the nucleus contains chlorophyll, a green coloring matter, while fungi do not. Algae are divided into four classes, when classified by their color, but we are interested here only in the first and second group, that is blue-green algae (Cyanophyceae) and green algae (chlorophyceae). The other two groups occur mostly in sea water. The chlorophyll is what gives the algae its characteristic green or blue color.

While the individual cell of the protoplast of an algae is complex in structure, it can be considered generally to consist of three principal parts: (1) the nucleus; (2) the cytosome or cell body, which envelops the nucleus and is composed of cytoplasm; and (3) the outer cell wall or shell surrounding the cytoplasm. It is the cytoplasm of the unit cell which, when aggregated in large masses, becomes a soft slimy substance of considerable thickness and size and causes all the trouble in condenser and process work.

Figs. 1*D*, 1*B*, and 1*C* show this clearly. Figs. 2 and 3 show water infested with algae, while Fig. 4 shows the same water filtered.

The writer has developed, by photosynthesis, some large specimens of cytosome as shown in the test tubes in Figs. 1*A*, 1*B*, and 1*C*.

The process by which the cytosome develops and grows is still a hypothetical one as far as the writer knows. However, he assumes that under the influence of light, water, and chlorophyll, a great amount of CO_2 is formed in some way, probably by decay. This CO_2 is evidently taken up again by the cells, and in some complex way is transformed into glucose and starch, probably under the influence of some form of amino acids. Of course, this is purely the writer's conclusion, and is based on the starchy character of the cytosome.

A quite similar process can be observed in the fermentation of wine or in making vinegar from apples where a similar slimy skin of considerable thickness is formed and it is from this process the writer got his idea. In the case of either algae or vinegar there is no cellulose present in the cytoplasm. (The cell wall surround-

ing the cytosome or cytoplasm consists of cellulose, but the cytoplasm itself does not contain any cellulose.)

It is not the algae as such which gives all the trouble in condensers or other apparatus, but rather it is the slimy mass or scum inherent with algae. In bleacheries, for instance, the algae itself may cause thousands of yards of goods to be damaged by staining the goods in some way or another, mostly green or brown.

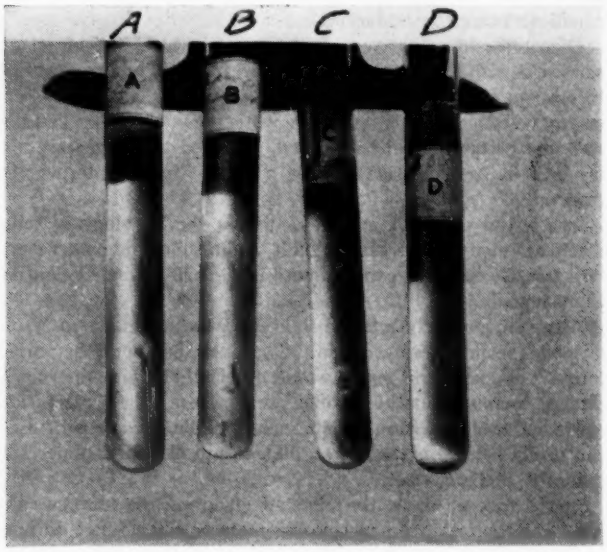

FIG. 1 ALGAE BEFORE AND AFTER TREATING WITH HYPOCHLORITE (*A*, *B*, and *C* show algae developed by photosynthesis; *D* is a sample of the same water treated with hypochlorite, and shows the algae dead at the bottom of the tube.)

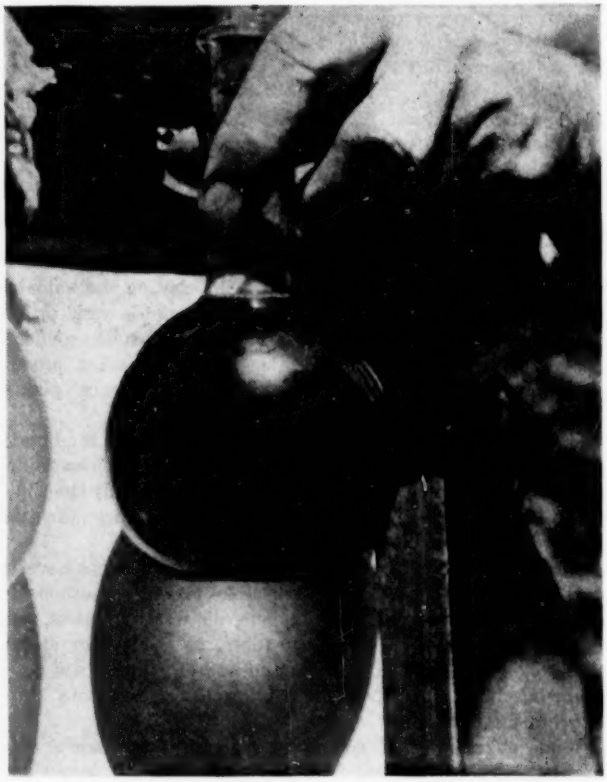

FIG. 3 ANOTHER WATER SAMPLE INFESTED WITH ALGAE

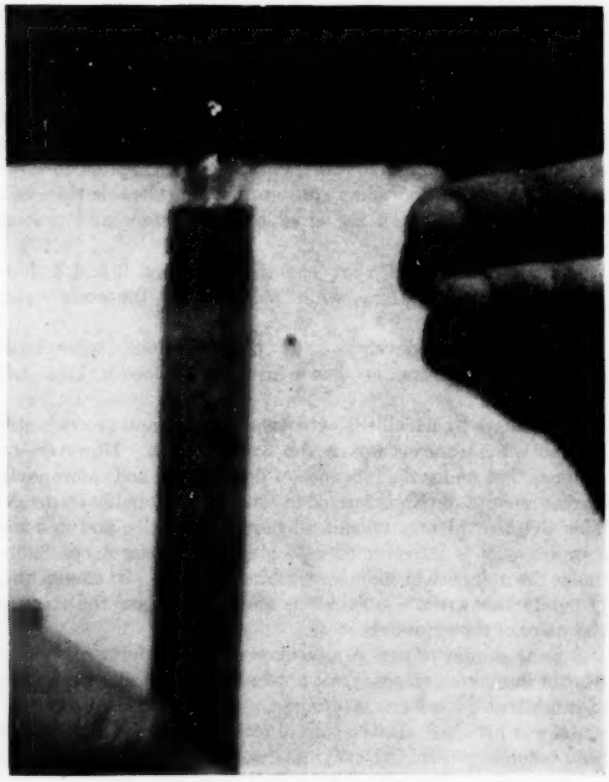

FIG. 2 WATER INFESTED WITH ALGAE

FIG. 4 THE WATER, SHOWN IN FIG. 3, AFTER FILTERING

Such staining is called "possum tack," and is caused when the cloth lays in kiers or bins for some length of time. Small puddles of water containing some algae form between the layers of goods. The water naturally drains in the bin, and the cloth, acting as a filter, holds the algae back. Thus the algae are deposited on the wet cloth, and form the characteristic streaks and stains.

With the common gravity or pressure filter, it is not quite possible to free the water of all algae unless the water is coagulated before and possibly after filtering. And even if the water were thoroughly free from algae, the fuzz and lint from the cloth, or the cloth itself, would only too soon create new algae if allowed to stand for any length of time in the bins, unless the cloth has a high residual chlorine content after bleaching which, however, is not desirable.

The writer conducted some tests with samples of bleached cotton cloth. The first sample was immersed in common clear well water. Algae developed in six days. The second sample was immersed in reservoir water already containing algae and was then exposed to sunlight. In two days the water and cloth sample were green and alive with floating cells, and had an oily and fishy smell. The writer immersed the third sample in city water; this sample held out 10 days before showing traces of algae. The fourth sample was immersed in city water and a 10 per cent hypochlorite solution; it was 20 days before algae developed in this sample.

There is no question but that chlorine or chlorides will inhibit or retard the formation of algae for some length of time and also kill algae already in the water, provided it is supplied continuously to the water in allowable and effective quantities. But as soon as this supply is stopped, only for a short time, the algae will appear again under favorable conditions, even within a few hours.

In inland industries, we have to deal mostly with the blue-green or green algae (waterbloom), which are the ones held together by a gelatinous sheath. The writer has no experience with the treatment of water with direct chlorine gas, but only with hypochlorite derived from the solution of chloride of lime. By calculation, there is about 39 per cent of chlorine present, but only 28.3 per cent is active with the oxygen radical, or approximately 11 grains per 1 lb of water. The writer experimented with a 4-Twaddell solution, but the results were rather disappointing. Figs. 1*A*, 1*B*, 1*C*, and 1*D* show such a treatment with the hypochlorite and while it arrested the further growth of algae, it destroyed neither the algae nor the gelatinous film. On the contrary, it seems to fix the film. Furthermore, the writer found that hypochlorite did not destroy the free swimming cells or gametes, and amoeba are always present where there are algae.

Like in all stagnant water loaded with algae, other organisms of the higher order can be found sooner or later. The writer does not know their names or origin, but supposes that these are carried from the air into the water, and probably are attached to vegetable matters or cotton fibers. Some may be mosquito larvae, which we call wigglers.

The wigglers, which are brownish red in color and develop to about $^3/_8$ in. in length, seem to be the chief enemy of algae. They seem to be especially fond of algae and incessantly eat a great mass of it. Unfortunately, a yellowish brown amoeba attacks and kills the wigglers.

One could conclude that if enough wigglers were present in the water they would destroy the algae and all that would be necessary, before using the water, would be to strain off the wigglers. The writer has not experimented along that line but found that hypochlorite has very little effect on these bugs unless used for a long time and in a strong solution which would eventually also kill the algae.

Somewhat disappointing as it was to use hypochlorite for condensers, air washers, and process water, the writer experimented with some other methods for directly eliminating the algae in the water, since filters let as much as 1 per cent in volume of the algae through; however, a strong solution of hypochlorite eventually arrested the growth of the algae, as shown in Fig. 1*D* where it can be seen the water is fairly clear and the algae dead at the bottom, it took nearly a full-strength solution of hypochlorite. Of course, neither in condensers nor in a bleachery can such a strong solution of hypochlorite be used without affecting the metal.

The writer first experimented with coagulation. Fig. 5*A* shows filtered water, containing some algae, which was treated with alum.

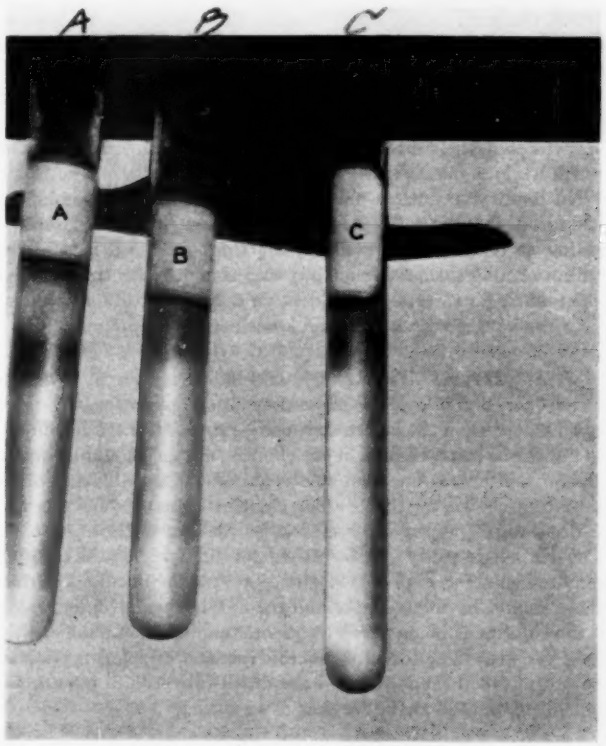

FIG. 5 FILTERED WATER, CONTAINING SOME ALGAE, TREATED WITH (*A*) ALUM, (*B*) ALUM WITH BICARBONATE OF SODA ADDED, AND (*C*) TRISODIUM PHOSPHATE AND HYPOCHLORITE

Fig. 5*B* shows the same water except bicarbonate of soda was added to the alum; the precipitate can be seen on the bottom of the test tube. The water was cleared perfectly, although it took some time.

Fig. 5*C* shows a precipitate made of trisodium phosphate (Na_3PO_4) and hypochlorite. It is this solution to which the writer would like to call the reader's attention, since it worked remarkably well and has many advantages. So far the writer tested this $Na_3PO_4 \times Ca(CLO)_2$ solution only in test tubes, but believes he has found a cheap, quick, and very effective coagulant that not only precipitates and actually kills the algae quickly, but also is noncorrosive to metal; furthermore, it precipitates all the hardness-producing salts, especially in well water, and actually softens the water. In other words, this combination of trisodium phosphate and hypochlorite not only is a strong coagulant but also a disinfectant and water softener.

Cloth samples in such treated water did not show any algae formation after 30 days of exposure. The strength of this test solution was 1 per cent Na_3PO_4 and 2 per cent $Ca(CLO)_2$ by volume.

The writer also found that this solution killed all other bacteria and insects in the water at least three times quicker than hypochlorite alone. There is only one drawback to that solution and that is that it intensified the smell of the dead algae; however, this could probably be overcome by aeration.

Of course, Na_3PO_4 has been and still is used for treatment of boiler feedwater, but the writer is not aware that it has been recommended as a coagulant and disinfectant for water in general and especially for algae extermination.

The cost is nominal—about $2^1/_2$ cents per lb for the trisodium phosphate and about 2 cents per lb for the chloride of lime. According to the strength of such a solution required, it would amount only to a few cents per 1000 gal of water.

But the main value, and the point the writer is coming to, is that it absolutely prevents any and all slime formation of the algae; also, it is practically noncorrosive and protects iron instead of attacking it. This last statement is based on the limited experimentation conducted by the writer. However, the writer believes that the prevention of slime formation alone would be worth while to justify further experimentation.

No doubt the author may already know of these materials, and has probably tried them; however, the writer would like the author to relate his experience along this line. But in case the author should not have made any experiments with the material mentioned, he certainly should be in a better position to do so than the writer, with his limited knowledge and apparatus.

W. A. Carter.[4] The writer would like to inquire if, as an aid to the operation of chlorine slime-prevention apparatus, any more rapid means than the laboratory death-rate studies can be offered to indicate when a change in the chlorine dosage should be made. There is often an unseasonable requirement for chlorine other than that shown by the test for chlorine demand and it is not realized until there is a partial loss of vacuum in the condenser. The death-rate study may be satisfactory in studying the chlorine requirements for a proposed slime-prevention installation, but there should be some quicker means of continually determining if the chlorine is being dosed frequently enough or for sufficiently long periods. The tests for chlorine demand or chlorine residual do not afford this answer, and the death-rate studies require too much time as well as the services of an expert.

Alex D. Bailey.[5] The writer would like to carry the history for this subject back beyond that which the author mentions. His attention was called to it by the paper on the treatment of water for condensing purposes with chlorine by L. L. Robinson,[6] who gave the origin of the idea and reports on tests conducted at the Hackney Electricity Works in England. About the same time a paper on the same subject was presented by H. W. Coulson,[7] who also reported on results at the Hackney Electricity Works.

As a result of this work, the engineers of the Commonwealth Edison Company, Chicago, took the matter up with representatives of Wallace & Tiernan Products and with the Electro Bleaching Gas Company. The representatives contacted did not know of the work done in England, but an agreement was made between the three organizations to conduct tests on the condenser of unit No. 3 at Northwest Station of the Commonwealth Edison Company. Twelve tubes were segregated in each of the two passes of the condenser and the water supplying these tubes was chlorinated. The test was started January 27, 1924, and continued until April 18, 1924. Although the results were quite satisfactory, it was decided to run a second test similar to the first, but using new tubes. This test was started April 20, 1924, and continued to June 21, 1924, and at that time the tubes were removed, split open, and comparisons were made with tubes using untreated water.

As a result of these tests, it was decided to treat all the water for this condenser, injecting the chlorine into the suction of the circulating pump. This test was started September 8, 1924, and ran until the end of October, the chlorine dosages varying from 0.25 to 0.45 ppm. In these tests, chlorine was fed continuously and the fact was established that the growth of slime could be prohibited, although it was not satisfactorily proved that it could be destroyed after it had formed. Because of the large amount of chlorine required and the high cost, which was then from 8 to 10 cents per lb, it was decided that the improvement would not warrant the expense of a permanent installation and its operation.

In the Transactions of the National Electric Light Association[8] there is a description of these tests, which is a part of the report of the Condenser Subcommittee of the Prime Movers Committee.

Shortly after the Crawford Station of the Commonwealth Edison Company was started, trouble was experienced with the sliming of the generator air coolers on unit No. 3, and chlorinating equipment was installed. This consisted of two chlorinators supplied by Wallace & Tiernan, one of which was of the vacuum type, intermittent feed; the other was of the old-style continuous feed. This equipment went into service August 16, 1926. The intermittent machine, probably the first of its type, proved unsatisfactory. It was subsequently rebuilt and put in service January 31, 1927, after which tests were continued until August of that year.

About this time, Dr. Enslow of the Chlorine Institute was contacted and he became quite interested in the results. On June 4, 1928, he came to Chicago and a meeting was held with representatives of Wallace & Tiernan, Electro Bleaching Gas, and the Commonwealth Edison Company. At this meeting it was agreed that the chlorination of all the circulating water for a large condenser should again be attempted using the intermittent process as this would reduce the amount of chlorine required. In the meantime the cost of chlorine had been considerably reduced. A very careful record of the performance of condensers for No. 1 unit at Crawford Station using raw circulating water was maintained for the balance of 1928, and arrangements were made to install intermittent chlorinating equipment on these condensers to be ready for service about the beginning of 1929. Those tests were successful and led to the permanent installation of chlorinating equipment on additional units.

M. S. Maurer.[9] Several parts of the author's paper express ideas which seem contrary to the writer's experience.

In the minimal chlorine death-rate studies, it appears that saline suspensions were used for the bacteria. These studies would seem to be of little practical value as they do not show the effect of the presence of organic matter. This is of major importance, for when the chlorine is added to a circulating water, it reacts with the organic matter first before acting on the bacteria.

It was shown by the studies in connection with the use of chloramines at Williamsburgh, that unless the organisms were

[9] Williamsburgh Power Plant Corporation, Brooklyn, N. Y.

freshly isolated and suspended in water taken from the circulating system, little if anything was accomplished by the laboratory work. It is well known that changes in the organic matter caused by bacterial growth will take place which affect the chlorine demand and therefore the germicidal efficiency. Thus, the time elapsing between taking the samples and running the tests is of great importance.

With regard to the ideas expressed by the author as to the formation of chloramines by the reaction of chlorine with ammonia occurring naturally in water, it appears to be generally recognized that chloramines are not formed from natural ammonia. We have examined a number of waters on the eastern seaboard in which the natural-ammonia content as determined by both direct Nesslerization and distillation was more than sufficient to form chloramines and in every instance, when an ammonium salt was added to the water, the chlorine demand was lowered. This is direct proof that the natural ammonia in these cases, did not form chloramines. It is true that chlorine will act more rapidly, in water free of organic matter, than chloramines. This property is lost, however, when the water contains sufficient organic matter to support the growth of bacteria in large numbers, as is the case in slime-forming waters. In this instance, chlorine reacts more rapidly with the organic matter than with the bacteria and a smaller amount of chlorine remains available for bactericidal action than where chloramines are used.

The author states that the formation of chloramines is of advantage in waters of abnormally high organic chlorine demand as it retards the combination of chlorine with the organic matter, thus requiring a lower quantity of chlorine to obtain a given residual. If this be true of high-organic-demand water then the same advantage must hold true in waters which have any organic demand whatever. As previously stated, all slime-forming waters have an organic content, and actual practice demonstrates that chloramines do have this definite advantage over straight chlorine in slime-forming waters.

In cases where the natural ammonia is high, unless an ammonium compound is added or in other words, a true chloramine treatment used, chlorine is at a decided disadvantage as the chlorine demand will probably be so high as to make a straight-chlorine treatment uneconomical.

The large generating station in the East referred to is the Williamsburgh plant of The Brooklyn Manhattan Transit Company. The author is entirely wrong in his statement as to the water conditions at this plant. The natural ammonia content is not low as stated, but high, and would be more than sufficient to form chloramines if they could be formed from natural ammonia. During the period when the author's company was trying out a straight-chlorine treatment at Williamsburgh, it was impossible to obtain slime control. However, by the addition of ammonium sulphate to this same water, the chlorine demand has been lowered and satisfactory slime control obtained. It would be interesting to know what reason can be ascribed as to why it is necessary to add ammonium salts at this plant, to get a chloramine treatment when the natural ammonia content is high.

In the cases cited in the Middle West and a small plant in the East, where the natural ammonia content is so high that excessive quantities of chlorine would be necessary to satisfy the demand due to the formation of chloramines, the writer is quite sure that the author is mistaken in the statement that chloramines would be formed, because if they were it would be unnecessary to add sufficient chlorine to combine with all the ammonia and only enough would need be introduced to form chloramines in amounts to give the desired germicidal action.

In waters containing natural ammonia there is usually an organic demand. It would seem the cases mentioned should be particularly adapted to the use of chloramines and were an ammonium compound to be added to any of these waters, the chlorine demand would drop and a more efficient bactericidal treatment obtained than if sufficient chlorine were added to satisfy the demand and give a germicidal residual.

With regard to the question of intermittent treatment, as interpreted in the past by the author's company, which necessitates complicated and expensive program equipment, it has been demonstrated by four large companies here in the East, namely, The Brooklyn Manhattan Transit Company, The Brooklyn Edison, The Interboro Rapid Transit, and the Public Service of New Jersey, that a half-hour dosage, once in 24 hr, is decidedly superior to short frequently repeated dosages. This is in accord with general bactericidal practice, the reasons for which are well known and it seems to be doubtful whether in any case the short frequent dosage would be preferable.

The mechanism of using a bactericidal treatment for slime control with the condenser in service is to use the circulating water as a carrier for the germicide which is to act on the organic growths on the tube surfaces. In the case of chlorine or allied chlorine compounds, the character of the water influences the amount of germicide available to kill the slime-forming organisms on the tubes. This germicidal residual is ordinarily determined with orthotolidin, and the orthotolidin is added immediately when the sample is taken. This immediate residual is not necessarily the germicidal residual available to kill the bacteria. At least 5 or preferably 10 minutes should elapse before the orthotolidin is added. The reason for this is that chlorine reacts first with the organic matter before reacting with the bacteria. This also applies to the organic matter in the layer of slime as well as the organic matter in the water. The sequence of events is the chlorine or chlorine compound first reacts with the organic matter in the water, then with any bacteria in the water and any residual remaining will then act first on the organic matter in the slime on the tube and last on the organisms in the slime layer. This is why the immediate residual has little significance and also one of the reasons for the half-hour dosage.

However, the most important thing in which we are interested is the slime layer on the tubes. This slime is very high in organic matter compared to the water from which it originates, and, as the author states, chloramines are superior to chlorine in the presence of high organic demand; it follows, due to this fact that chloramines will be advantageous over chlorine in acting on the actual layer of slime. This difference in action on organic matter results from chloramines being a much weaker oxidizing agent than chlorine.

Any water exhibiting an organic chlorine demand and which will form slime can be regarded as polluted. It is stated in the paper that chloramines are much slower in their action in slime control than chlorine, yet it seems to be generally recognized that in polluted water this is not so and the two are approximately equal in speed of killing in the presence of the organic matter, which is always present in slime-forming circulating water. It is difficult to reconcile some of the ideas the author expresses about chloramines with what has been published by his company on this same subject. For example, in Wallace and Tiernan's[10] Technical Publication No. 11 it is pointed out that the germicidal value of chloramine is almost three times that of chlorine. Further advantages of chloramine over chlorine are shown in Wallace and Tiernan's[10] Research Publication No. 327 where it is also pointed out that the use of chloramine is more specific than straight chlorine and that Wallace and Tiernan[10] found chloramines a great improvement over straight chlorine when used on slime-forming bacteria; also in acting on slime-

[10] Wallace and Tiernan Products, Inc., Belleville, N. J.

forming bacteria, chloramines require only one fourth the dose that chlorine required for the same length of contact and that, for the same dosage as chlorine, chloramines required only one fourth the period of contact.

This same publication also points out that the difference between chlorine and chloramine is that chlorine is a strong oxidizing agent and chloramine a very weak oxidizing agent; therefore, when bacteria are to be killed in the presence of a chlorine demand, the use of chloramines results in a larger proportion being available as a germicide than is the case with straight chlorine.

Further advantages of chloramine over chlorine are also shown in Wallace and Tiernan's[10] Research Publication No. 305.

The use of chloramines for the elimination of slime, at Williamsburgh and several other places, has indicated that they have the advantage over chlorine as stated in the Wallace and Tiernan[10] publications and that the ideas expressed by the author do not seem to be in accord with the results obtained.

Author's Closure

Mr. Aldinger has presented interesting details of a particular water treatment, in the handling of a type of problem common in the process industries. In the paper presented in December, 1937, the author was dealing with but one phase of the broad subject of water treatment, only that involved in the chlorination of very large volumes of cooling-water flow, as contrasted with the relatively smaller volumes of water that require sterilization in the recirculated spray pond or cooling-water systems, or in industrial-process water plants.

As was pointed out in the opening remarks of the paper, the present-day industrial uses of chlorination are founded on the accomplishments of chlorine in the field of drinking-water sterilization. An extensive review of the literature, including very old and more recent United States and foreign patents, discloses innumerable applications of a wide variety of chemicals and of special mechanical devices, having as objectives a method of bacteriological treatment that would prove to be reliable under any one of the many conditions common to the water-treatment field. These many alternate methods have not advanced into the realm of practical application, since in each case one or more important features have been found lacking, that have made chlorination so universally utilized at the present time. These features include availability of the chemical in convenient form, the extremely low cost now characteristic of chlorine, the development and advance in design of reliable proportioning and control apparatus, and the simple tests available for checking satisfactory chlorinator operation.

At the present time, in addition to the practically uniform use of chlorine in sterilization of drinking-water supplies, chlorination is also in general use in the smaller cooling-water plants, and in industrial-process water treatments. These smaller applications involve continuous rather than intermittent use of either chlorine or chloramines.

It has been the author's experience that slime growths are equally as troublesome, if not more troublesome in the smaller power and process water plants, and represent proportionately greater economic losses. It is true however that less frequently do these losses reach the same magnitude.

Wide experience is valuable in deciding upon the best and most economical method of accomplishing the desired result, without the risk of adverse reactions in the water-treatment plant, or in subsequent process steps, and in deciding whether continuous or intermittent applications of chlorine or of chloramines can best be utilized. The selection of type of treatment is dependent upon the nature of the contaminating organisms, the physical details of the treatment plant and the water distribution, and upon the nature of the process in which these treated waters are to be used.

Mr. Carter has inquired for a more rapid means by which it may be determined that the slime-prevention treatment is under proper control. Coincidentally with presentation of the original paper in December, 1937, experiments were undertaken and developments are now well under way, which involve electrometric means of analysis of water and slime-forming tendencies. It is proposed to report these developments more fully at a later date.

Mr. Bailey has called attention to an error on the part of the author, in failing through oversight to include in the paper presented in December, 1937, details of the Chicago experiments, a report of which had appeared in 1926 in the Transactions of the National Electric Light Association. This omission was corrected in an expanded version of the paper, which has received widespread distribution in reprint form. The author welcomes this opportunity to make a further apology.

Mr. Maurer's discussion is based on limited experience, and it is readily understandable that conclusions such as expressed might be reached without having a sufficiently broad background to permit of judging the relative merits of chlorine and of chloramines for a specific application. These conclusions fail to take into consideration basic differences in results obtained by these sterilization methods, as they may be made use of in drinking-water treatments, in the general industrial-process and paper-mill water-treatment field, as against the more specific applications in the condenser-cooling-water treatment.

Careful reading and unclouded interpretation of the original paper will serve to answer the questions raised. As experience is extended, the observations made in the paper will be confirmed, and a better understanding will be obtained of the various factors which must be taken into consideration in deciding in what types of applications the continuous or intermittent uses of chlorine or chloramines may prove to be most advantageous.

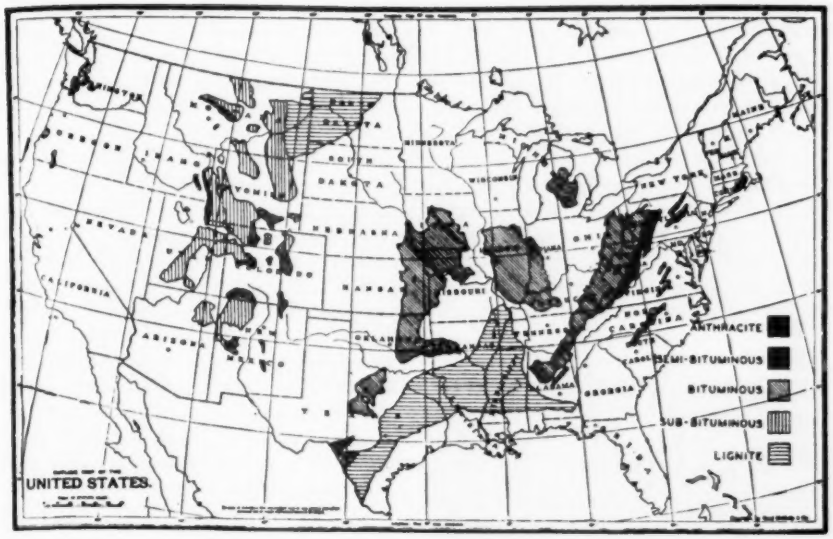

FIG. 1 COAL FIELDS OF THE UNITED STATES

Lignite—a Grate-Fired Fuel of the Future in the Southwest

BY CARL J. ECKHARDT, JR.,[1] AUSTIN, TEXAS

The paper describes the development of methods and apparatus for the practical use of Texas lignite as a grate-fired fuel. After presenting information on the extent and character of the deposits, and the constituents and characteristics of the fuel, the author describes early attempts at using it on hand-fired grates and follows the development through the overfeed-stoker stage to the present type of traveling-grate stoker using forced-draft and special furnace construction. A comparative table of heat balances indicates the improvement made. The author then discusses operating experience on boiler units with capacities up to 75,000 lb of steam per hr which give efficiencies as high as 76 per cent.

A résumé is also given of information on the firing of pulverized lignite, and increasing use of this fuel is predicted not only for grate and pulverized firing but also as a source for liquid and gaseous fuels.

THE FUEL reserves of the Southwest are divided by their constitution and characteristics into two distinct categories. One group is composed of the liquid and gaseous fuels, which can be used effectively at points far removed from their source as well as within the producing areas. The second group is composed of the solid fuels. A considerable portion of the Southwest's solid-fuel reserve possesses characteristics which limit its use to regions in the proximity of the mines.

The status of such states as Louisiana, Arkansas, Oklahoma, and Texas, with regard to the production of fuels of the first class, is well established because this section's distinction as a fuel-producing area is characterized by its prolific production of natural gas and petroleum products. The Southwest has produced 58 per cent of the natural gas consumed by the nation and 63.8 per cent of its crude oil for the last decade. The solid fuels of the area under consideration are as a general rule not superior to comparable solid fuels in other sections of the country. The region can, moreover, claim no great distinction for the magnitude of the production of this type of fuel at the present time. The failure to exploit its low-rank solid-fuel reserve to a greater extent must be attributed to the traditional regard of an area, within which fuel abounds, for fuels of a high rank and its disregard for fuels of the lower rank.

The prolific production of natural gas and petroleum products of the region is not being occasioned by the industrial development of the Southwest alone. On the contrary a great portion of these admirable fuels is being consumed in other sections of the country. Although the region is making a liberal contribution to the solution of problems confronting consumers of fuels in other sections of the country, it has made a comparatively small effort to develop processes for the utilization of vast amounts of potential energy which by their very nature are destined to be consumed in the area in which they are found. For the foregoing reason the low-rank solid fuels, which abound in this section of the United States, have assumed no position of importance in current industrial programs.

The Southwest produces a host of raw products of a vital order in prodigious quantities. Because artificial barriers have made necessary the processing of such products in other sections of the

Contributed by the Fuels Division and presented at the Spring Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New Orleans, La., February 23–25, 1939.

Discussion of this paper was closed March 25, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

country, the industrial development of the area has been held in abeyance. In the interim both fuels and raw materials in great abundance are being transported to other sections. Inasmuch as the deterrents are not warranted by natural circumstances, the Southwest will, when it liberates itself from these deleterious influences, resort to a much greater extent to the use of its low-rank solid fuels. Then such fuels as lignite, which must be consumed in the producing area, will assume a position of vital importance because industrial enterprises may be located directly upon and near the lignite beds where the use of this fuel will be prompted by economic expediency. The wisdom of achieving the fulfillment of such a plan is sound beyond any question of doubt. The time of its actual fulfillment remains a matter of conjecture.

FIG. 2 VIEW OF LIGNITE BED

More than 23,000,000,000 tons of lignite are deposited in Texas alone. The term lignite is generally used to denote "those coals which are distinctly brown and either woody or claylike in their appearance." In rank this material lies between peat and subbituminous coal. Although the biochemical action of the accumulation period of the formation of this fuel was quite complete, the absence of great thrust pressures in the course of the coalification period limited both dehydration and devolatilization processes to such an extent that it has remained a coal of low rank.

The depth of the lignite beds now being exploited varies from 15 to 160 ft. In many instances such factors as shallow overburdens, subterranean watercourses underlying the lignite beds, and the almost complete absence of rock make strip-mining methods expedient. At single mines as much as 65,000,000 tons of this material may be mined by such methods at depths ranging from 15 to 45 ft. For depths greater than 60 feet shaft-mining methods are generally employed. Such lignite beds, which are lenticular in character, vary from a few inches to as much as 16 ft in thickness.

The lignite which is now being mined possesses a claylike rather than a woody appearance and it has as its principal identifying characteristic a comparatively high moisture content. The magnitude of this moisture content "as mined" approximates 35 per cent. Its principal accompanying constituents are: Carbon, 40 per cent; hydrogen, 3 per cent; sulphur, 0.7 per cent; and ash, 9 per cent, all expressed on an "as mined" basis. Its heating value on the same basis varies from 7000 to 7500 Btu per lb.

Despite frequent reports to the contrary, lignite can be successfully burned as a grate-fired fuel. In the past many efforts have been made to burn this material upon grates of various types and designs. The reports of the results achieved have quite generally indicated that little, if any, success attended these efforts. Unfortunate indeed is the fact that almost without exception the fuel rather than the designing agencies was maligned because of such failures. Practically all unfortunate experiences of this kind should have been attributed to misapplication of equipment and improprieties in design. Instead such failures were believed to be due to the high moisture content of the fuel, to its comminution while in storage, to its disintegration while burning, and to its other burning characteristics.

The University of Texas in seeking the fulfillment of one of its fundamental purposes undertook, therefore, the task of making an investigation of the problems involved in the utilization of this fuel. Inasmuch as commercial agencies having means of loading larger units were in a better position to conduct research work related to the use of lignite in a pulverized form, the investigation has thus far been limited to grate-firing problems. The information which follows has as its background the investigations conducted at The University of Texas.

The water losses in the case of such lignitic fuels are by no means as great as they are quite generally supposed to be. Although the moisture content approximates 35 per cent, the actual heat loss due to moisture in the fuel varies from 5 to 6 per cent in the case of appropriately designed units. The heat loss due to the formation of water from the burning of the hydrogen in such units varies from 4 to 5 per cent and the heat loss due to moisture in the air approximates 0.3 per cent. The foregoing information indicates that water losses in the case of lignite render only approximately 10.5 per cent of its heating potential ineffectual. Although this aggregate loss is materially higher than that experienced in the case of higher-rank solid fuels and it is somewhat higher than that of fuel oil, the actual water losses in

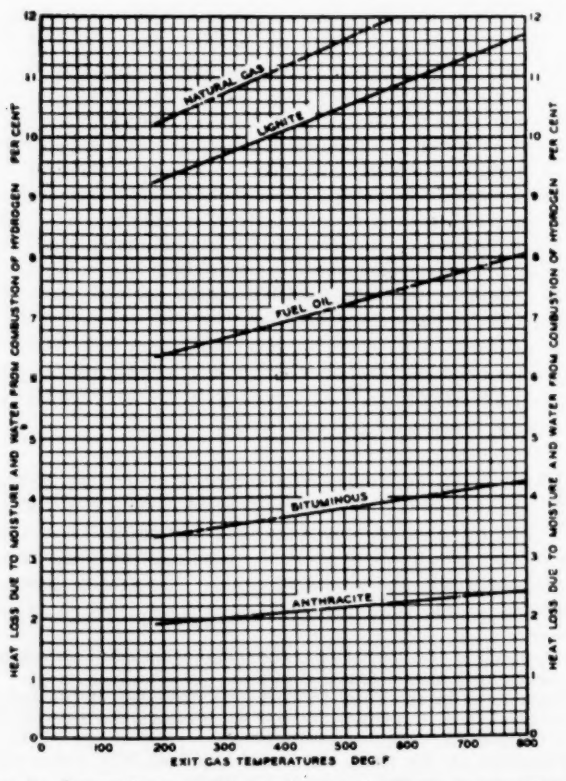

FIG. 3 CHART SHOWING WATER LOSSES INVOLVED IN THE USE OF TYPICAL LIQUID, GASEOUS, AND SOLID FUELS FOR A GIVEN ENTERING AIR TEMPERATURE

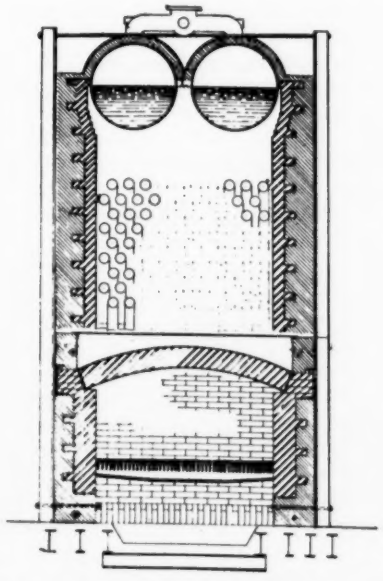

FIG. 4 VIEW OF SIMPLE LIGNITE-BURNING STEAM-GENERATING SYSTEM

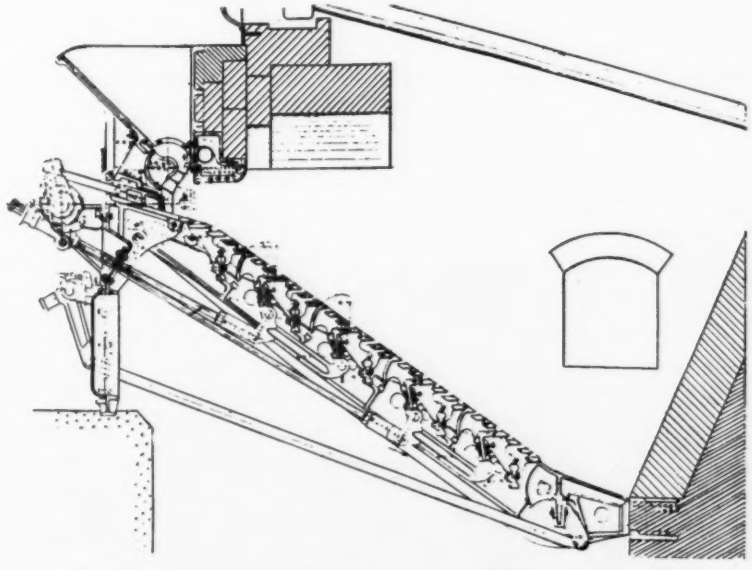

FIG. 5 VIEW OF LIGNITE-BURNING STEAM-GENERATING SYSTEM INVOLVING THE USE OF FRONT-OVERFEED TYPE OF STOKER

the case of lignite are not greater than comparable losses in the case of such an admirable fuel as natural gas.

The greatest opportunity for the reduction of water losses lies in dehydrating the lignite prior to its introduction into the furnace and in reducing exit gas temperatures to an economical minimum. Although satisfactory dehydration processes have been developed, at the prevailing fuel prices in the region under consideration, they are not commercially feasible. This fuel has, as a matter of fact, suffered its greatest disadvantages in the province of carbon and dry-gas losses. For that reason, in the consideration which follows, particular emphasis will be placed upon heat losses due to unconsumed gaseous combustible, unconsumed carbon in refuse, and dry chimney gases.

Original efforts made to burn lignite were made with a boiler, furnace, and grate possessed of greatest simplicity. Inasmuch as the lignite possessed a high moisture content, the ignition of this fuel was assumed to present a serious problem. Extended-front-type furnaces were employed in order that ignition arches might be used to effect the ignition.

Natural draft made mandatory the use of grates having liberally sized openings for the passage of air. The furnaces were arranged with such limited proportions that boiler heating surfaces were placed in the immediate proximity of the fuel bed itself. The difficulties actually experienced in operating such units might naturally have been expected by the designing agencies.

Improper control of the air supply resulted in the introduction of excessive quantities of air and in excessively high exit gas temperatures. The gases entered the first pass of the boiler in a stratified condition with zones of high oxygen and low carbon-dioxide content, and adjacent zones of low oxygen and high carbon-monoxide content. The use of a unidirectional forward flow of the gaseous products of combustion precluded the possibility of securing any degree of turbulence in furnaces which were too small to afford a reasonable period of time for the completion of the combustion process. The use of large air openings in the grates made unavoidable deleterious sifting losses.

Later efforts to eliminate desultory sifting losses employed the use of both chain- and traveling-grate stokers under natural-draft conditions. The arches continued to be used at the front of the furnace, no turbulence was provided, and furnaces were made entirely too small. Such units were frequently found to be unsatisfactory because of their inability to carry heavy loads and their incapability of responding appropriately to highly variable loads. The deficiencies of such units might well have been attributed to the failure of designing agencies to make due provision for those elements which are known to be absolute requisites for the completeness of the combustion process.

FRONT-OVERFEED STOKER

These experiences prompted the use of a different type of fuel-burning system which might be expected to eliminate serious sifting losses experienced in the case of the earliest units and at the same time to eliminate the restrictions of rapid responses to variations in load. For this purpose a front-overfeed type of stoker was next applied. The use of a grate surface which was inclined from the front to the rear of the furnace made possible the use of air openings placed in a horizontal rather than vertical plane. Natural draft was again used, but the size of the air openings was increased and the front arch was made materially shorter. Operating experience soon demonstrated the fact that in the use of this equipment the solution of old problems was accompanied by the introduction of new ones.

The introduction of air to the fuel bed in a horizontal plane to a free-burning fuel reposing upon a rather steep inclination, together with the oscillation of the grate bars, caused avalanching difficulties at moderate and comparatively high loads. The agitation of the fuel bed caused clinkering difficulties. Fractional loads could not be carried satisfactorily because of the absence of an appropriate control of the air supplied for combustion. Despite these deficiencies an improvement in performance over earlier units was effected. It is by no means improbable that by modifying the design of this system the magnitude of the deficiencies and difficulties experienced might have been rendered less potent.

TRAVELING-GRATE STOKERS

As the necessity for the design of larger units arose, the use of mechanical means for providing the air required for combustion

and for removing the products of combustion became imperative. By this circumstance the objectionable influence in the form of resistance to flow of primary air through numerous small air openings in the grate surface was overcome. In order that this free-burning lignite might be fired by a fuel-burning mechanism which provided a continuous undisturbed fuel bed from which the refuse disposition might be accomplished without cyclic fuel-bed disturbances, traveling-grate stokers were next applied. The multiplicity of the compartments through which the passage of the primary air to the various sections of the grate surface could be controlled not only afforded an opportunity for the reduction of dry-gas losses but also made feasible the use of perheated air.

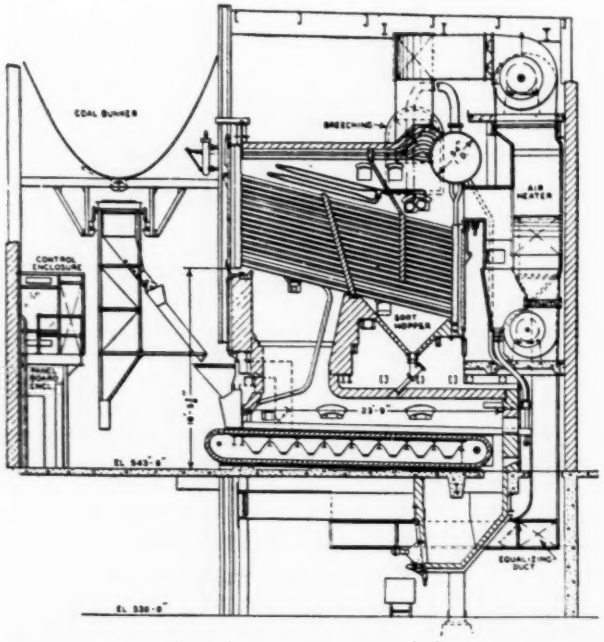

FIG. 6 VIEW OF LIGNITE-BURNING STEAM-GENERATING SYSTEM INVOLVING THE USE OF TRAVELING-GRATE STOKER AND MECHANICAL DRAFT

The principal departure from early designs in the case of the latest units consists of the almost complete abandonment of the front arch and the introduction of the use of a long low-hanging rear arch. By virtue of the fact that the ignition of lignite can in reality be accomplished with consummate ease, the elimination of the front arch involved no sacrifice in this respect and it materially reduced stratification tendencies.

With this type of design ignition is not only initiated, but its stable continuity is assured by the passage of hot gases from the rear of the furnace toward the front, and by the deposition of fuel particles partially burned in suspension as they are carried forward by the gas stream.

The reversal of the direction of flow of the gas stream reduced ashpit losses previously encountered with units having unidirectional backward flow of the products of combustion. The furnace arrangement is, moreover, such that the velocity of the lean gases flowing forward over the fuel bed is sufficient to create a desirable turbulence at the front of the furnace at the point at which the rich gases arise from the fuel just introduced. Inasmuch as the rear arch covers approximately 60 per cent of the grate surface, when the load on the unit is increased the amount of air admitted through the grate surface under the arch is likewise increased. A corresponding increase in the velocity of the forward-flowing gases intensifies the violence of the scrubbing action by which the rich and lean gases are mixed.

For high capacities air injection over the fuel bed is accomplished through the front furnace wall. For the reason just given, the turbulence just below the throat of the furnace is decreased as the capacity at which the unit is operated is reduced. The use of air admitted at the front of the furnace over the fuel bed is advisable at very light as well as very heavy loads. Just below the throat of the furnace the forward flow of the lean gases, the upward flow of the rich gases, and the backward flow of the secondary air admitted through the front furnace wall produce a scrubbing gaseous cylindroid. The height of the heat-absorbing surfaces above this cylindroid is sufficient to afford time for the completion of the combustion process. The heavier fuel particles entrained in the gas stream are thrown out onto the fuel bed and the length of travel of the lighter fuel particles is sufficient to assure the complete combustion of their combustible constituents before they are cooled to a temperature at which combustion is no longer supported. The carbon loss into the system beyond the furnace is for that reason of a negligible order. Table 1 shows heat balances for the three types of firing described.

PERFORMANCE

Five years of operating experience with units capable of generating from 30,000 to 75,000 lb of steam per hr has demonstrated that such lignite-burning steam-generating systems can be operated with remarkably high availability factors. Units of this design can be operated at the maximum capacities for

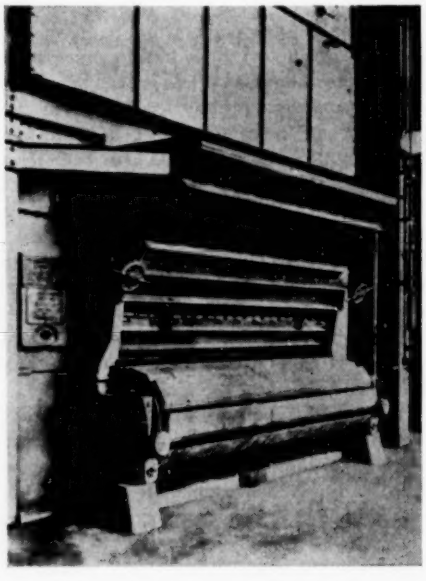

FIG. 7 VIEW OF TRAVELING-GRATE STOKER SHOWING MECHANISM BY MEANS OF WHICH FUEL-BED THICKNESS CAN BE VARIED

which they are designed with efficiencies as high as 75 per cent. Repetitive tests have demonstrated that under optimum conditions efficiencies as high as 76 per cent can be achieved. Although the air supplied for combustion is preheated to temperatures of from 250 to 375 F, in the 5-year period mentioned not a single stoker part has been burned out. In a like manner little difficulty has been experienced with solid refractory walls or with arches of refractory tile. Although from 1 to 12 per cent of the ash passes into the combustion loop, little difficulty has been experienced due to this circumstance. Frequent lancing of the narrow passages of the air preheaters has been found to be

	Stationary hand-fired grates		Front-overfeed stoker, natural draft		Traveling-grate stoker, mechanical draft	
	Btu per lb	Per cent	Btu per lb	Per cent	Btu per lb	Per cent
Calorific value of fuel as received	7066	100.0	7205	100.0	7475	100.0
Absorbed by water and steam	3715	52.6	4683	65.0	5681	76.0
Loss due to moisture in lignite	457	6.5	433	6.0	419	5.6
Loss due to water from hydrogen	301	4.2	295	4.1	302	4.0
Loss due to moisture in air	..	..	29	0.4	15	0.2
Loss due to dry chimney gases	..	..	1117	15.5	577	7.8
Loss due to unburned gases	..	..	0	0	0	0
Loss due to unburned carbon in ash	422	6.0	324	4.5	181	2.4
Unaccounted-for losses	2171	30.7	324	4.5	300	4.0

expedient. The use of side and scroll liners in induced-draft fans has eliminated difficulties which might otherwise have been experienced due to the abrasive action of the fly-ash particles which pass through the fan in the absence of a fly-ash precipitator.

Although it has been stated that, "Large quantities of unburned lignite drop through the grate surface even though the openings are very small," investigations conducted indicate that such statements may not be made with regard to appropriately designed systems. The actual amount of solid material passing through the grates of traveling-grate stokers amounts to approximately 0.1 per cent of the fuel fired. Inasmuch as a considerable portion of the material which sifts through the grates burns in the compartments and imparts its heat to the air passing to the grate surface, the actual heat loss is considerably less than 0.1 per cent of the heating potential of the lignite. It may, therefore, be neglected entirely without producing any appreciable difference in the performance as it is customarily computed.

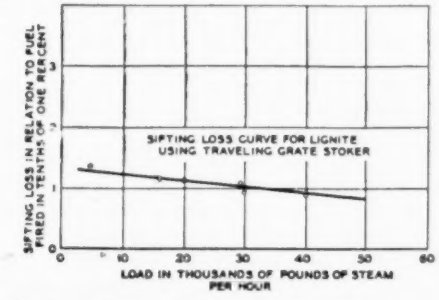

FIG. 8 CHART SHOWING AMOUNT OF LIGNITE AND ASH WHICH SIFTS THROUGH GRATE SURFACE OF APPROPRIATELY DESIGNED SYSTEMS

The foregoing information indicates that a factor which has frequently been regarded as possessing prohibitive importance can in reality be reduced to absolute insignificance.

As the combustion rate of such steam-generating systems is varied, both the amount of fuel introduced and the thickness of the fuel bed may be varied in a like manner. At the same time the amount of air supplied and its point of introduction may be changed in a corresponding manner throughout a comparatively wide range of operating conditions. Because of the speed and accuracy with which these variable factors can be

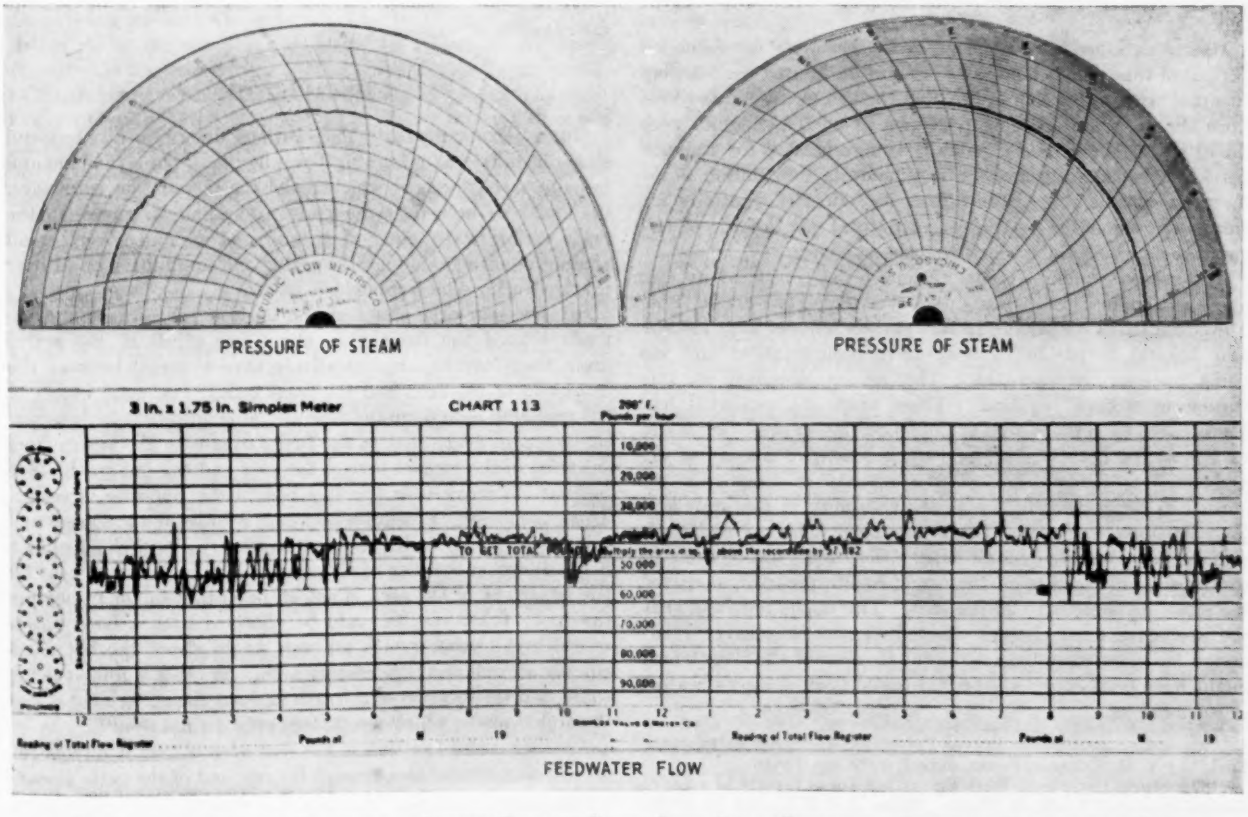

FIG. 9 CHART SHOWING RESPONSE OF LIGNITE-BURNING GRATE-FIRED STEAM-GENERATING SYSTEM TO VARIATIONS IN LOAD

controlled, there can no longer be any justification for the belief that lignite is an unsatisfactory grate-fired fuel because steam-generating systems, deriving their energy from this source, cannot be operated at high capacities and are incapable of responding to highly variable loads.

It has been said of lignite that, "With improper draft conditions holes will be formed in the fuel bed which will cause bad distribution of the air and poor combustion." This statement is true not of lignite alone but of all other solid fuels as well. There can be no justification for such a statement with regard to properly designed grate surfaces. In the case of the traveling-grate stokers the magnitude and arrangement of the air openings can be carefully fixed in the selection of the grate keys. In burning lignite on such fuel-burning equipment no difficulty of the nature mentioned need be experienced at all.

Pulverized Firing

In the foregoing part of the paper only grate-fired units of small and moderate sizes have been discussed. The purpose of the discussion has been to indicate that lignite can be satisfactorily burned on a grate surface. It should not be inferred that lignite can only be used to advantage in small units or as a grate-fired fuel. This paper has been limited to a discussion of grate-fired installations only because reliable information has already been published with regard to the use of this fuel in pulverized form. A brief review of two such papers will call to the reader's attention the source of such information. Early efforts to burn Texas lignite in pulverized form on a commercial scale were made at Comal Station of San Antonio Public Service Company where three steam-generating systems each capable of generating approximately 225,000 lb of steam per hr were installed. The reports[2] indicate that satisfactory results were obtained. These systems involved the use of forced- and induced-draft fans and recuperative air preheaters of the plate type.

Operating efficiencies as high as 79 per cent for extended periods of time and as high as 81 per cent for limited periods were reported when using lignite predried to such an extent as to reduce the moisture content to 29 per cent. These units were found to be reliable and capable of being operated for 4-month periods between inspections. Inasmuch as this station is removed a considerable distance from its source of lignite, it has since been converted to the use of natural gas because of circumstances which did not involve fuel cost alone.

The greatest amount of lignite now being consumed by any single station in Texas is being used at Trinidad Station of Texas Power & Light Company. In that station units of both 185,000 and 325,000 lb per hr capacity have been installed and are being successfully operated. The results obtained at this station have been reported.[3] These units are somewhat less complicated than those used at Comal Station in that they resort to the use of natural draft and do not involve the use of air preheaters or economizers. This simplicity in design was regarded as being contributive to the reliability of the units and their low operating cost. The performance achieved with such units involves yearly over-all boiler efficiencies ranging from 76 to 77 per cent based upon the use of lignite predried to reduce the moisture content to 26 per cent. The report indicates that the saving in fixed charges effected by the simplicity of the design has been more than sufficient to offset the savings which might have been expected from the installation of air preheaters or economizers.

[2] "Operating Experience Proves Pulverized Lignite a Satisfactory Fuel," by V. H. Braunig, *Power*, July 2, 1929, pp. 13–16.

[3] "Operating Experience With Pulverized Texas Lignite in a Large Central Station," by N. G. Hardy, Trans. A.S.M.E., vol. 58, 1936, paper FSP-58-4, pp. 267–275.

Fundamentally the use of lignite does not involve materially greater complications than other fuels of a solid nature. That systems of pulverized-fuel firing can be applied effectively in the case of large steam-generating systems has been definitely demonstrated. In the case of small units, the application of stokers seems advisable. Such stoker-fired units are capable of being operated in an entirely satisfactory manner. In the case of small units, the improvements in performance made possible by pulverization are generally more than offset by the preparation costs and the additional fixed charges resulting from a higher initial capital investment for preparation equipment. It is not impossible that, when the use of lignite becomes widespread, effective low-cost systems for pulverizing and firing lignite in small units may be developed.

Just cause for alarm does not exist in the Southwest because of any pessimistic outlook regarding either the exhaustion of its tremendous sources of potential energy, the classes of fuel previously mentioned, or for that matter any serious diminution of its bountiful natural resources. Cause for alarm does, however, exist because of the ruthless methods by which amounts of the more admirable fuels, almost beyond human comprehension, are being extravagantly wasted and because of the utter disregard of the area for its fuels of a lower order. In order to extend the benefits derived from the use of the more admirable fuels as far into the future as possible, definite steps must be taken to reduce wasteful practices which involve the better grades of fuel and to increase the amount of the lower-grade fuels consumed. The period of sufficiency of both liquid and gaseous fuels is assumed to be materially shorter than that of solid fuels. Approximately half of the nation's solid-fuel reserve consists of subbituminous coal and lignite. As the period approaches, in which these low-rank fuels will begin to assume a serious importance, lignite will not only be used as a grate- and pulverized-fired fuel, but it will, no doubt, likewise be used in the manufacture of liquid and gaseous fuels.

Discussion

Henry Kreisinger.[4] The author describes a successful stoker installation for burning Texas lignite. Three fundamental principles are involved which make the installation successful: (*a*) long rear arch over the grate; (*b*) small air spaces in the grate giving nearly equal distribution of air and a very small amount of siftings through the grate; and (*c*) addition of air over the fire for burning combustible gases.

(*a*) The rear arch starts at the back of the furnace and extends toward the front over about two thirds of the active grate area, leaving a comparatively narrow throat between the front end of the arch and the front wall. The main object of the rear arch is to force the products of combustion to flow over the incoming fuel; that is, the fuel moves with the stoker from the front of the furnace toward the rear and the hot products of combustion move over the fuel bed in the opposite direction. Thus, the incoming fresh fuel is swept over by the hot gases and is brought quickly to ignition temperature. The arch acts like a baffle directing the flow of the gases. The radiation of heat by the refractory of the arch is not an important factor in heating the fuel. Good results could be obtained with a bare water-cooled arch, because such an arch would direct the hot gases equally as well as the refractory arch. In other words, it is the shape and the location of the arch and not the material of which the arch is made, which accomplishes the desired results.

Another useful function of the rear arch is that it directs the air entering, around and through the rear end of the grate toward

[4] Engineer in Charge, Research and Development, Combustion Engineering Company, Inc., New York, N. Y. Mem. A.S.M.E.

the front part of the furnace, where it mixes with the combustible gases rising from the fuel bed. These gases generally contain no free oxygen and need air for their combustion.

(*b*) The small air spaces in the grate offer a high resistance to the flow of air as compared with the resistance of the fuel bed. Inasmuch as the air spaces are equally distributed over the grate area, the air distribution is nearly uniform even though the condition of the fuel bed may vary. In other words, the flow of air is determined mainly by the resistance of the grate which is constant and only to a small extent by the resistance of the fuel bed which is small and may vary.

(*c*) The gases rising from the front part of the active fuel bed contain a large percentage of combustible and very little or no free oxygen. Air is, therefore, supplied under pressure through the front wall at the level of the throat. This air owing to its high velocity bores into the stream of combustible gases and produces both rapid mixing and quick combustion of the gases. It is necessary that there be sufficient combustion space above the throat available for the mixing and for the combustion of the gases.

E. A. Wood.[5] Texas lignite undoubtedly has wide possibilities of usefulness. Strange as it may seem, The University of Texas uses lignite in its power plant and, because of the fine research work that has been done by the author, it saves money for the University. Up to the present time, neither oil nor natural gas has been able to compete successfully with lignite at The University of Texas. This is true in spite of the fact that there is no railroad spur at the University's power plant. The lignite has to be hauled by rail from Bastrop, Tex., a distance of 47 miles to Austin; thence from Austin to the University by truck, a distance of 2 miles.

Because of the Texas Planning Board's interest in the utilization of the state's natural resources by industry and because of the author's research and practical demonstration of the utility of this particular resource, the board has become very much interested in the possibilities of the future uses for Texas lignite. There are more than 23,000,000,000 tons of this fuel available in Texas. Consequently, this fuel should be of interest to many industries. The fact that it has not been of much interest in the past is probably largely due to the reasons given by the author, namely, too much moisture, poor combustion, ability to slack, and because it dropped through the grate.

It would appear from the paper that these difficulties have now been overcome and that Texas lignite should enjoy a much better reputation as a fuel in the future than it has in the past. Of course, its usefulness will be limited by present freight rates within a certain radius, which will equal the economical haul. Fortunately, however, the lignite beds of Texas lie close to the most heavily populated sections of the state and not too distant from the Gulf Coast, where great ports have already been developed. Among others should be mentioned Houston, Port Arthur, Beaumont, Galveston, Texas City (location of the Carbon and Carbide Company's new plant), Corpus Christi, Port Isabel, and Brownsville. Water transportation, either by barge on the Intracoastal Waterway, the Mississippi and its tributaries, or by ocean-going vessels is therefore readily available for those industries seeking a cheap and abundant fuel for manufacturing purposes.

In addition to The University of Texas, the Austin Street Railway Company in Austin, a cotton-oil mill in Austin, the Morton Salt Company at Grand Saline, the Round Rock Lime Company at Round Rock and others use lignite as fuel. At Marshall, the Darco Corporation is using lignite to make "Darco" an activated-carbon product used as a filtrant.

[5] Director, The Texas Planning Board, Austin, Tex.

Dr. E. P. Schoch, director of the Bureau of Industrial Chemistry of The University of Texas, reports tha the "has perfected a simple method for removing all the moisture from lignite, while keeping the material essentially in its original lump form and filming it throughout with a total of about 2 per cent of petroleum oil to make it waterproof. The process, mechanically, is practically identical with the procedure for treating wet timbers with creosote oil under pressure. Of course, it employs petroleum oil instead of creosote oil. This process has just been announced from the laboratory, and active steps for its commercialization are under way in Canada."

W. R. Woolrich.[6] It is fortunate for the Gulf-Coast area that its future industrial-fuel demand can be filled by a generous reserve of lignite. In much of the area in which lignite is available, the rainfall is very limited and uncertain and the rivers fluctuate widely. Thus for industrial power the rivers cannot be considered potential prime power sources to take the place of oil and gas when these fuels become less abundant. Lignite will be the future fuel for many of these areas.

The author's contribution to engineering research, in developing efficient and economical methods of burning lignite on chain-grate stokers, will have more and more historical significance as the existing fuel reserves of other more desirable forms of fuel become exhausted.

It is gratifying that the developed method eliminates the need of drying the fuel before firing under power-plant boilers. Lignite can be successfully dried for domestic use but the cost is considerable.

The Bureau of Industrial Chemistry of The University of Texas has developed a method of removing the excess moisture which seems most promising. At a relatively low cost, a very satisfactory domestic fuel can be provided by this new method. However, while natural gas and oil are quite generally available in most of the Southwest, no great expansion of lignite usage in domestic stoves and heaters is anticipated.

About 25,000 tons of lignite are burned annually in the University's plant under Professor Eckhardt's direction. This supplies the fuel needs for power, heat, and light to The University of Texas campus buildings on a 24-hour-per-day basis. Interruptions to service are practically unknown at the University power plant.

Author's Closure

The investigative work, which has heretofore been done at The University of Texas in the case of the utilization of lignite as a grate-fired fuel, has in its entirety been of a preliminary order. It has had as its objective the dissemination of information calculated to dispel the most serious erroneous beliefs which have been formulated with regard to this fuel. It is hoped that in the ultimate a sufficient amount of authoritative information may be made available by which the use of this fuel will be demonstrated to be economically expedient to a far greater extent than it now is. The abundance of very admirable fuels in the State of Texas and its adjoining states and the absence of a specific industrial-development program have given little, if any, impetus to research work calculated to improve the effectiveness with which solid-fuel deposits of the lower rank might be utilized.

The State of Texas is at this time producing forty per cent of the nation's petroleum, more than thirty-three per cent of its supply of natural gas, eighty-five per cent of its sulphur, and in prodigious quantities many other minerals by far too numerous to mention here. The value of its mineral products exceeds that of any other state in the country. Many valuable mineral de-

[6] Dean of Engineering, University of Texas. Mem. A.S.M.E.

posits are not now being exploited at all. Of the minerals produced, by far the greater portion is processed in other sections of the nation. This state produces almost twice as much cotton as any other state in the Union as well as the preponderant portion of the nation's wool and mohair. From a standpoint of its agricultural and ranching products it has assumed a position of great importance. Despite these and many other accomplishments it has continued to remain a poor region.

It is obvious that despite the fact that its natural resources have been exploited at a rapid rate, the region has not profited from transactions by which its raw materials and potential energy in the form of fuel have both been transported to other sections of the nation. The establishment of industrial enterprises for the utilization of Texas' forests in the paper industry and the establishment of initial factories for processing chemical deposits as well as cotton and wool gives evidence of the fact that American business has become conscious of the attractive possibilities offered by this section of the country for the conduct of industrial enterprises. Virtually all natural circumstances promote this consciousness. It does not seem unreasonable to hope that all deterrent artificial barriers will have been broken down in the not-distant future.

When the industrial development of this region is seriously undertaken then the utilization of fuels which can only be utilized gainfully in the region under consideration will not only be indicated, but will likewise be prompted by economic expediency. The fact that such fuels as lignite offer no attractive possibilities in regions far removed from their source should not be inferred to indicate that they cannot be expected to assume a position of importance in the producing areas. The research work must obviously be done now in order that the use of this fuel may be made as purposeful as possible.

By-Product Fuels in the Steel Industry

By E. G. FOX[1] and W. B. CLEMMITT,[2] CHICAGO, ILL.

A normal annual supply of by-product gases, having a heat content equivalent to about 32,000,000 tons of coal, results from the production of metallurgical coke and from the smelting of pig iron. This paper deals comprehensively with the uses within the steel industry of coke-oven gas, blast-furnace gas, and mixtures of the two gases, which constitute the by-product fuels. After outlining the characteristics and combustion properties of each, the authors give in some detail their applications to the various heating requirements of steel production. The process of mixing the two gases to obtain the maximum heat value is explained thoroughly. The fact is stressed that by-product fuels be utilized in processes where the greatest economic value will result. The method of arriving at the potential values of these gases in relation to that of tar, fuel oil, and coal is fully expounded, several examples of cost analyses being cited to illustrate the procedure.

APPROXIMATELY 37,000,000 tons of pig iron were produced in the United States in 1937. To supply metallurgical coke for this operation, it was necessary to coke about 54,000,000 tons of coal. The total gases resulting as by-products from these operations had a heat content equivalent to about 32,000,000 tons of coal. If the screened-out coke breeze and the tar be added, the total of potential by-product fuels, resulting from steel-plant operations, amounts to some 35,000,000 tons coal equivalent. This is equal to about 7.5 per cent of the national coal consumption. The effective use of these by-product fuels is obviously a matter of some import.

The principal by-product fuels of the steel industry, with an indication of their relative heat content in a balanced plant, are as follows:

Blast-furnace gas, per cent	55.0
Coke-oven gas, per cent	35.0
Coke breeze, per cent	6.5
Tar, per cent	3.5

Coke-Oven Gas. Coke-oven gas contains about 25 per cent of the heat value in the coal from which it is produced. Derived by releasing the volatile content of coal by heat in the absence of air, it comprises principally hydrogen and hydrocarbons and is low in carbon monoxide, carbon dioxide, and nitrogen. After being exhausted from the ovens, it is treated for removal of by-products. Extensive cleaning operations are essential to by-product recovery. The resulting product is a relatively clean gas of about 520 Btu per cu ft delivered substantially saturated with water vapor, at atmospheric temperature and gas-holder pressure.

While there is a wide range in the quantity and the heating value of the gas delivered from an individual oven during the coking operation, dependent upon the time elapsed since charging, the product from a battery of ovens which are charged in sequence, is very uniform. Changes in the coal mixture may affect both the gas quantity and analysis. Changes in the coke-production rate, effected by varying the coking time, affect the rate of gas production correspondingly. Such changes are infrequent. Operation is continuous 24 hr per day and 7 days per week.

Coke-oven gas is delivered either from the holder or from the supply line to boosters, which increase the pressure for distribution. For use at the bulk-consuming units in the steelworks, the gas should be delivered at a pressure of at least 5 lb per sq in. Small consumers, such as normalizing furnaces, commonly require pressures from 5 to 10 lb per sq in. It is customary practice to boost the gas for these uses in local compressors to a pressure between 15 lb and 20 lb per sq in.

Coke-oven gas burns with a transparent but rather white flame, which tends to be somewhat buoyant. It requires theoretically about 5 cu ft of air per cu ft of gas for perfect combustion. Very little excess air is required in practice, due to the high ratio of air to gas and the consequent intimacy of mixing. The flame is characteristically short. The gas will hold ignition temperature under less favorable conditions than most industrial gases, because of the high flame temperature and rapid rate of ignition. Coke-oven gas is not commonly preheated, as any substantial preheat (in excess of 500 F) causes the hydrocarbons to break down, resulting in deposition of carbon in regenerator or recuperator chambers.

Blast-Furnace Gas. Blast-furnace gas contains about one half of the heat value in the coke charged into the blast furnace. The analysis, heat value, and top temperature of blast-furnace gas differ according to the kind of iron or ferrous alloy being produced. The heat value usually ranges between 85 and 100 Btu per cu ft. For a given operation, the analysis is not entirely uniform, a range of plus-or-minus 5 per cent in heat value being typical. Blast-furnace operations are subject to delays ranging from five minutes to an hour or more, incident to tuyère changes and other operating emergencies. During such periods, gas production is discontinued. The rate of blowing may be varied over a wide range to suit production to demand. About once in three years a furnace must be blown out for relining and repairs which consume about two to three months. Since most plants have but a few blast furnaces, the shutting down of one furnace deducts substantially from the production of gas. The trend toward larger blast furnaces accentuates this condition. In general, it may be said that the supply of blast-furnace gas is subject to much wider variations than the supply of coke-oven gas.

Due to its bulk, it is not ordinarily considered feasible to store large quantities of blast-furnace gas. A 10,000,000-cu ft gas holder contains only about 2 hr gas output of one 1000-ton blast furnace. Consequently, it is necessary to adjust the consumption of blast-furnace gas to the supply.

Blast-furnace gas leaves the top of the furnace at a temperature between 250 and 700 F and at a pressure between 15 in. and 60 in. of water. It has a dew point of about 120 F corresponding to a moisture content of about 30 grains per cu ft, this being contained in the blast and picked up from the burden which may be wetted to restrict top temperature and dust pickup. It is generally cleaned in wet stationary towers to about 0.25 grain per cu ft, the gas leaving the towers saturated and carrying considerable entrained moisture. Improved towers, with cyclone dust-and-moisture eliminators, deliver saturated gas of about 0.1 grain dust per cu ft. Further cleaning may take place in rotary disintegrators or in electrical precipitators. By these means the gas may be cleaned to less than 0.01 grain dust per cu ft.

Gas which is to be used to underfire coke ovens, and that in-

tended for gas-engine use, is generally cleaned to 0.01 grain per cu ft or better. Gas which is to be used at open hearths and heating furnaces should not contain in excess of 0.05 grain per cu ft.

Blast-furnace stoves can be designed with large checker openings (3.5 to 4 in.) to use gas having 0.25 grain dust per cu ft. Such stoves have efficiencies on the order of 80 per cent. Stoves having somewhat smaller checker openings (2.5 to 3 in.) can use gas having 0.15 grain dust per cu ft. Such stoves are about 85 per cent efficient. Stoves with small checker openings (2.0 to 2.5 in.) may be built to give 90 per cent efficiency. Such stoves require gas containing not more than 0.03 grain dust per cu ft.

Blast-furnace gas is delivered from wet-cleaning operations at a pressure as low as 1 in. or as high as 20 in., depending upon the nature of the gas-cleaning equipment and on the pressure required to effect distribution. The pressure at which the gas leaves the blast furnace may be sufficient to pass it through the several cleaning operations, transport it through distributing mains, and deliver it to consumers at a pressure of 2 to 6 in. water necessary for its utilization. In such event, the pressure is supplied by the relatively efficient blast-furnace blowing apparatus. In other instances, a lower furnace top pressure is desired and it is necessary to boost the gas pressure for distribution to about 25 in. Due to its low heating value and low pressure transport, blast-furnace gas requires relatively large mains for distribution.

Process Consumers of By-Product Fuels

Melting, refining, heating, and heat-treating are major steps in the production of steel. The cost of fuel for these operations is about 15 per cent of the total cost of conversion processes. The steel plant affords a large market for its own by-product fuels.

Coke Ovens

For many years by-product ovens in steel plants have been underfired with coke-oven gas. Most of the ovens constructed during recent years are adapted for underfiring with blast-furnace gas. The operation is one involving relatively low temperatures, for which blast-furnace gas is well-suited (coke pushed at 1750 to 2200 F). Both the blast-furnace gas and the combustion air are preheated. In order to prevent the clogging of flues, very clean blast-furnace gas is required, containing not to exceed 0.01 grain of dust per cu ft. The coking process is entirely continuous and there are no interruptions or substantial variations in gas use. Reliability of gas supply is essential, as stoppage of underfiring affects the quality of the coke, and expansion and contraction of refractories may lead to substantial injury to the oven structure. It is possible to change over from blast-furnace-gas underfiring to coke-oven-gas underfiring in an hour or less, but several hours may be required to adjust operations satisfactorily to the change. Therefore, frequent change-overs are undesirable. Usually no provision is made for firing of auxiliary fuels, but ovens are given first preference as to gas supply. Precautions may be taken, such as providing gas-holder storage.

Blast-Furnace Stoves

The moderate temperatures which are required for blast-furnace stoves (air-blast temperature 1000 to 1500 F) can be obtained from blast-furnace gas without preheat of either gas or air. Great reliability of gas supply is not essential. If a blast furnace is not being blown, stove heating is unnecessary. The refractories in blast-furnace stoves can store considerable heat. The storage capacity of the stoves is utilized by permitting the gas input to stoves to vary with fluctuations of gas production and use, proper combustion being maintained by automatic burner control. If the stoves are equipped with adequate pressure burners which place the combustion chamber of the stove under pressure, it is often possible to burn gas at a maximum rate equal to twice the average rate. In this manner the stoves act as a flywheel, tending to absorb some of the fluctuations in blast-furnace-gas supply.

The storage capacity of the blast-furnace stove permits of reduction in firing in the event of a temporary gas deficiency. This can be made up subsequently by increased firing. It is possible to reduce the blast temperature and the consequent sustained requirement of gas for firing the stoves. However, such action should be anticipated by about fourteen hours to permit compensation by charging additional coke to the blast furnace, the time element being that required for such coke to descend to the tuyère zone in the furnace.

Blast-furnace stoves have always been fired by blast-furnace gas exclusively. No auxiliary fuel is provided. Because of special conditions existing in certain plants which desire to release blast-furnace gas for use elsewhere, projects have been made for burning oil and natural gas at the stoves.

Open Hearths

The open-hearth department is usually the largest consumer of process heat in a steel plant. At the same time, it requires the highest temperatures. It is a batch process involving melting and refining operations. The total time of a heat will range from 8 to 16 hr. During the melting period, the heat input may be increased substantially above the average rate; during refining operations only enough heat may be applied to maintain temperatures, restricting the input to as low as 15 per cent of the average rate. Fig. 1 shows how the fuel input and the heat release in an open-hearth furnace vary through the heat.

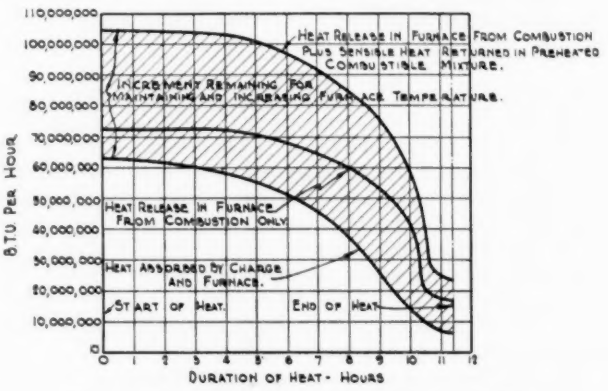

Fig. 1 Heat Release and Absorption for One Open-Hearth Heat

Coke-oven gas has been successfully applied to open-hearth furnaces. The gas burns with a transparent flame which is lacking in radiating power. Consequently, greater dependence must be placed on heat transfer by convection. Gas velocity, gas distribution, and turbulence play a role.

To avoid difficulties associated with transparent flame, it is customary to burn tar or oil in combination with coke-oven gas. The flame is directed close to the surface of the bath where its local luminosity expedites heat transfer to the near-by bath more effectively than to the more remote furnace roof. A combination is satisfactory in which 10 to 25 per cent of the heat input is in the tar or oil, the balance being in the coke-oven gas. However, in plants where the coke-oven-gas supply is limited, more of the heat input may be in liquid form.

Mixed coke-oven and blast-furnace gas is being successfully and increasingly applied to open-hearth furnaces. This mixture burns with a rather transparent, bluish flame. In at least one instance in the United States, the gas mixture is being preheated

to a temperature high enough to cause some cracking of hydrocarbons, a luminous flame resulting. The mixture tends to a lower theoretical flame temperature than straight coke-oven gas, and consequent lower furnace temperature. Absence of potential excessive heat head encourages even heat distribution and minimizes local overheating of refractories. Some variation in the composition of the mixture is permissible.

The fuel requirements of a single open-hearth furnace vary. There may be as many as fifteen furnaces in one shop, and some plants have several shops. In such plants the effect of diversity is to cause a substantially uniform fuel demand. Open hearths commonly operate continuously throughout the week.

Reliability of fuel supply is considered essential, although no serious damage will result if the fuel supply should fail for an hour or so. Most furnaces burning mixed gas are equipped to burn oil or tar in the event of failure or inadequacy of gas supply. Hence the open hearth may be considered as a large and steady consumer for which mixed blast-furnace and coke-oven gas is well suited. It is somewhat adaptable and accommodating in the event of variation or interruption of gas supply.

Soaking Pits and Heating Furnaces

Soaking pits and heating furnaces differ strikingly from open hearths in thermal requirements, in that they involve a lower range of temperature, such as 2200 to 2500 F as contrasted with the 2900 to 3250-F range required in the open hearth.

In soaking pits and heating furnaces, the function is to elevate the steel to rolling temperature, evenly distributed throughout the mass. The question of heat-penetration rate arises. A somewhat higher rate of heat penetration may be permissible during the earlier stages of heating, a limited rate of penetration during the later stage being desirable to obtain uniformity of temperature. The rate of penetration to cold steel is limited by possible damage to the steel resulting from wide temperature differences between surface and interior. The permissible heating rate is influenced by the quality of steel being heated.

Soaking pits and heating furnaces may be fired with coke-oven gas, mixed gas, or straight blast-furnace gas. The use of the latter two fuels is relatively recent. Coke-oven gas has long been applied. It is clean and convenient, but tends to be harsh if combustion air is preheated. Blast-furnace gas gives excellent results at soaking pits, where a moderate heat input is required for slow heating, with most of the heat transfer by convection. Straight blast-furnace gas has been used in continuous-heating furnaces, but the cost of such furnaces is rather high. Separately heated regenerators, for preheating the combustion air to a high temperature, are necessary. Mixed blast-furnace and coke-oven gas makes an excellent fuel for reheating furnaces. The mild, distributed heating obtained with mixed gas is particularly advantageous in furnaces heating thin sections As compared with producer gas, the cleanliness of mixed gas renders it more adaptable to use of automatic combustion controls. A mixture of about 33 per cent coke-oven gas and 67 per cent blast-furnace gas, having a heat value of about 230 Btu per cu ft, or any richer mixture, can be employed. It is not usual practice to vary the mixture at individual furnaces, but the mixture supplied to a common mill line, feeding a group of heating furnaces, may be changed without undue inconvenience. This possibility permits some flexibility in adjusting the supply of the two component gases to the demand.

Individual soaking pits and heating furnaces are relatively small consumers so that variations in their demands are readily absorbed by diversity in any extensive installation. Since most mills discontinue operations during week ends, the fuel requirements of these furnaces reduce nearly to zero over a period of about 20 hr each Sunday.

Annealing and Heat-Treating Furnaces

Annealing, normalizing, and heat-treating operations ordinarily involve temperatures on the order of 1200 to 1700 F. Slow, uniform heating is desirable. Preheat of combustion air is not ordinarily practiced. For such duty, blast-furnace gas or a lean mixture of coke-oven and blast-furnace gases, having inherently moderate flame-temperature characteristics, is ideal. The fact that such furnaces are generally small consumers and are often rather remotely located may cause the cost of distribution of blast-furnace gas to them to be prohibitive. On the other hand, annealing furnaces of the radiant-tube type require the use of straight coke-oven gas or a rich mixed gas.

Firing Boilers With Blast-Furnace Gas

It has long been customary to burn a major portion of the blast-furnace gas under boilers. This practice has been due in part to the usual proximity of the boiler plant, the ease and low cost of application, and the readiness with which supplementary fuels can be provided at boilers. It is common practice to burn blast-furnace gas in combination with powdered coal or fuel oil, or to provide for the exclusive burning of one of these supplementary fuels in the event of a deficiency of blast-furnace gas. When burned in combination, the supplementary fuel feed may be governed automatically as required to meet steam demands and blast-furnace-gas availability.

Blast-furnace gas is an eminently satisfactory fuel for boilers if these are adapted to its use. Because of the low flame temperature and consequently low furnace temperature, it is desirable that the combustion air be preheated. This is particularly essential when blast-furnace gas is used in a steam generator with waterwalls. Because of the relatively large volume of products of combustion (1.4 times coal), ample furnace volume and adequate provision for convection-heat transfer are necessary. When burning cold blast-furnace gas, care must be exercised not to reduce the rate of firing so low as to permit the furnace to cool below ignition temperature.

Blast-furnace gas may be fired to boilers as received from the dust catcher at a temperature of about 300 F, with the moisture content in superheated condition and carrying about 3 grains of dust per cu ft (standard), or it may be fired in cold saturated condition after wet cleaning. The hot dirty gas may produce about 5 per cent more steam, a factor of considerable import. The avoidance of gas-cleaning costs is an additional saving. The amount of dust carried into the furnace by hot, dirty, blast-furnace gas, is comparable with the ash in pulverized coal. This dust in the gas may have a salutary influence on combustion in that the hot dry dust particles glow and assist ignition. On the other hand, hot gas may require a larger gas main, which may be brick-lined to retain the sensible heat in the gas. More or less trouble may be experienced in keeping such a main clean, particularly if the amount of gas transported and the consequent gas velocity vary over a wide range.

In a few instances, blast-furnace gas is cleaned in electrical precipitators of dry type, retaining most or all of its sensible heat. A cleanliness such as 0.25 grain dust per cu ft is attained. Such gas is well-suited for boilers and blast-furnace stoves having large checkers.

If washed gas is fired under boilers, it is preferable that a cleanliness in the order of 0.15 grain dust per cu ft or less be attained. It is particularly desirable that the gas carry a minimum of entrained moisture. Wet dirty gas carrying perhaps 0.3 grain of dust and considerable entrained moisture can be utilized, but much trouble is experienced at the burners and in the gas lines due to sludge, and boiler tubes become encrusted. The cold wet dust tends to extinguish the gas and interferes with ignition at low ratings. Furthermore, entrained water is an immediate

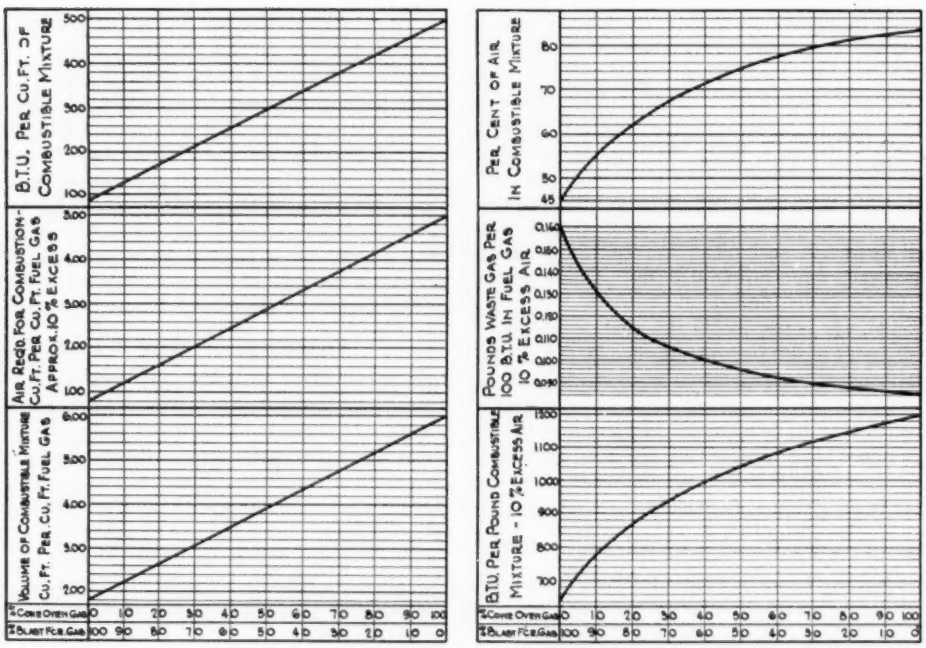

Fig. 2 Characteristics of Coke-Oven and Blast-Furnace-Gas Mixtures

and drastic debit against the net heat value of the gas, since it must be evaporated and superheated, with the absorption of almost 1/4 Btu per grain of water.

A choice between hot dirty gas and cool washed gas for boilers must depend on local conditions. If only a minor variable fraction of the gas is to be burned under boilers, it is most feasible to utilize the gas in the condition of its preparation for other uses. If, however, a major portion of the gas is to be burned under boilers regularly, the economies and advantages of hot gas should receive some consideration.

Coke-oven gas is seldom fired under boilers as it has been considered too valuable for other uses. However, it may prove desirable to burn some coke-oven gas under boilers on week ends. If coke-oven gas is substituted for blast-furnace gas in a boiler arranged for burning the latter, provision may be necessary to prevent overcooling of the lesser volume of combustion products in the air preheater or economizer, as pitting may result, particularly in view of the large amount of water vapor in the combustion products of coke-oven gas.

Gas Engines

Formerly a substantial portion of the blast-furnace gas was sent to gas engines driving blast-furnace blowers or electric generators. With improved practice in steam plants, the large space requirements, the heavy investment and maintenance charges associated with gas engines, are difficult to justify. The inflexibility of this use and the inability to substitute other fuels are serious disadvantages. Gas engines must be spared by steam-driven units. The advantages which accrue to the burning of the last variable increment of blast-furnace gas under boilers, supplemented by other fuel, do not accrue to gas-engine operations; in fact, gas engines are consumers which demand first consideration in the matter of regularity, reliability, cleanliness, and uniformity of supply.

Fuel Mixtures

As previously mentioned, coke-oven gas is frequently used in combination with tar or oil at open-hearth furnaces. Coke-oven gas has been added successfully to hot producer gas. There would appear to be a limited demand for such a combination, except as a means for disposing of an excess of coke-oven gas. Coke-oven gas has also been used in combination with still gas and the mixture has been used in combination with oil.

Principles of Mixed Gas Application

In the selection and application of fuels for steel-plant furnaces, it is desirable that two important considerations be met in order that the applications may be most effective and also most efficient. First, it is desirable that furnace-temperature conditions be developed which are well-suited to the process to be performed. Second, it is desirable that fuel consumption be minimized through the reduction of stack losses.

The latter consideration commonly requires that the heat in stack gases be used to preheat the combustion air, or both the air and fuel gas. The combustion products leave an open-hearth furnace at about 2700 F; they may leave a soaking pit or a side-door heating furnace at 2000 F; they often leave continuous-heating furnaces at temperatures up to 1000 F. For fuel economy, it is important that a substantial part of the heat contained in the products of combustion at these temperatures be recovered.

If part of the heat in the products of combustion is utilized to preheat the combustion air and/or the fuel gas, the effect of such preheat is to raise the temperature developed in the furnace by the fuel being used. An amount of preheat, which may be desirable from a fuel-economy standpoint, may not result in the most advantageous furnace temperatures and consequent heating performance.

The availability of two gaseous by-product fuels of widely differing characteristics offers opportunity, in the steel plant, to adapt the fuel to the needs of the application through the selection of one fuel or the other, or through use of mixtures of the gases in most advantageous proportions. The advantages which accrue through the use of mixed gas are being increasingly recognized.

The curves in Fig. 2 show pertinent data concerning mixtures of blast-furnace and coke-oven gas and their combustion charac-

teristics. The volume of combustible mixture per 100 Btu in the fuel, for blast-furnace gas, is about 1.66 times that corresponding to coke-oven gas. The weight of waste gases, per 100 Btu in the fuel, is 1.9 times greater for blast-furnace gas than for coke-oven gas. Because of the greater volume and weight of the products of combustion, recovery of waste heat from these products is somewhat more significant as related to the leaner gas mixtures, particularly those containing less than about 30 per cent coke-oven gas.

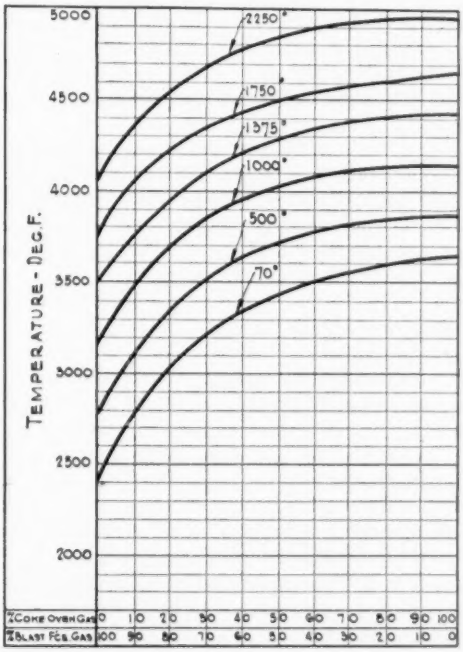

FIG. 3 THEORETICAL FLAME TEMPERATURES; MIXTURE OF BLAST-FURNACE AND COKE-OVEN GASES
(Combustible mixtures preheated to various temperatures; 10 per cent excess air.)

The amount of fuel and heat which can be handled by a given furnace is limited by speed of combustion, gas velocity, and draft considerations on the one hand, and by ability to deliver heat to the charge on the other. The lesser volume and weight of combustion products per 100 Btu in the fuel contributes to greater permissible heat release in a given furnace with coke-oven gas than with blast-furnace gas. The shorter coke-oven-gas flame is another favorable factor. Furthermore, the higher effective flame-temperature characteristic of the richer fuel increases the temperature difference or gradient between flame and charge, thereby favoring both radiant and convection-heat transfer. The richer fuels enjoy a distinct advantage with respect to rapid heating of cold steel.

It should be noted, in this connection, that preheat contributes to greater total heat release in a given furnace without encroaching on the limitations incident to heat release resulting from combustion. Fig. 1 gives an indication of the contribution to heat release made by preheat.

The greater relative volume of combustion products is advantageous to the leaner fuels, particularly with respect to moderate heat release when the temperature of the charge is high and the fuel feed is restricted. The larger relative volume of products may fill the furnace volume better, thus improving heat distribution; it may aid convection-heat transfer, thus minimizing the temperature difference necessary between the charge and the flame. The longer flame also favors uniformity of temperature through the furnace. The leaner fuels enjoy a distinct advantage as to quality of heating.

The curves, Fig. 3, show the influence of gas mixture and preheat on flame temperature. The lowermost curve shows theoretical flame temperatures corresponding to various mixtures of blast-furnace and coke-oven gas when burned cold in combination with cold combustion air. The next higher curve shows the effect of preheating the air or gas or both to such extent that the combustible mixture has a temperature of 500 F. Other curves show the effect of higher amounts of preheat.

It is impossible to attain the theoretical temperatures shown in these curves. The nearest approach to them can occur in an empty furnace or one in which the charge is fully heated. Under such conditions, all the heat released in the furnace is required to compensate for furnace losses and to maintain the furnace temperature. The maximum actual mean furnace temperature approximates 85 per cent of the theoretical flame temperature, depending partly on furnace design, exposure for radiation, and insulation.

When a cold charge is introduced into a furnace, it absorbs part of the heat released, thereby restricting the portion of the heat which is available for maintaining furnace temperature. The result is the drawing down of the mean furnace temperature, perhaps to about 50 per cent of the theoretical flame temperature.

As the charge becomes heated, the gradient between the furnace temperature and the charge tends to decrease. The charge therefore absorbs a smaller portion of the heat release. The furnace temperature increases. An increasing portion of the heat release per unit of fuel is then available and is required to maintain the higher heat level. The furnace temperature attained at any moment is determined by the portion of the heat release which is available to elevate the furnace temperature. If heating were continued indefinitely, the condition would eventually be attained under which the charge would absorb no further heat and "empty-furnace" conditions would apply.

Under typical working conditions, a portion of the heat release is absorbed by the charge and the mean furnace temperature approximates 75 per cent of the theoretical flame temperature.

Through application of these approximate ratios or percentages to the theoretical flame temperatures shown in Fig. 3, the following deductions may be made. These are merely explanatory of established practices.

1 An increase in preheat results in an increase in furnace temperature, which accelerates the rate of heating. An increase of 750 F in preheat may elevate the furnace temperature an amount, such as 200 F.

2 The richer fuels enable favorable heating rates (indicated by the disparity between theoretical flame temperature and mean furnace temperature) to be maintained at higher furnace temperatures.

3 A cold charge will draw down furnace temperatures further with a lean fuel than with a rich fuel; consequently heating is more rapid with the richer fuel. If a very lean gas is used with low preheat, furnace temperatures may be drawn down by a cold charge and cool furnace so low as to jeopardize ignition of the gas.

4 The use of a richer fuel permits the attainment of a given furnace temperature, with a given proportion of the heat release available for the charge, at a lesser preheat.

5 A temperature of about 3250 F cannot be attained, even with empty-furnace conditions, through use of a mixture containing less than 30 per cent coke-oven gas with 1000 F preheat. If 1750-F preheat is employed, a fair rate of heating may be attained. With this amount of preheat, a furnace temperature of 3250 F could hardly be attained with straight blast-furnace gas. All the heat input would be required merely to attain such a heat level.

6 With the richer fuels, unless the charge does absorb a substantial portion of the heat input, furnace temperatures will rise far beyond limits which the refractories can stand. This demonstrates the need of careful adjustment of fuel quantity to restrict furnace temperatures when rich fuels are combined with high preheat. If there is lack of uniformity of heat distribution or of absorption by the charge, use of a rich fuel with high preheat may easily lead to dangerous flame and furnace temperatures in localized areas. If less preheat is employed, the danger of excessive local temperature is reduced.

7 A rich gas mixture in combination with high preheat may be used to advantage to bring the charge up to melting temperature but, if a lean mixture is employed near the end of the heat,

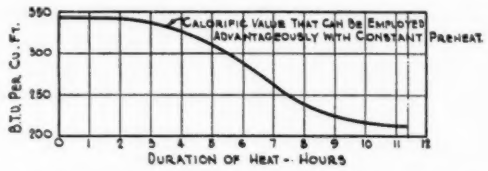

FIG. 4 POSSIBILITY OF VARYING CALORIFIC VALUE OF FUEL

when it is desired to deliver little heat to the charge, the danger of attaining damaging furnace temperatures through failure to restrict the fuel feed quickly enough, or through uneven distribution and local heating, is minimized. The manner in which this practice is applied is indicated in Fig. 4. This figure may well be viewed in relation to Fig. 1. In actual practice, the Btu content of the gas mixture is adjusted in steps, as the heat progresses, rather than along a smooth curve as shown in Fig. 4.

8 If mixed gas, containing about 80 per cent coke-oven gas by volume (420 Btu per cu ft) be used, it is possible to attain a furnace temperature of 3250 F with a good rate of heat input into the charge, if the combustible mixture is preheated to 1750 F. Such a mixture might be used advantageously during the initial stages of the heat. Since about 80 per cent of this mixture is air, preheat of the air only to about 2150 F gives an equivalent result. If this amount of air preheat is applied during the later stages of a heat to a gas containing 20 per cent coke-oven gas (170 Btu per cu ft), the combustible mixture will have a temperature of about 1300 F. With such a mixture, a furnace-temperature level of 3000 to 3250 F could be maintained only provided there is little or no heat input into the charge. Thus a mixture containing about 20 per cent coke-oven gas is a minimum which can be used to hold temperature in an open hearth where only the air is preheated to a maximum feasible temperature of about 2150 F.

9 As applied to heating furnaces requiring a heat level of about 2500 F, blast-furnace gas must be given high preheat if a fast rate of heating is to be carried up to rolling temperatures. A heating furnace, using blast-furnace gas fuel with 1000-F preheat of the combustible mixture, might be sluggish as rolling temperatures are approached.

10 If rich gas mixtures are used with high preheat, the furnace charge may be heated at high rates up to and well beyond desired rolling temperatures. Hence such combinations tend to be rash, causing uneven heating or washing of the steel. For heating furnaces which will employ high preheat, the use of lean fuel mixtures is indicated. Where but little preheat is to be employed, richer mixtures become desirable. If no preheat is to be employed, only the richest fuels will be adequate.

It should be recognized that the curves indicate general conditions applying when the gases are burned with about 10 per cent excess air at the furnace. Variations from this condition affect the situation. An increase in excess air not only increases the weight of waste gases, but it lowers the flame temperature substantially. The curves do not take into consideration the effect of chemical reactions on open-hearth-furnace temperatures. In general the curves represent conditions which are attainable with favorable design, construction, and practice.

PREHEAT AND RECOVERY OF STACK LOSSES

The amount of preheat which may be most advantageous from the viewpoint of furnace operation, is not a fixed quantity. When a charge of cool steel is being heated or melted, a high degree of preheat could be utilized without danger of attaining excessive furnace temperatures. On the other hand, when little heat is being delivered to the charge, a limited amount of preheat would be desirable, particularly with rich fuels, in order to limit the theoretical flame temperature and the consequent furnace temperature.

No practical method has been developed for varying preheat. It is prevailing practice to provide fixed preheat facilities, resulting in fairly uniform preheat. For a given fuel, it is desirable that the amount of preheat be such that a moderate rate of heat delivery to the charge can take place when the charge approaches or attains its maximum desired temperature.

As a general indication of relations between furnace temperatures, preheat, and recovery of heat in the products of combustion, the following examples are cited:

1 With fuel mixtures containing more than 60 per cent coke-oven gas, advantageous furnace conditions in a 2500-F furnace are obtained with no preheat and consequently no waste-heat recovery. With straight blast-furnace gas, burned at a furnace equipped with regenerators or recuperators, a recovery of about 55 per cent of the sensible heat in the combustion products between 2000 and 800 F is indicated to be adequate to the attainment of good furnace temperatures.

While it is true that heating furnaces burning coke-oven gas are often equipped with regenerators or recuperators, such provision is primarily directed at the recovery of waste heat. Some increase in theoretical flame temperature inevitably results, with a consequent tendency to furnace temperatures higher than necessary. Preheat tends to shorten the flame and is thus inimical to heat distribution resulting from slower combustion.

2 In an open hearth, using straight coke-oven gas, advantageous furnace conditions are obtained with a heat recovery of about 80 per cent of the heat in the waste gases contained in a 2700- to 1400-F range, or about 45 per cent of a 2700- to 400-F range. With a mixture containing about 25 per cent coke-oven gas (200 Btu per cu ft), a heat recovery of about 80 per cent of a 2700- to 800-F range is necessary from a furnace-operating standpoint. This would be a full practical recovery for this range in view of inevitable heat losses in the regenerators due to radiation and possible infiltration.

In general, the leaner mixtures afford greater possibilities for complete waste-heat recovery without attendant furnace conditions of a character which require close regulation of fuel input and uniform distribution of combustion and heat absorption in order to avoid excessive furnace temperatures. This statement does not apply to cases where the waste heat recovered is not returned to the furnace, i.e., to the cases where waste-heat boilers are used.

Improved types of recuperators which are now available, are factors favorable to the more extensive application of lean gas mixtures for heating-furnace duty.

QUANTITATIVE RELATIONSHIPS

The selection and mode of application of by-product fuels in the steel plant is naturally influenced by the availability of those fuels. Individual plants differ widely, dependent primarily upon the relative coke-, pig-iron-, and steel-making capacities;

the kind of coal, ore, and iron; whether all steel is by the open-hearth process; the amount of scrap used; the extent of rolling operations, etc. Existing pipe lines, furnaces, regenerators, and other equipment influence the practice adopted in by-product gas utilization. It may be enlightening, however, to consider the relations of gas supply and possible demand for a rather typical new plant where such restrictions were nonexistent. Table 1 is taken from a project for the Dnieprostal Steel Works in the Ukraine, U.S.S.R. The initial plant as projected, included four blast furnaces with coke ovens adequate to supply these furnaces. Most of the steel-melting capacity employed the open-hearth process, although some electric furnaces were included. A more or less typical complement of mills was involved. Electric power was to be received from the Dnieprostroy hydroelectric development near by. Steam turboblowers were installed to serve the blast furnaces.

TABLE 1 PROCESS-HEAT REQUIREMENTS IN A STEEL PLANT IN RELATION TO BY-PRODUCT-GAS SUPPLY

	Heat required				
Department	Total heat C-O[a] and B-F gases, per cent	Heat in B-F gas, per cent	Heat in C-O gas, per cent	All process heat, steam included, per cent	Process heat, excluding steam for blowers and coke ovens, per cent
Coke ovens (ovens)	17.4	27.2	48.5	16.2	19.0
Process steam	5.1	7.9	14.1	4.7	...
Blast furnace (stoves and losses)	18.1	28.2	50.5	16.8	19.6
Turboblowers	10.5	16.0	28.5	9.8	...
Open hearth	28.1	43.8	78.5	26.1	30.5
Soaking pits	8.2	12.7	22.6	7.6	8.9

	107.6	167.3	298.9	100.0	100.0
Deficit	7.6	67.3	198.9		

[a] C-O signifies coke oven; B-F signifies blast furnace.

While 64 per cent of the heat content of the by-product fuels at the plant indicated in Table 1 is in the blast-furnace gas, this represents 91 per cent of the gas volume. Nine per cent of the volume is coke-oven gas, containing 36 per cent of the total heat. If the two gases were mixed in toto, a lean mixture would result having a heating value of about 125 Btu per cu ft. Such a fuel would not be well-adapted for use at the open hearths and heating furnaces, for which a richer fuel is desirable. Moreover, if all the gas were mixed at one point, it would not be possible to select for each consuming plant the kind of gas or the mixture best suited to its requirements. Nor would it be possible to vary the mixture at the open hearth with the progress of the heat. It is more rational to distribute the gases separately and to use portions of the blast-furnace gas without mixing, thereby obtaining a richer mixture for the balance.

It is entirely logical to allocate straight blast-furnace gas for use at coke ovens and stoves. This gas is well-adapted to these operations. The layout of the plant in question is favorable to easy distribution of blast-furnace gas to these consumers. Moreover, these consumers require gas seven days a week, therefore introducing no week-end storage problem.

After thus allocating 55 per cent of the blast-furnace gas to stoves and coke ovens, the remaining 45 per cent might be mixed with the coke-oven gas. The resulting mixture would contain about 82 per cent blast-furnace gas and 18 per cent coke-oven gas, the heat value being about 165 Btu per cu ft. This is still too lean for open-hearth and heating-furnace use.

An additional 12.7 per cent of the blast-furnace gas may be used advantageously at the soaking pits. If about 15 per cent of the blast-furnace gas be allocated to annealing furnaces and to boilers to produce steam for coke ovens and blast-furnace use, a total of about 84 per cent of the blast-furnace gas will have been utilized. The remaining 16 per cent, mixed with all the coke-oven gas, gives a mixture of about 63 per cent blast-furnace gas and 37 per cent coke-oven gas, with a heat content of about 240 Btu per cu ft. Such a gas can be employed at open hearths and heating furnaces if provision is made therefor.

The foregoing analysis shows in a general way how the by-product fuels available in a plant may be allocated to process-consuming units. The relations given in Table 1 apply to capacity operations. If the plant as a whole, or any departments thereof modifies its production rates, the relations change. It is of course necessary to provide for any combination of conditions which may arise. If auxiliary fuels are required, investments are involved which must be included in the economic picture.

Economic Factors Involved in Allocation of Gases

It has been indicated that there are several definite potential consumers of blast-furnace and coke-oven gases in steel plants. Some practical considerations influencing the allocation of these gases have been mentioned. It is further of consequence that these gases be used where they will realize the greatest economy. Stated in another manner, it may be said that the gases should be sold to consuming plants which can pay the most for them. Table 2 gives some conception of the merit of various applications and indicates the factors involved.

In the case of oil, the cost of fuel plus necessary storage, heating and pumping, plus maintenance and fixed charges on storage and handling equipment, brings the cost to about $0.247 per million Btu. In a plant which must fire oil or tar, the value of the tar is substantially the same as that of oil, unless tar can be sold at a premium.

The cost of producer gas is indicated to be substantially lower, per million Btu, than oil. The cost figures for mixed gas are

TABLE 2 EVALUATION OF BY-PRODUCT GASES[a]

Elements of cost per million Btu in fuel	Oil or tar	Coal for producer gas	Coke-oven gas and oil, 50% mix	Mixed gas; coke-oven and blast-furnace, 230 Btu per cu ft

[a] Approximate or typical costs assumed:
Steam coal, cost ..... $3.50 per ton, delivered
Gas coal, cost ..... $4.00 per ton, delivered
Fuel oil, cost ..... 3½ cents per gallon
Electric power, cost ..... 8 mills per kilowatthour
Fixed charges ..... 15 per cent

Transportation cost based on 1200 ft of gas pipe line between respective gas sources and consuming department; length of lines might be doubled without material change.

based on a mixture having 230 Btu per cu ft. The charges include only the costs of preparation and delivery of the coke-oven and blast-furnace-gas components. In the case of a mixture of coke-oven gas and oil, the fuel cost of the oil only and all handling costs for both fuels are included. Fixed charges on all fuel preparation and transportation requirements are included.

In comparing these fuels for use at an open hearth, cognizance must be taken of the differences in fuel input required. The use of producer gas introduces substantial losses in producers. Mixed gas shows the highest economy for reasons already indicated. Fuel-consumption figures will vary in individual cases. The relations shown in Table 2 are typical, indicating that, under the conditions assumed, oil fuel costs $1.19 per ton ingots. If half the oil is replaced by coke-oven gas, the fuel cost per ton ingots is $0.63. The fuel value of the coke-oven gas for this application is the difference, i.e., $0.56 per ton ingots. The requirement of coke-oven gas is 2.4 million Btu per ton ingots. The value of the gas is $1.19 — 0.63/2.4 = $0.234 per million Btu.

Similarly, if coke-oven gas and oil were used in lieu of producer gas, the value of the coke-oven gas would be $1.18 — 0.63/2.4 = $0.229 per million Btu. This figure may be discounted if the producers already exist, so that their fixed charges continue whether or not the replacement fuel is used.

If mixed blast-furnace and coke-oven gas is used in lieu of oil, the value of the mixed gas is $1.19 — 0.068/4.5 = $0.25 per million Btu.

If mixed blast-furnace and coke-oven gas is used in lieu of producer gas, the value of the mixed gas is $1.18 — 0.068/4.5 = $0.202 per million Btu.

At the heating furnaces similar conditions exist. If mixed gas is used, somewhat lower fuel consumption may be expected. The figures tabulated show that, if mixed gas is used in lieu of oil, the value of such gas is about $0.273 per million Btu. If used in lieu of producer gas, the value of the mixed gas is about $0.332 per million Btu.

Similarly at the soaking pits, it is indicated that mixed blast-furnace and coke-oven gas has a value of about $0.283 to $0.318 per million Btu, under the conditions assumed. Since such a mixture can be replaced by straight blast-furnace gas with equivalent performance, blast-furnace gas has a value on this order for this application.

The values of mixed gas, as determined, refer to the component of coke-oven gas at the ovens before boosting the pressure for transmission, and the component of blast-furnace gas at the blast-furnace plant prior to cleaning and boosting.

These figures indicate that, under the conditions assumed for the example, heating furnaces and soaking pits can bid a higher price for mixed gas than can open hearths. This result is in conformity with general experience, but local considerations may affect the situation substantially. The cost of supplying mixed gas to scattered mill furnaces is likely to be higher than the cost of delivery to a bulk consumer such as the open hearth. Heating furnaces with regenerators or recuperators suitable for mixed gas may also involve additional first cost.

These figures for valuation of mixed gases for open-hearth and heating-furnace use are not inclusive of savings in refractory costs which may occur through use of milder fuels. Nor do they include such important factors as improved quality of steel resulting from better heating, decreased scale loss or elimination of the necessity for removal of suphur from coke-oven gas, which may be possible if it is diluted with blast-furnace gas. Other local or intangible factors may have a bearing.

Blast-furnace gas, burned under boilers, replaces coal which costs about $0.16 per million Btu, including preparation costs. If the gas is burned in cold saturated condition, the boiler efficiency is about 4 points lower with the gas than with coal. The gas thus has a replacement value of about $0.152. From this must be deducted $0.015 for preparation and transport, giving a net comparative value of the untreated gas of about $0.14. If the gas is burned hot, a substantial increase in heat value results from retention of the sensible heat and cleaning costs are avoided. On this basis the gas has a value of about $0.15 per million Btu.

If blast-furnace gas replaces coke-oven gas for underfiring coke ovens, it attains a value equal to that of coke-oven gas, less the rather nominal cost of preparing and transporting the blast-furnace gas for this use.

It has been rather customary to evaluate coke-oven gas according to the price which it will bring if sold to a utility. In some cases such an evaluation may not be entirely justified. If producer gas or oil is used in plant processes, the price which such consumers can bid for the gas for replacement purposes is a more realistic measure of value. Furthermore, it should be noted that coke-oven gas acquires a substantial increment of excess value if, through mixture with blast-furnace gas, it enables the latter to acquire a value such as $0.27 per million Btu for process use, as compared with $0.15 per million Btu for boiler use.

The foregoing examples bring out the fact that in many plants blast-furnace gas is the major by-product fuel. The problem is to use that lean fuel in processes where it has a higher value than when used under boilers. This can be accomplished if available coke-oven gas is directed to enrichment of a mixture rather than to separate application. Rather lean mixtures can be used if preheating is adequate. The use of mixed gas offers advantageous heating performance simultaneously with improved economy.

The Characteristics of Atmospheric-Type Burners When Used With Natural Gas

By E. D. HOWE[1] and H. G. JOHNSON,[2] BERKELEY, CALIF.

In this paper it is determined that the design of atmospheric-type gas burners depends upon the stability of the flame produced, which is related to the speed of flame propagation in the combustible mixture. Experiments made upon single-port gas burners have served to show that the effective velocity of flame propagation is greater than the velocity of flame propagation in still mixtures. It has been found that natural gas can be burned at a rate of approximately 30 cu ft per hr per sq in. of port area. The authors summarize the matter of hydraulic design of inspirators in the form of an equation, the validity of which is demonstrated by experiment. This equation suffices to determine the mixture ratio when the gas rate and density are known.

FOR SEVERAL YEARS investigations have been under way at the University of California on the problem of designing atmospheric-type gas burners. This work was initiated by the Pacific Coast Gas Association Fellows and has lately been carried on by other graduate students and by Works Progress Administration research workers.

The particular design problem involved is that of the atmospheric- or Bunsen-type gas burner. This type burner may be regarded as consisting of two units, i.e., the inspirator and mixing tube, and the burner head or exit port. The inspirator-and-mixing-tube assembly acts as a jet pump, utilizing the kinetic energy of the gas jet to entrain the primary-air supply and force the mixture of gas and air through the burner-head passages and ports. The burner head serves to distribute the combustible mixture as desired within the furnace or space to be heated and also to form a barrier between the flame and the fresh mixture being delivered. Although the inspirator, mixing tube, and burner head are often cast in one piece they are treated separately in this paper, because the same design of inspirator and mixing tube may be used with any one of a variety of burner heads. Such a burner is shown schematically in Fig. 1. From a study of this diagram, it is evident that the combustible gas entrains some air as it leaves the jet and mixes with the primary air in the mixing tube. The mixture flows through the burner ports, beyond which the flame occurs. Additional or secondary air for completing the combustion is drawn from the space around the burner.

The design of this type of burner consists in determining (*a*) individual and total port areas; (*b*) gas-orifice diameter; (*c*) inspirator proportions and dimensions. The procedure in this paper will be to indicate the performance characteristics of the two elements, thereby placing limits on the design.

Performance of the Burner Head

The rate of heat generation possible with a burner head depends upon the stability of the flame. This in turn is a function of the primary mixture ratio, the velocity of the mixture through the ports, and the flame speed in the primary mixture. The range of stable operation of a burner head is limited by the phenomena of flash back and blowoff. A further limit to the useful range is imposed by the yellow-tipped or sooty flame. Flash back occurs when the flame speed is greater than the mixture speed through the ports so that the flame flashes back through the port openings. Blowoff occurs when the flame speed in the mixture is less than the mixture speed through the ports, thus causing the flame to blow away from the ports. The yellow-tipped or sooty flame occurs when the total air supply from both primary and secondary sources is insufficient to burn the gas along the center line of the burner port.

The useful limits of operation of a burner head are graphically presented in Fig. 2, which indicates the results of several investigations (1, 2)[3] using natural gas in single-port burners. The equipment is shown in its final form in Fig. 3. It consists of a sharp-tipped burner tube and the metering equipment necessary to determine the air-to-fuel ratio as well as the velocity of the mixture through the ports. No inspirator was used, as such equipment does not lend itself readily to accurate metering. In Fig. 3, it will be observed that air and fuel are separately metered, mixed, and then passed into the burner tube. A by-pass outlet is used so that various mixture velocities through the burner tube

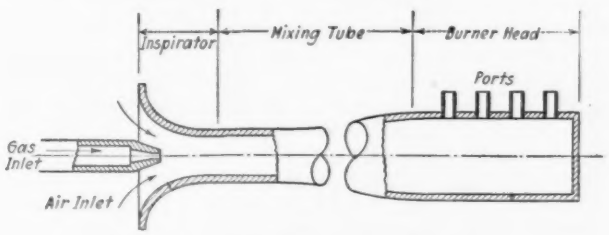

Fig. 1 Atmospheric-Type Gas Burner

may be obtained for the same total flow of mixture. This type of regulation was adopted in order to simplify the maintenance of a constant-mixture ratio. The quantity of mixture passing through the burner is metered as indicated.

The curves, Fig. 2, are the results of arbitrary definitions of the unstable phenomena. Blowoff and flash back are not critical since, under some conditions, they may be induced by slight disturbances of apparently stable flames. The definitions used are as follows:

(*a*) Blowoff is said to occur when the flame is in the act of blowing off almost continuously and when it leaves the burner within 10 to 15 sec after ignition.

(*b*) Flash back is said to occur when the flame moves slowly back into the burner port within 5 sec after being ignited.

The shape of the flash-back curve is similar to that of the flame-speed curve for still mixtures, Fig. 4. Both curves terminate at the two limits of inflammability of the primary mixture and have

Contributed by the Fuels Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, San Francisco, Calif., July 10–15, 1939.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

maximum values near the 100 per cent theoretical air point. That the two curves should be similar in shape is logical as will appear after some reflection. The maximum mixture speed at which flash back occurs is greater than the velocity of flame in still mixtures.

The shape of the blowoff curve may be explained in terms of flame speeds. Blowoff is an edge phenomenon, i.e., the part of the flame first to exhibit instability is that just at the burner tip. At this point secondary air enters the flame, thereby diluting the mixture and changing the flame speeds. For a rich mixture, with

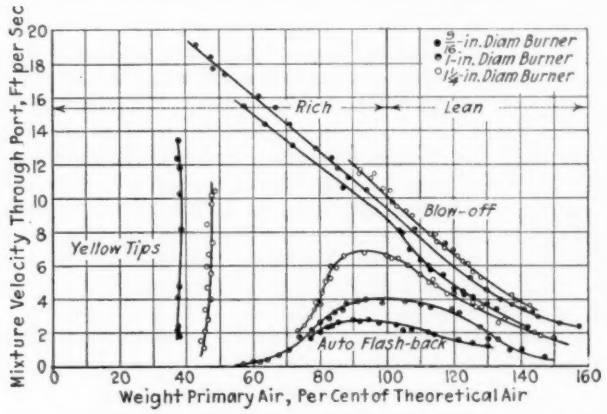

FIG. 2 PERFORMANCE CURVES FOR SINGLE-PORT BURNERS

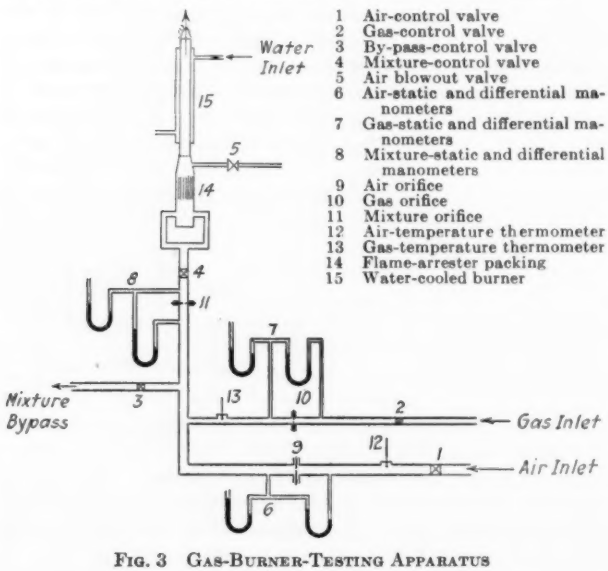

FIG. 3 GAS-BURNER-TESTING APPARATUS

a yellow-tipped flame, the effect of air entrainment is to increase the flame speed in the outer part of the flame. If the primary mixture is too rich to be inflammable, the flame speed in the mixture is zero and considerable air must be entrained to produce a flame speed great enough to give rise to blowoff. The amount of air entrained increases with the mixture speed through the ports. For primary mixtures, within the limits of inflammability, less air must be entrained for blowoff. Hence the blowoff curve should logically have the general shape shown. The yellow-tipped-flame curve should be nearly vertical, i.e., independent of mixture speed. This follows from the fact that the diffusion of secondary air toward the axis of the jet is a function chiefly of jet size, not of jet speed.

Inspection of Fig. 2 shows that the area of the region of stable operation increases as the port diameter is decreased. The boundary of the yellow tip moves toward the richer mixtures, while the flash-back curve descends more than does the blowoff curve. Studies (1, 3, 5) made with multiport burners show that the results found with these large-diameter single-port burners may be applied directly to the design of stove-top and heating-furnace burners. The primary mixture for natural gas should contain from 40 to 50 per cent of theoretical air and should issue from the ports with a speed between 0 and 8 ft per sec. Thus the design of the burner from the standpoint of port area requires a minimum of 1 sq in. of port area for each 30 cu ft per hr of natural gas burned.

The effect of secondary air upon the performance curves is shown in Fig. 5, the curves there plotted referring to the stability of the inner cone. The data were determined using the same burner and metering equipment as for the open flames. Secondary air was excluded from the burner tip by a flame separator as shown. This separator consisted of a glass tube, larger than the burner tip, placed coaxially with it and sealed to the tip at some distance from the outlet edge. This separator was similar to that ascribed to Smithells (6) and accomplished the division of the flame into two parts; the inner cone burning at the normal burner tip and the outer cone at the end of the separator tube where secondary air was available. The flash-back curve under

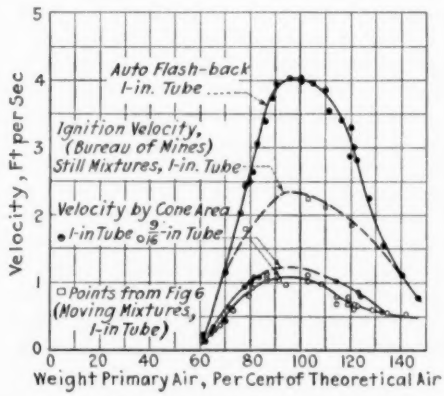

FIG. 4 IGNITION-VELOCITY CURVES FOR NATURAL GAS

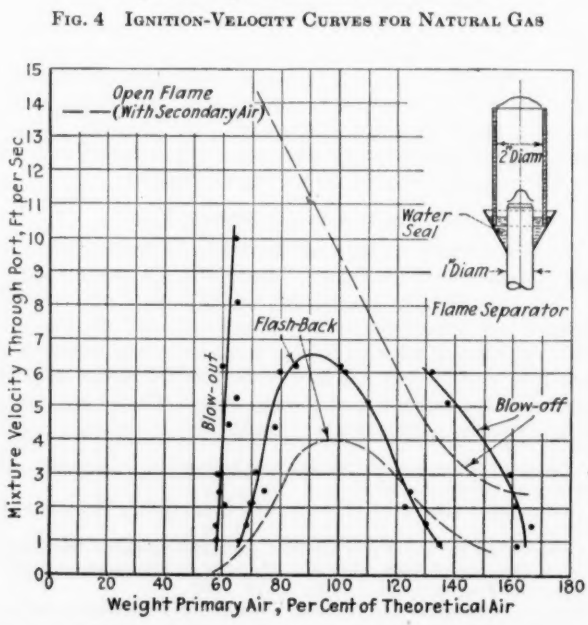

FIG. 5 PERFORMANCE OF 1-IN. BURNER EXCLUDING SECONDARY AIR

these conditions is seen to exceed that under normal conditions. The difference shown is not significant as it was possible to cause flash back at higher speeds in the open flame by disturbing the air about the flame. The blowoff curves for the two conditions differ widely in two parts. First, this curve for rich mixtures doubles back to terminate with the flash-back curve. This follows from the fact that without secondary air the flame cannot be maintained outside the limits of inflammability. Second, the blowoff curve for no secondary air lies definitely above that for the open flame in the lean-mixtures region. This fact is regarded as indicating that appreciable dilution of the mixture near the base of the inner cone does occur in the open flame. This conclusion assumes that the effect of dilution by the burned gases entrained by the primary mixture is negligible.

Extrapolation of Results to Other Gases

All of the work so far completed at the University of California has been done using Kettleman Hills natural gas, the average analysis of which is 76 per cent CH_4 and 24 per cent C_2H_6. If the performance curves for the same burner head using some other fuel mixture are to be predicted, it is necessary to relate them to the more fundamental characteristics of the fuel. For this reason the following properties of the fuel-air mixtures were studied: (*a*) limits of inflammability, (*b*) speed of flame propagation.

The limits of inflammability were obtained from extrapolation of the flash-back curves. As is shown in the appendix, these values agree well with the computed values, the comparison being 55 per cent and 190 per cent measured, as against 56.3 per cent and 186 per cent computed.

The determination of the speed of flame propagation presents a more serious problem. The several experimental methods for measuring this quantity include:

(*a*) Measurement of the speed of uniform motion of a flame through a stationary mixture confined in a long tube.

(*b*) Measurement of the average rate of flame-front propagation in a steadily burning Bunsen flame.

(*c*) Measurement of the rate of expansion of soap bubbles filled with combustible gas following spark ignition at the center of the bubble.

(*d*) Measurement of the speed with which the flame moves back through the burner tube following the occurrence of flash-back.

The flame speeds obtained by the several methods do not agree well, since the conditions are quite different. For instance, combustion for type (*a*) is nearly constant volume; that for types (*b*) and (*c*) nearly constant pressure; while that for type (*d*) is between these two other classes. Again, types (*b*) and (*c*) differ, since in the Bunsen flame secondary air is present at the flame front, thereby causing a variation of mixture ratio in the flame front, whereas the soap bubble is practically impervious to the surrounding air.

Types (*b*) and (*d*) were selected as the methods most nearly corresponding to the combustion of gas in the atmospheric-type burner. Consider first type (*b*): This method involves the simultaneous determination of the surface area of the inner flame cone (flame front) and the volume rate of flow of the particular primary air-gas mixture through this flame front. The cone area was determined from tracings of the inner-cone outline made on pieces of cellophane held against the ground glass of an enlarging camera which was focused on the steadily burning flame. This scheme assumes the inner cone to be symmetrical, a condition closely approximated in many of the tests. The flame-front area is determined from the tracings by dividing the cone area into several conical frustums and summing the resulting areas. This method gives results comparable to those of others (9) and utilizes the available facilities to the best advantage. The flame speeds so obtained are plotted in Fig. 4. Also plotted in Fig. 4 are the flash-back curve and a flame-speed curve obtained at the Bureau of Mines (10) for a methane-ethane mixture of nearly the same consistency as natural gas. This latter curve shows the speed with which the flame front moved through a gas-air mixture confined in a closed-end, 1-in-diam tube. Comparison of the two flame-speed curves shows agreement in the locations of zero and peak values. The magnitudes of flame speed as obtained by the cone-area method are definitely less than those obtained for still mixtures. Since, for rich mixtures, the entrainment of air increases the flame speed, it is difficult to account for the experimental difference.

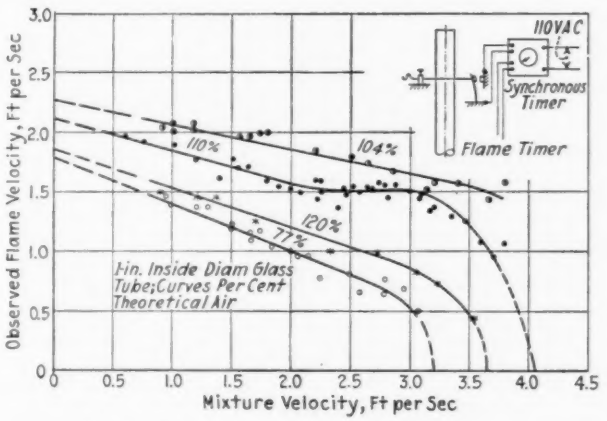

Fig. 6 Flame Velocities in Moving Mixtures

The second series of experiments was undertaken to determine the effect of motion of the mixture upon the flame speed. The flame speeds measured were determined for a flame under flash-back conditions. A long glass tube, shown in Fig. 6, was substituted for the single-port burner tip in the apparatus shown in Fig. 3. A steady flow of mixture was produced in the tube at a rate less than that for flash back. The mixture was ignited by a high-tension-spark discharge. After ignition the flame moved back along the tube at an essentially uniform speed. To check the uniformity of this speed electrical gaps were placed at 6-in. intervals along the tube. The movement of the flame past any gap tended to increase the conductivity of the gap, thereby permitting an electrical potential to drive a slight current through the grid circuit of a vacuum tube. This current was amplified and used to operate a chronograph pen. The results of this series showed uniformity of speed. Difficulty encountered with amplifiers led to abandonment of this scheme for the determinations of speed.

A second method, visual in nature, was next used for checking. In this arrangement a leather belt was mounted on two pulleys so that its length was adjacent to and parallel with the glass tube. White marks were painted across the face of the belt. In operation the belt was driven at constant speed, causing the white marks to move downward along the tube. By running the belt at several different constant speeds for one given mixture ratio and gas rate, a speed could be found and measured for which the belt and flame appeared to keep "in step."

The apparatus finally developed for observing flame speeds is shown in Fig. 6. It consists of a glass tube with two pairs of holes drilled through it. The two holes of each pair are diametrically opposite each other and the two pairs are 30 in. apart. A slender cotton thread was stretched across each pair of holes, serving to hold open a contactor. Passage of the flame would burn through the thread, thereby closing the control circuit of a synchronous timer.

The results of these tests are shown in Fig. 6. The coordinates of the curves are speed of the flame relative to the tube (as measured), and speed of the mixture. The absolute flame speed was considered unobtainable due to the fact that the mixture velocity varies from point to point along the diameter of the tube, whereas the flame front appears to move as a unit. Extrapolation of the curves to zero-mixture speed should yield values in agreement with the still-mixtures data. Points so obtained are plotted in Fig. 4, and are seen to lie close to the still-mixtures curve. It was hoped that extrapolation of the curves in Fig. 7,

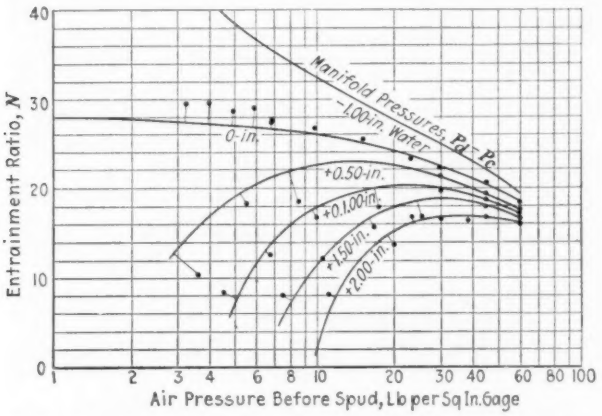

FIG. 7 PERFORMANCE CURVES FOR A VENTURI-TYPE ATMOSPHERIC INSPIRATOR
(Air operated; No. 48 spud; 1 1/8-in. throat.)

to the zero observed flame speed, would yield the flash-back velocity. As is seen from the chart, no dependable extrapolation can be made because of the dispersion of the points. The points obtained are of low accuracy as there was instability of motion. Also, it was found that, if forced into the tube entrance, the flame would move down into the tube at mixture velocities greater than that for flash back. It thus appears that stability of the open flame, from the standpoint of flash back, is increased by the secondary air. The flame shapes observed visually while the flame front was moving are similar to those in the literature (9). In most cases the flame front remained constant in shape during the passage of the flame throughout the tube. Since the flow was in most cases viscous, requiring a large change in velocity along any tube diameter, the maintenance of this constant flame front would require a variation of flame speed along the diameter of the tube. This conclusion is in accordance with the measurements.

Applying these findings to the performance curves of the burner head, a few generalizations may be made. First, the flash-back curve will be some distance above the curve for the flame speed in still mixtures. Since the latter curve is available for many gases, it will naturally form the basis for design. The velocities for flash back are roughly the squares of the flame speeds in the still mixtures for natural gas. If the performance curve for the burner head with one gas is known, the curves for any other gas may be estimated in terms of the flame-speed curves for still mixtures.

PERFORMANCE CURVES FOR THE INSPIRATOR AND MIXING TUBE

The proportions to be used in shaping the inspirator and mixing chamber must be such as to reduce hydraulic friction to a minimum and at the same time provide for sufficient mixing. These problems have been previously investigated (4, 11) and are adequately covered in the literature. The question as to how a given assembly will perform, when various gases are used and when wide ranges of pressure are applied, has not previously been fully treated. Equation [1] has been derived for this purpose and has been demonstrated to hold for one inspirator. The inspirator tested had the following dimensions:

Gas orifice, No. 48 drill size with 30-deg total angle of approach.

Throat, 1 1/8 in. diam × 6 in. long, beginning 1 1/2 in. from orifice outlet.

Expanding section, 12 in. long, expanding to 2 1/2-in. diam from 1 1/8 in. throat.

This unit was tested using air as the driving fluid. Constant back pressures were maintained at the outlet end. The driving-fluid rate was measured with a calibrated orifice and the mixture-discharge rate with a pitot tube. The results of the tests are shown in Fig. 7. The equation developed has been used to compute the solid curve in Fig. 7. This equation is

$$P_d - P_e = \frac{V_i W_i}{g A_t} + \frac{W_i^2 v_2}{g A_s}\left[\frac{1}{A_t} - \frac{1}{A_s}\right] N^2 - \frac{W_i^2}{g A_t^2}(1+N)(v_1 + N v_2)\left[1 - \frac{e}{2} + \frac{e}{2}\left(\frac{A_t}{A_d}\right)^2\right] \quad \ldots [1]$$

P_d = back pressure at burner outlet
P_e = pressure of air to be entrained just before entering induction tube
V_i = velocity of inducing fluid in jet
v_1 = specific volume of inducing fluid in jet
v_2 = specific volume of air to be entrained just before mixing
A_s = area of air passage just before mixing
A_t = throat area
W_i = weight rate of inducing fluid
N = mixture ratio in $\frac{\text{lb air}}{\text{lb gas (or inducing fluid)}}$
e = efficiency with which kinetic energy of mixture is converted into pressure head

The derivation (12) of this equation is based upon the usual energy equation for hydraulics. The flow may be regarded as incompressible when the driving fluid is first dealt with after leaving the orifice.

Inspection of the curves shows satisfactory agreement between the experimental and computed values. The curve applicable to the stove-top or heating-furnace burner is the one with zero manifold pressure, the efficiency being lowered to include the losses in burner-head passages and through the burner-head ports. This curve shows a constant mixture ratio at low-speed pressures, as has been found by previous investigators (12). At high gas pressures, the mixture ratio decreases, i.e., the mixture becomes richer in fuel. This latter fact probably accounts for the improved operation of certain burners when the gas-supply pressure is changed from low to high.

Applying this information to the design of atmospheric-type burners, it is seen that the equation derived may be applied to a particular case with confidence. The performance of the burner as a whole, from wide-open to closed gas cock, will produce a constant mixture ratio for gas-supply pressures less than 1.5 lb per sq in. gage. Changes in the fuel used will result in predictable changes in the air-fuel mixture produced. The adjustable air shutter on most burners will cover a large range of the fuels encountered.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the work of the various experimenters who have been connected with this project: Messrs. Hugh Hyde and A. S. Leonard, Pacific Coast Gas Association Fellows; C. Cordero, W.P.A. research project worker; A. H. Sulliger, T. S. Voorheis, and H. W. Gaunce, graduate students.

The helpful suggestions of Prof. L. M. K. Boelter of the University of California and of Mr. Frank Wills of the Pacific Gas and Electric Company have greatly expedited the work. Thanks are also due to the Pacific Coast Gas Association for permission to use portions from papers previously published under its auspices.

Appendix

Limits of Inflammability of Natural Gas

The method used to determine the limits of inflammability of natural gas is that of Le Chatelier as outlined by Jones (7). The formula is

$$L = \frac{100}{\sum \frac{p}{n}}$$

where L = per cent gas in limit mixture
p = per cent by volume of gaseous constituent on air-free and inert-free basis
n = per cent by volume of same constituent at limit of inflammability with air when it alone is present as fuel

The limits of inflammability of single gases in air are obtained from experimental curve (7, 8).

$$L_1 = \frac{100}{\frac{76}{5.24} + \frac{24}{3.22}} = 4.55 \text{ per cent gas in air}$$

$$L_2 = \frac{100}{\frac{76}{14.02} + \frac{24}{12.45}} = 13.6 \text{ per cent gas in air}$$

Expressed in terms of per cent theoretical air $L_1 = 186$; $L_2 = 56.3$.

Burning Pulp-Mill Waste From Sulphite Mill

By GROVER KEETH,[1] ROTHSCHILD, WIS.

After first outlining the problem of stream pollution, as applied to sulphite pulp mills, this paper describes the recovery of lignin from digester waste and the elimination of stream pollution by the Howard process. This process produces a lignin fuel which can be and is burned in power-plant furnaces for the production of steam. Mechanical problems, such as the development of a filter press and various methods of burning the fuel so produced, are explained.

THIS PAPER relates to the use of industrial wastes as boiler fuel and specifically concerns some developments recently carried on under the author's supervision in burning, as a boiler fuel, a lignin organic product recovered from waste sulphite liquor at the Marathon Paper Mills Company, Rothschild, Wis., by the Howard process of treating such liquors.

Waste sulphite liquor results from the making of paper pulp by the acid-sulphite process. As drained from the pulp in the blowpits, these liquors are reddish brown in color and contain the organic matter dissolved from the wood in the pulping process. This dissolved organic matter represents the noncellulose constituents of the wood which are in part lignin substance and in part carbohydrate or sugar substances derived from the hemicellulose components of the wood. The yield of air-dried pulp is 45 to 50 per cent of the air-dried weight of the original wood, hence the amount of dissolved organic matter carried in the waste sulphite liquor is approximately 1 ton of such dissolved organic matter for each ton of pulp produced.

The annual production of sulphite pulp in the United States is around 1,400,000 tons and at least an equivalent tonnage of dissolved organic matter is carried in the waste liquors from such pulp production. This large tonnage of organic matter, in such waste liquors which now are almost entirely discharged into sewer outlets at the pulp mills, invites utilization to recover products of inherent value. It has become more and more necessary at least to find economical means of disposal for such liquors to avoid pollution of lakes and streams into which they are discharged.

Only limited amounts of such liquors are now being utilized in the manufacture of commercial products; such as, tanning materials, core binders, road-dressing materials, etc. Various proposals and attempts have been made to effect disposal of these liquors to avoid stream pollution; e.g., aeration, ponding, and concentration by evaporation to a fuel product. None of these has thus far afforded a satisfactory solution to this disposal problem and a discussion of their possibilities is outside the scope of this paper, save briefly to mention the evaporation of these liquors to a fuel product. In such procedures the liquors, either with or without neutralization, are evaporated in multiple-effect evaporators to a concentration of around 50 per cent solids to give a liquid product which can be burned as a boiler fuel. This procedure is handicapped by several inherent difficulties and has not afforded an economical disposal method. The liquors as draining from the pulp in the blowpits are necessarily mixed with wash water, hence it is not practical, with existing standard equipment, to collect more than about 60 per cent of the total liquor in sufficiently concentrated form to permit economical evaporation, even with multiple effects. The liquors are acid and, even after neutralizing, corrosive gases are evolved during evaporation; hence expensive acid-resisting evaporation equipment is necessary. Incrustation of evaporating surfaces is encountered and the high viscosity of the concentrated liquor results in low heat-transfer rates and the necessity of forced circulation in the evaporators.

On the other hand the Howard process is a patented fractional-precipitation treatment of these waste liquors which does not involve evaporation. This permits treating more dilute liquors than can be economically evaporated and allows processing a gallonage of liquor sufficient to carry 90 to 95 per cent of the total organic matter dissolved in the pulping process, the remaining amount being carried in wash liquors too dilute to warrant processing. This process has been under study and development at the Marathon Paper Mills Company, for the last ten years, under the direction of Guy C. Howard, an experienced chemical engineer who originated the process. A commercial plant is now in operation for treating all of the waste sulphite liquor at this pulp mill by this precipitation process. The objectives in the development of this process have been to find a disposal method for these liquors, which could be used at our own and other pulp mills, to avoid stream pollution through discharging such liquors into waterways, and also to develop means of utilizing the lignin and other constituents of these liquors as chemical raw materials for the production of various products of commercial value.

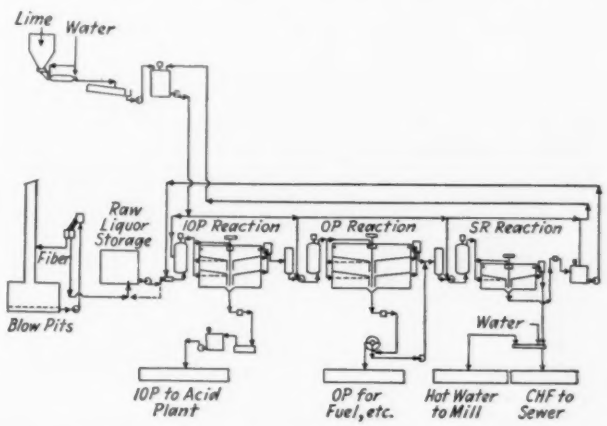

FIG. 1 FLOW DIAGRAM OF HOWARD PROCESS FOR TREATING WASTE SULPHITE LIQUORS

The Howard process is a three-stage precipitation treatment of the waste sulphite liquor which, as shown in the flow diagram, Fig. 1, may be briefly described as follows: The hot waste liquors are collected from the blowpits into raw-liquor storage tanks for equalization in concentration and then pumped through three reaction tanks in series, Fig. 2, in each of which a lime reagent in controlled amounts is added to the liquor. After each reaction tank, the liquor passes through a settling tank of the Dorr type, Fig. 3, for removal of a precipitated product. From the first settling tank an inorganic sludge product, containing

[1] Chief engineer, Marathon Paper Mills Company. Mem. A.S.M.E.

Contributed by the Fuels Division and presented at the Spring Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New Orleans, La., February 23–25, 1939.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

calcium sulphite, is removed as a slurry and pumped to the acid plant for making fresh cooking acid, thereby affording a credit to the process for its lime and sulphur values. The precipitate settled out in the second settling tank is an organic product which is removed as a sludge and filtered on a rotary vacuum filter of the Oliver type, Fig. 4, to give a filter cake which is the lignin fuel product with which this paper is particularly concerned. The precipitate in the third settling tank is a mixture of precipitated organic matter and unconsumed lime reagent. This mixed precipitate is removed as a sludge which is returned to the process as the lime reagent added to the liquors in the first reaction tank. The overflow liquor from the third settling tank is the process effluent which is passed through a liquor-to-water heat exchanger for recovery of its heat into wash waters used in the pulp mill and thence is discharged to the sewer. From 3500 to 4000 gal of waste liquor is processed per ton of pulp and this gallonage carries 90 per cent or more of the organic matter dissolved from the wood in the pulping process. The gallonage of the process effluent is approximately that of the waste sulphite liquor fed to the process but the original raw liquor has been materially altered by the hot-alkaline treatment to which it has been subjected by this processing. About half of its organic-matter content has been precipitated and removed; the sugars

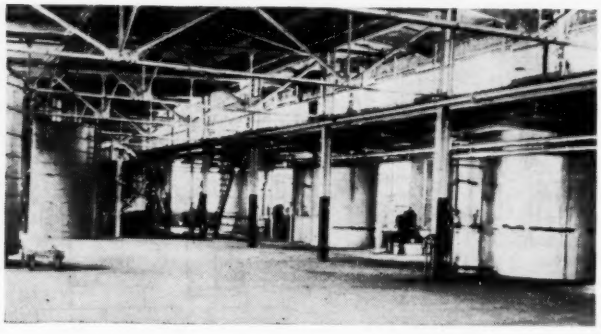

FIG. 2 REACTION TANKS FOR EQUALIZING RAW LIQUOR IN CONCENTRATION

in the raw liquor have been broken down to unfermentable derivatives; the original acid raw liquor has been made alkaline with lime; and a material portion of the sulphur content has been removed. As a result, the biochemical oxygen demand (BOD) of the process effluent, which is the criterion of its stream-pollution characteristics, has been reduced 80 to 90 per cent in comparison with the BOD of the untreated liquor. The process effluent therefore represents a greatly improved liquor from the standpoint of stream pollution and, under most pulp-mill conditions, can be safely discharged into sewer outlets.

The process thus affords a disposal means for handling such waste liquors which is self-contained in that its recovered products can be used by the pulp mill for making fresh cooking acid and as a boiler fuel, without the necessity of outside marketing of products. Further, the process is applicable to practically all sulphite pulp mills as an economical method of avoiding stream pollution.

The production of this lignin fuel product will range from 1000 to 1250 lb dry weight per ton of pulp produced, depending on the kind of wood used and details of the cooking operation. This means the recovery of 50 to 65 tons per day of such fuel product from the waste sulphite liquor, resulting from a daily production of 100 tons of pulp.

Some of the lignin filter cake, coming from the rotary vacuum filter at Marathon, is used as a chemical raw material for the production of special lignin products, but a considerable tonnage of it remains to be used as a boiler fuel. At installations of the process in other pulp mills, practically all of this filter cake will have to be utilized as a boiler fuel because of its large tonnage and insufficient market for special products made from it. Since the economics of the process depends largely on the fuel value of this filter cake as a credit to the process, we were confronted with the necessity of finding the most economical method of utilizing it to yield maximum heat value.

The wet filter cake is a light chocolate-colored colloidal organic material in flocculated condition which dries to a friable black granular product. It is essentially a basic calcium salt of lignin-sulphonic acid together with some nonligneous organic impurities carried in the mother liquor of the wet cake and is

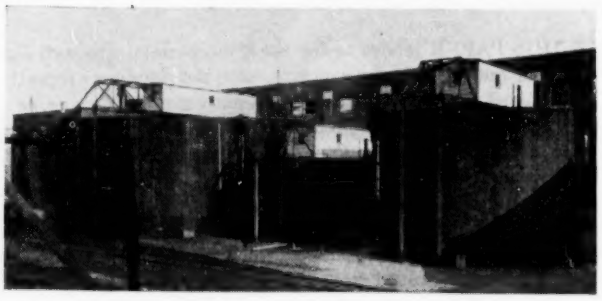

FIG. 3 DORR TYPE SETTLING TANKS

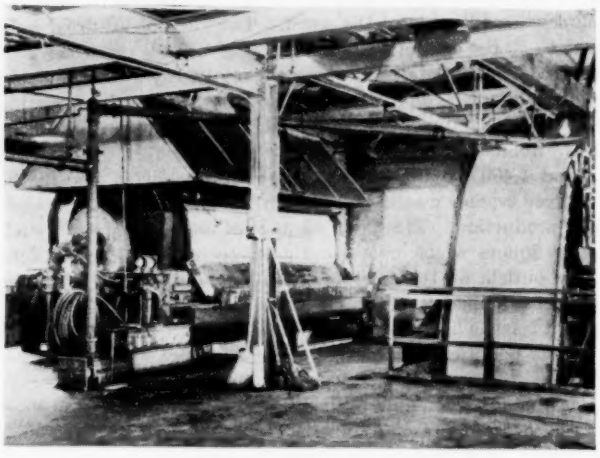

FIG. 4 ROTARY VACUUM FILTER, PUMP TO PRESS, AND TOP OF FILTER PRESS

alkaline with caustic lime. Its ash content by ignition is about 18 per cent. It has a calorific value of 8000 to 8500 Btu per lb dry basis. At its normal alkalinity of about pH 11, it filters readily to a cake containing 68 to 70 per cent moisture. An 8-ft diameter × 12-ft face rotary vacuum filter, Fig. 4, is sufficient to handle 65 tons dry weight of this cake per day. Various endeavors with the present filter have been made to reduce the moisture content of the cake but without success, because of its colloidal character and tendency to shrink and check on the filter drum. A cotton-duck filtering medium is used and the filtrate is clear. At this moisture content the cake discharges cleanly in flake form and appears quite dry but, on mixing, it readily puddles to a semifluid paste which can be pumped by a screw pump.

The material leaving the vacuum filter is now ready to be made into chemical products or fuel. The moisture content, however, is too high to burn for the production of useful heat.

Early experiments conducted with small amounts of dried material, led us to the belief that we could burn it usefully, if we could reduce the moisture content to 50 per cent. These experiments also indicated that, if the moisture content were reduced to 58 per cent or less, the material would no longer puddle. One of our greatest problems was to find the most economical method whereby the moisture could be reduced to 50 per cent and, at the same time, 65 to 70 tons dry weight could be handled per 24-hr day. This latter tonnage requirement and the nonfibrous colloidal character of the filter cake eliminated any press of standard design.

The methods given consideration were:

1 Partially or wholly drying the filter cake in fuel-fired direct-heat driers of the rotary or other type. This is practical to do but is expensive because of the large moisture content of a 70 per cent cake, with a consequent high fuel requirement to evaporate this moisture.

2 Partially or wholly drying the cake in a steam-heated tubular rotary drier, such as is in common use for drying brewery products. Economical drying can be accomplished by this means, provided the drier can be located alongside the boiler in which the fuel product is to be burned, thereby permitting the return of the high-pressure condensate to the boiler; saving the sensible heat in the fuel product as it discharges from the drier; and recovering heat from the vapor discharge of the drier. We have dried a considerable tonnage of wet filter cake in this type of drier satisfactorily.

3 Partially or wholly drying the cake with boiler-stack or other waste-heat gases. This is theoretically an economical procedure since no charge is necessary for the waste-heat gases. However, the available heat for drying in stack gases at 300 to 400 F, as produced from modern boiler plants, is rather low, consequently, large volumes of such gases would be required even partially to remove the high water content of a 70 per cent cake.

4 Removing water by pressing the cake mechanically. This would seem the most economical method of reducing the moisture content of this fuel cake, provided it could be accomplished. We therefore concentrated our efforts on this procedure.

Laboratory pressing tests indicated that the moisture content of this filter cake could be reduced to 50 per cent moisture on pressing at 200 lb per sq in. with 1 min retention under pressure for a 1-in. cake. At 70 per cent the cake contains 2.33 parts of water to 1 part dry solids and at 50 per cent contains 1 part water to 1 part dry solids, hence this relatively low pressure had removed over half the water content of the filter cake. Higher pressures failed to reduce the moisture content materially below 50 per cent, from which it was concluded that only the free water had been removed and that the moisture content of the cake could not be reduced lower than 50 per cent by mechanical pressing. At 50 per cent moisture the cake crumbles readily and can be burned alone or mixed with coal.

After much investigation and experimental work, we decided to make use of the principle in a press that had been designed by R. M. Thompson. We felt that, as constructed by him, it was too complicated and cumbersome for our needs. Incidentally, this is the only major piece of equipment required by the process which we were unable to find on the market.

In principle this press, Fig. 5, is a vertical, wedge-shaped chamber in which the material is pressed in its downward travel between two belts approaching one another. The belts are endless and tractor-like in construction and are made by attaching grid sections, Fig. 6, to three roller sprocket chains. The grid sections are 48 in. long, which constitutes the width of the belt, and are 6 in. wide in the direction of travel, with perforated

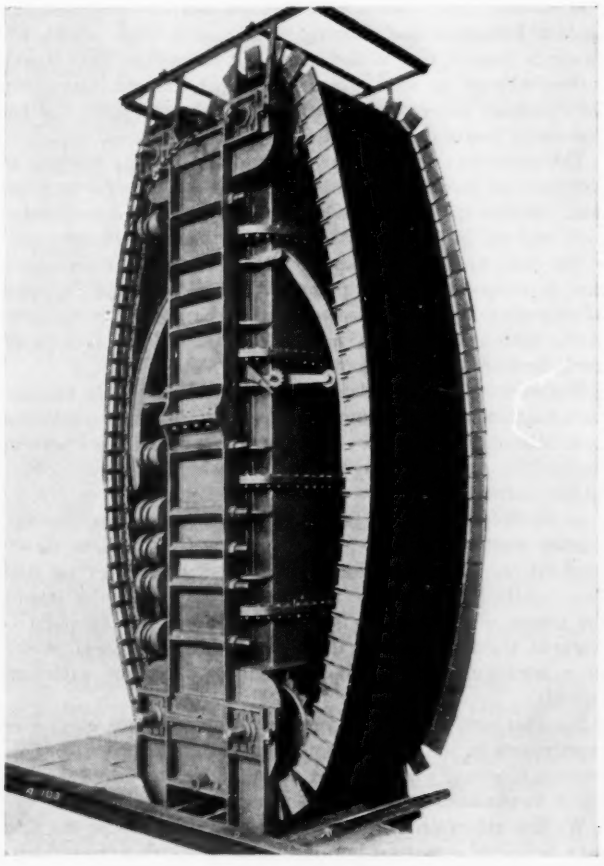

FIG. 5 FILTER PRESS

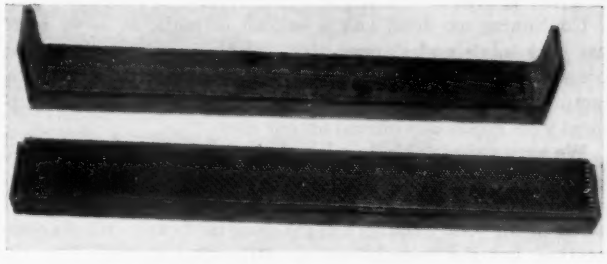

FIG. 6 MALE AND FEMALE GRIDS OF PRESS

metal faces. One of these belts is supported on a three-sprocket shaft at the top of a vertical supporting member and travels vertically downward to a drive sprocket at the base of this supporting member, thence returning to the top sprocket. The rollers in the belt chain run on tracks in this vertical supporting member.

The other chain is supported and driven in a similar manner, save that the top sprocket is offset somewhat to give an inclined travel to the belt downward, and the lower drive sprocket is carried in a floating bearing to move against spring tensions with increased clearance between the belts at the bottom, i.e., with increased thickness of cake.

The belts are driven by a $7^1/_2$-hp motor through reduction gears and a flexible coupling on the floating shaft in a manner similar to the roll drive used in steel mills.

The grid sections on one belt have flanged edges which overlap the grids on the opposite belt to give edge closure for the compres-

sion chamber and rubber astragals are used to give tightness against leakage. The filtering mediums through which the liquor is pressed out of the cake are two endless, loose-woven cotton belts 48 in. wide, which travel with the grid belts downward through the compression chamber and are supported on the perforated face of the grid belt.

The press was designed for a maximum working pressure of 250 lb per sq in. on the material and for a belt travel of 12 ft per min. At this speed the press would handle 70 tons dry weight of such cake per 24 hr at 1 in. thickness for the pressed cake.

The cake, as it comes from the filter at 68 to 70 per cent moisture, is pumped by a screw pump to the feed hopper of the press. After passage through the compression chamber, it is delivered at the bottom of the press in a cake 48 in. wide by about 1 in. thick, having a moisture content of 50 to 55 per cent.

Numerous mechanical defects which developed in the machine have been corrected, but nothing has occurred which would lead us to believe that the theory is wrong. The machine is operating successfully and producing a filter cake which averages close to 50 per cent moisture.

In our investigations of reducing the moisture content, we also studied waste-heat driers of several types, as well as direct-fired driers. Two obstacles prevented our going very far with these methods. First, the fact that for our particular layout, the source of waste heat is some distance from the point of origin of the fuel; second, the vacuum filter press cake reverts to a semiliquid condition and handling would be extremely difficult.

Simultaneously with our press development, we carried on experiments in the boiler room using both filter cake from the vacuum filter and material that we had dried to various degrees, which we obtained from our pilot plant.

We first attempted to burn a mixture of wood refuse and filter cake in one of our wood-burning furnaces which have ordinary Dutch ovens with flat grates and undergrate blowers—no result. Next we tried filter cake and various mixtures of coal—again no satisfactory result.

Continuing we dried half a carload of material to 85 to 90 per cent solids and shipped this, together with a quantity of press cake from the Oliver filter to the plant of a stoker-manufacturing company, the facilities of whose experimental equipment were generously offered for our use.

We were successful in burning the dried material in pulverized form in a rotary acid-sludge burner, and on a forced-draft chain-grate stoker. We tried to burn 30 per cent solids and 70 per cent water in the rotary burner and got along fairly well with the combustion, but the material was so sticky that it plugged up the feeder. We did find that, if the material were dried to about 50 per cent solids, we could get it through the feeder and handle it in the burner.

The combustion characteristics of this lignin fuel product are that, since it apparently contains no low-temperature volatiles, it is sluggish and slow to ignite in comparison with bituminous coal but that, at and above some critical decomposition temperature, the lignin material gasifies directly and completely into what are probably carbon monoxide and hydrogen, which burn readily above the fuel bed.

We also found in these experiments that the ash consisted of small white particles, which upon analysis, proved to be largely quicklime in sufficient quantities to produce a theoretical credit (if use could be made of it) in the acid plant at the beginning of the cooking process. However, it was contaminated with other calcium salts which must be kept out of the cooking acid.

After the foregoing experiments, we made a number of attempts to burn this material on our own underfeed stokers, together with coal. The principal result of these experiments was to find out that, when we had approximately one-fourth lignin and three-fourths coal, severe slagging occurred.

Investigation was also made with an inclined-grate Dutch-oven furnace for wood burning. If the material were wet, it would stick at the top of the grate and, if it were dry enough not to stick, it rolled to the bottom and burned so unevenly as to be unsatisfactory.

Mixtures of lignin material with fuel oil and with pulverized coal were also tried. The former experiment resulted in burning the oil and leaving the press cake in the furnace. No results were obtained with the coal mixture.

In the meantime, in order to improve our boiler room both as to capacity and efficiency, we had installed several spreader-type stokers. We then commenced experimenting with lignin fuel on these stokers and found, after a number of attempts, that, so long as the fuel was in the neighborhood of 50 per cent solids, we could use a mixture of approximately 15 per cent coal and 85 per cent lignin, operating continuously at from one to one-half times boiler rating. Some investigators of the waste-liquor problem have called attention to the possibility of damage to the boiler from corrosion. We are glad to say, however, that, after two years of burning this material, most of it in one boiler, we have found no indication of trouble arising from this source. This is apparently due to the alkaline character of the fuel ash.

Knowing that some mills, which would become interested in this process, would be equipped with coal pulverizers and, having learned by experiment that the material could be readily handled in the dry state in a pulverizer, we have gone to considerable length in attempting to burn the lignin by this method. It has been tried in five different plants with three different types of pulverizers. These tests indicate that, when it is only 50 per cent dry, it cannot be handled at all in a mill with close clearances but can be handled in an open-type mill. In a mill of this type, the capacity is reduced and therefore the horsepower per ton becomes high as compared to coal. For this reason we have, for the time being, dropped further experiments with pulverizers although it has not been decided to abandon them entirely.

So far as operating troubles go, it was stated previously that we have had no boiler-steel corrosion. Undoubtedly, if the furnace lining were acid, it would flux rapidly with the ash. Our firebrick comes from the Missouri field and has given the usual service life.

Due to the high lime content of the ash from this fuel, we have had to be more than ordinarily watchful of dust leaks from breechings and flues, because it is unpleasant to get any of this dust in one's nostrils. Again, we remove ashes with a steam vacuum system and have found it necessary to keep the ash dry to prevent the formation of mortar in the ash tank.

The final question to answer with a product of this nature is: At what efficiency can it be burned? To answer this question we engaged the services of Paul Pool, consulting combustion engineer for the M. A. Hanna Company, Cleveland, to conduct a boiler test with this fuel.

In order to eliminate any question as to how long a boiler could be operated with this material, it was decided to make the length of the test 36 hr. As no facilities for weighing the feedwater were available, a recently calibrated Bailey steam-flow–air-flow meter was used to give the weight of steam generated. Some difficulties were experienced in determining flue-gas analyses, due to the fact that the chemicals in the Orsat were rapidly rendered ineffective. Work is being done in our laboratory to determine the reason for this. Due to the uncertainty in the flue-gas analysis, the heat balance calculated is probably incorrect. However, the fact remains that, in order to have evaporated enough water to generate an average of 185 per cent rating with the

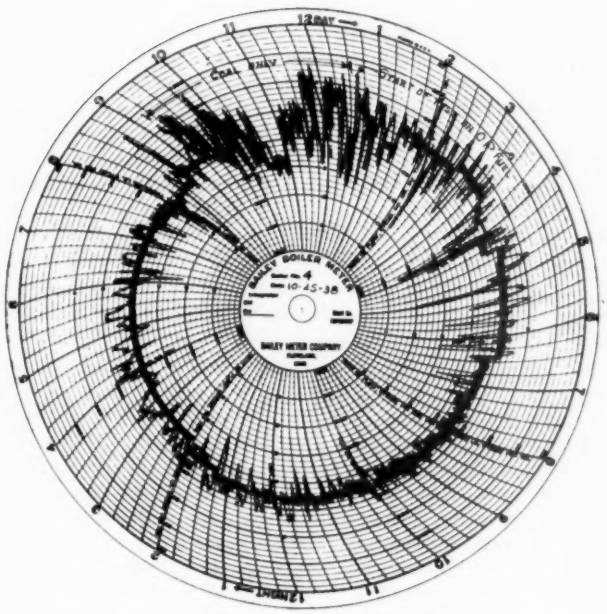

FIG. 7 CHART FROM STEAM-FLOW AIR-FLOW METER

weighed fuel supplied the stoker, the efficiency must have been quite close to that obtained. Expressed another way, we produced an average of 26,039 lb of steam per hr from a 386-hp Stirling boiler, equipped with a stoker having 96 sq ft of active area and a furnace volume of 1003 cu ft.

When operating at the rating just mentioned we were using all of the fuel which the recovery plant was then producing. Indications were that this rating could have been increased had there been more of the fuel available. At the beginning of the test, we used a fuel mixture of 15 per cent coal and 85 per cent lignin by weight as received. This was later changed to approximately 8 per cent coal and 92 per cent lignin, at which mixture the test was continued to the end with a much better steam chart. Fig. 7 is a chart from the steam-flow–air-flow meter covering the first portion of the test. The first 3 hr of this chart show the performance with coal only. The next 3 hr show a mixture of 15 per cent coal and 85 per cent lignin. The next $2^1/_2$ hr show the period during which we were gradually reducing the coal to 8 per cent, and the remainder, the performance with 8 per cent coal and 92 per cent lignin at which mixture the test was completed.

It should be noted that in Table 1, under proximate analysis, no figures are given for fixed carbon or volatile matter. The reason for this is that, so far as we have been able to determine, there is no fixed carbon in this fuel. Carbon is undoubtedly present

but, as mentioned previously in this paper, we believe that, when the fuel reaches some distillation temperature, it breaks down into several gases, probably the most prominent being carbon monoxide and hydrogen.

The boiler on which this test was conducted has no provision for preheated air. We have, however, come to the conclusion that preheated air should be tried and believe it to be within the realm of possibility that, with preheated air, we could reduce the amount of coal required still further, perhaps even discontinue it entirely.

Another point under investigation, at the time this paper is being written, is that of furnace volume. We believe it to be quite possible that part of our difficulty with the Orsat equipment is due to some of the gases generated from this fuel being mechanically carried through the setting before they have had a chance to burn.

It will be noted that an efficiency of 64.35 per cent is quoted for the lignin fuel as burned. This means that we have recovered 64 per cent of the available heat in the solids leaving the digesters which were precipitated; however, as stated previously all of the organic matter has not been precipitated, so that the heat recovery of the total solids discharged from the digester, is lower than the figure just mentioned. Just how much, we do not know because we do not know what sort of fuel this remaining organic matter would make.

In closing, the author wishes to acknowledge assistance in the preparation of this paper from Guy C. Howard, inventor of the process, and George H. Urban, who is in charge of the boiler room.

Bagasse Furnaces

By E. W. KERR,[1] BATON ROUGE, LA.

This paper deals with the design of furnaces for burning bagasse, a woody product resulting from the removal of sugar juice from cane. Its calorific value when dry is about 8300 Btu, which is reduced considerably because of the moisture content averaging about 50 per cent. Because of the high moisture content large combustion-chamber volume is essential and the net boiler efficiency is limited. However, in a properly designed and balanced sugar factory, the heat from the bagasse will generate the necessary steam for operating it although some additional fuel (usually oil) is required during mill stops. Practically all makes and types of boilers are used for burning bagasse, water-tube boilers predominating. The author classifies the types of bagasse furnaces as grate, hearth, and combination grate and hearth. Examples of each are described and tests covering a wide range of furnace types over a long period of time are cited. The best installations range from 55 to 60 per cent boiler and furnace efficiencies; average practice about 50 per cent. A furnace developed recently by the late G. P. Ward has given an efficiency of 66 per cent.

BAGASSE or megass, as the English call it, is the woody matter remaining after the juice has been removed from sugar cane by mills. It is composed principally of fiber and moisture together with small quantities of sugar and other solids including dirt. The amount of sucrose in bagasse depends upon the number of crushings, the maceration and the pressure applied, especially on the last crushing. For example, a nine-roller mill (three crushings) will give bagasse with, say, 2.75 per cent sucrose, whereas with four crushings the sucrose in bagasse may amount to 2.25 per cent or less.

The amount of moisture in bagasse is approximately the same for different numbers of crushings, provided the pressure at the last crushing is the same in each case. The moisture varies somewhat also with different varieties of cane. The bagasse from hard-fiber cane is apt to have a lower moisture content than that from soft-fiber cane. One of the Louisiana-cane varieties not only has low fiber, with a correspondingly small weight of bagasse, but also the fiber is soft and retains more moisture. The result is that this bagasse is difficult to burn, causing the firemen to conclude erroneously that it has a lower heating value per unit weight of fiber.

In making calculations of the heating value of bagasse, it is customary to assume a moisture content of roughly 50 per cent, although modern mills produce bagasse of lower moisture than this, in fact quite commonly 45 to 48 per cent. It has been noticed that windrowed cane, if left in the fields for a considerable length of time, results in bagasse that is soft, high in moisture and difficult to burn. In addition to the fact that the net value is less as the moisture increases, excessively moist bagasse is hard to burn because it lies heavily on the grate or hearth, with the consequent difficulty of supplying sufficient air for combustion.

The amount of ash in bagasse (principally from dirt) depends upon the cleanness of the cane, which in turn depends largely upon the methods used for handling it in the fields. In Cuba and in other tropical countries, the cane is usually very clean, being loaded mostly by hand. In Louisiana, where much cane is handled mechanically, dirt may be picked up with the cane, especially in muddy fields. The amount of ash and for that matter sucrose has considerable effect upon the tendency to form clinker in the furnace. In relation to combustion space, this is of importance also, since it determines the time interval necessary between cleanings of the combustion chamber, including the space back of the bridge wall. In some cases, the combustion chamber behind the bridge wall is made very high in order that large amounts of ash may accumulate, before the remaining space is choked sufficiently to necessitate cleaning. In fact, one of the principal problems in designing a good bagasse furnace is to eliminate or reduce the amount of fly ash passing over the bridge wall into and underneath the boiler.

The woody fiber is, of course, cellulose. Ultimate chemical analyses made on bagasse from a Cuban factory gave the following composition:

	Per cent
Hydrogen	5.8
Carbon	46.31
Oxygen	45.82
Nitrogen	0 26
Ash	1.81

Calorific tests of bagasse by means of calorimeters have been made by various investigators, including some by the author. The values vary all the way from about 8000 Btu to 8600 Btu, the average being about 8300 Btu per lb of dry bagasse. With a 50 per cent moisture content, the gross calorific value of 1 lb of bagasse (moist) entering the furnaces will be approximately one-half this or, say 4000 Btu.

When the cellulose burns, hydrogen is formed, which in turn ignites and forms water. Therefore, the heat of combustion of the bagasse is not only required to evaporate free moisture, and raise it to stack temperature but also an added quantity resulting from hydrogen combustion. The net result is a reduction in the heat available for boiler absorption to about 2300 Btu.

Bagasse as it comes from the mill is light, weighing roughly 10 lb per cu ft in a pile. It is relatively easy to burn with sufficient air properly applied. Due to the high moisture content, a large combustion space, surrounded by linings of high-temperature refractory, is required for efficient combustion. The gases of combustion being so greatly diluted with steam (from the moisture), proper turbulence is especially necessary to insure against stratification and incomplete combustion. It is a simple matter to burn bagasse with low excess air in either grate or hearth furnaces of proper proportions. The author has found CO_2 as high as 18 per cent with negligible amounts of CO; in fact, 16 per cent CO_2 is common for good results. Due to the large combustion space, the heat release per cubic foot of furnace volume is relatively small. Actually, the best bagasse-furnace designs of recent years have a heat release per cubic foot of furnace volume in the order of 20,000 Btu per hr. This is very low as compared with the heat release in modern furnaces burning such fuels as coal, oil, and natural gas at high ratings, where a release as high as 100,000 Btu per cu ft of furnace volume per hr is attained.

The weight of bagasse per ton of cane varies with the fiber content which approximates 10 to 15 per cent. In Louisiana

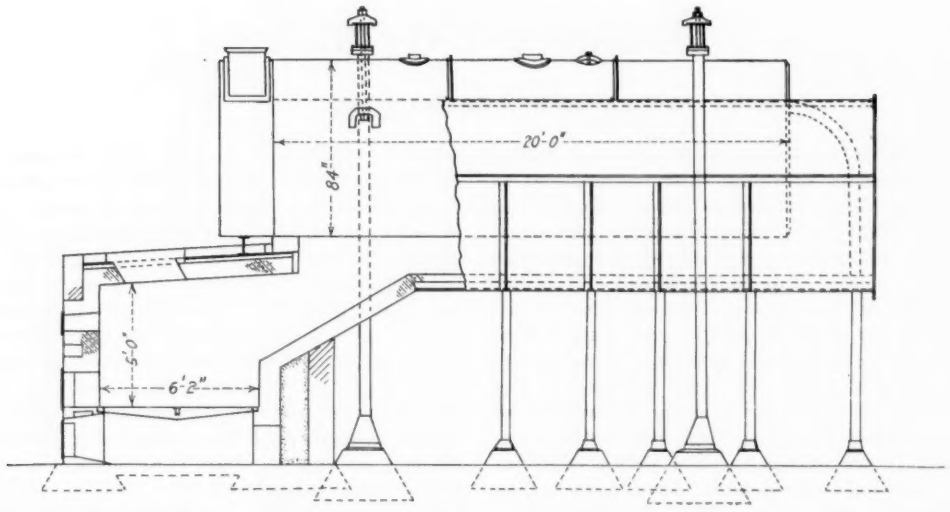

FIG. 1 HORIZONTAL RETURN-TUBULAR 250-HP BOILER AT VERMILLION SUGAR FACTORY WITH INSULATION AND STEEL CASING

where 13 per cent fiber in cane is a good figure, about 550 lb of bagasse (moist) is produced per ton of cane. For a factory of 1000 tons daily capacity, the bagasse would develop roughly 1500 boiler hp. In a properly designed and balanced sugar factory, the heat from the bagasse will produce the necessary steam for operating it. However some extra fuel (usually fuel oil) is nearly always necessary during mill stops, including weekly shutdowns for cleaning boilers, evaporators, etc., even when bagasse storage is provided. Provisions for burning the oil must be made either in the bagasse-burning boilers or in separate boilers.

Incidentally, one of the problems of the sugar-factory designer is to shorten the length of shutdowns for cleaning. However, up to the present time, the average factory has to be shut down periodically to clean the evaporators and other equipment in the fabricating department, whether or not it is necessary on account of the boilers. It is difficult to burn oil efficiently in the same combustion chamber with bagasse. Air supply through checker-work, even when located in the combustion chamber (other than the bagasse chamber), is also unsatisfactory due to fly ash and cinders. The tendency, therefore, is toward the use of steam- or mechanical-atomizing burners with registers, located in the side or rear walls or in some cases in a tunnel, for admitting air around the burners. It has been rather customary to install steam-atomizing oil burners through a 4-in-diameter hole in the front wall of the Dutch oven, rather high and to one side, in order not to spray the oil on the bagasse. However this does not permit a sufficient air supply; in fact, any considerable oil fire at this location is destructive of the furnace lining.

Boilers, in which bagasse fuel is fired comprise practically all types and makes. Most of them, when properly furnaced and operated, give good results. However, with a tendency toward large factories and higher ratings, the watertube type has gained in popularity. Large boiler units have proportionately less radiation loss. Operating at high ratings, a lower initial cost results.

The author was connected for many years with a large company in Cuba which had a total of over 100,000 boiler hp in its factories, 40 per cent of which was in straight-tube, watertube boilers (principally Babcock & Wilcox). The remaining 60 per cent was in horizontal-return-tubular boilers most of them 8 ft in diameter. In general, it was true of these factories that the average fuel-oil consumption for the watertube and horizontal-return-tubular boilers did not differ materially.

The steam requirements and oil consumption of sugar factories are affected largely by the design of the factory, including such factors as: Insulation of piping; balance in the production and utilization of exhaust steam; efficiency of heating and evaporating equipment (number of bodies, etc.). Nevertheless, the efficiency of the boiler plant is the most important factor in the matter of extra fuel consumption. In other words, if maximum efficiency is attained in the combustion of the bagasse and the conversion of its heat into steam, there will be slight need for extra fuel.

Reference has already been made to the fact that the bagasse from a 1000-ton factory should develop around 1500 boiler hp. This load, if developed with oil as fuel, would require some 14,000 gal of fuel oil per 24 hr. This indicates the large fuel requirement involved and emphasizes the importance of providing suitable furnaces and operating them at maximum efficiency. Originally, the oil consumption in the several factories in Cuba, with which the author was connected, averaged between 3 and 5 gal per ton, but, after several years, it was reduced to about 0.15 gal. Much of this reduction was effected through changes made in the design and in the operation of the boilers and the furnaces.

Coming now to the design of bagasse furnaces, the designer has to provide for the following: (*a*) Combustion volume sufficient for complete combustion of the moist bagasse at the desired rating; (*b*) a reasonable initial cost of boiler and furnace, keeping in mind that the average sugar factory in Louisiana operates only 2 to 3 months per year and in the tropics 3 to 5 months; (*c*) a reasonable radiation loss from walls of furnace and boiler setting; and (*d*) provision for cleaning and removing ash and cinders. Evidently the brick surface for a given horsepower rating is relatively high for a bagasse boiler, the furnace of which extends far in front of the boiler. Also increased combustion volume is obtained at the expense of increased radiation loss and vice versa.

Various means have been used for reducing the radiation loss. Among these occurs the use of a steel casing as shown in Fig. 1, a lining of asbestos being applied between the brick and the steel casing. Many of the installations in Cuba of the general type shown in Figs. 2 and 3 have insulation brick $4^1/_2$ in. in thickness in the side and front walls of the furnace and in the side walls of the combustion chamber. Insulating brick, usually 7 in. thick, are also applied under the floors of the furnace and combustion chamber. In some cases, a sheet-steel deck, as in Fig. 3, is installed, forming a closed space above the suspended flat roof of the furnace into which the forced-draft fan discharges. The slightly heated air is conducted from this space by means of ducts

to the air box and tuyères, thus eliminating radiation loss from the roof.

In order to minimize labor and loss of time for ash and clinker removal, the furnace design should permit removing the ash and clinker from the grate or hearth rather than from beneath the boiler behind the bridge wall. The former can be done during operation, whereas the latter may require taking the unit out of service. The solution of this problem has become increasingly important and difficult with the higher ratings of recent years.

Bagasse furnaces may be classified under three heads, namely, grate, hearth, or a combination of grate and hearth. The majority of grates for bagasse are flat, the bagasse being dropped on the center and forming a conical pile. However, in some countries the grates, made in steps, are inclined at a sharp angle, the bagasse being fed to the upper and front end as it burns. Flat grates are constructed either of stationary or hand-operated shaking bars, the latter being common in Louisiana. Flat grates are shown in Figs. 1, 2, and 4. Fig. 5 shows an inclined-grate furnace of recent design in which hand-operated pushers and dump grates at the lower end are used to facilitate cleaning and clinkering. The majority of grate furnaces are operated with natural draft although some have undergrate forced draft with centrifugal fans or steam-jet blowers, there being many of the latter in old Louisiana installations. FIG. 6 HEARTH (HORSESHOE) FURNACE IN CONNECTION WITH TWO HORIZONTAL RETURN-TUBULAR 250-HP BOILERS; NO PROVISION IS MADE FOR BURNING OIL FUEL

grate blowers if forced cause carry-over of ash and cinders, even up through the stack, in some cases. The steam-jet blowers consume considerable steam which cannot be recovered.

In hearth furnaces, Fig. 6, the bagasse is dropped on a hearth of "horseshoe" of rectangular shape at ground level, air being supplied through cast-iron tuyères from an air chamber surrounding the hearth to which air is delivered by a blower. In more modern installations, the blower is of the impeller type set in the furnace walls. The hearth furnace affords maximum opportunity for control of capacity and air supply, and is especially suited for large boilers. In older designs, a single-hearth horseshoe was used for as much as 1200 bhp, frequently supplied by two 600-hp boilers. However, today the tendency is to subdivide the hearth into two or more sections for a single boiler of the same or smaller size, in order to facilitate cleaning during the run, also to promote increased ratings. In recent years, a considerable number of hearth furnaces has been installed in connection with horizontal-return-tubular boilers of 150 hp or less, with satisfactory results. This method of introducing air seems especially advantageous in the combustion of bagasse from certain varieties of cane.

Another feature in modern furnaces, especially of large size, is the use of suspended flat arches instead of sprung arches of circular shape to form the furnace roof. In the older and smaller sizes sprung arches were used and were satisfactory and cheap. However, where the spread exceeds 7 ft or so, the upkeep caused by the thrust and high furnace temperatures justifies the suspended flat type of arch which has come into common use and proved very satisfactory. Fig. 7 shows a furnace with sprung arches for a Babcock & Wilcox boiler of 859 hp. It will be noted that there are three arches, namely, a single arch of wide spread over the hearths, a single arch of wide spread over the bridge wall, and twin arches of narrow spread between the bridge wall and the boiler. The Cuba Cane Sugar Corporation at one time had a great many arches of this type which were expensive to maintain, in fact requiring rebuilding operations at regular intervals. Boilers of similar size installed later were provided with suspended arches, with very satisfactory results. One particular arch, of circular contour as shown in Fig. 3, was found very satisfactory, the author being associated with H. Clyde Gregory and the late G. P. Ward in its development.

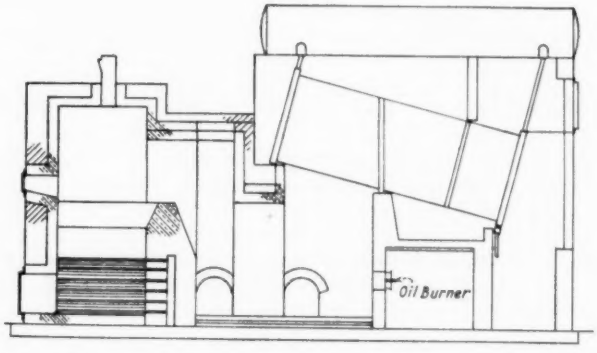

FIG. 7 BAGASSE FURNACE WITH SPRUNG ARCHES; THE UPKEEP OF THIS TYPE IS EXPENSIVE DUE TO THRUST, ETC.

Many boiler tests have been made by various investigators, the data from which are available. The author, while connected with the Louisiana State University, made fifteen boiler tests in 1909. In these tests, the weight of bagasse fed to the boiler was determined by weighing the cane supplied to the mill and subtracting the weight of juice which was measured in clarifier tanks. In this series, the average boiler efficiency was 46.3 per cent with an average rating of 125 per cent. The boilers were mostly 150 hp, or smaller, of the horizontal-return-tubular type. The furnaces were of the Dutch-oven type similar to Fig. 1, but without the steel casing or insulation. The efficiencies though low were representative of the time. Great accuracy was not possible under prevailing conditions. Furthermore, the bagasse moisture content was high, the mills being inefficient.

In 1910 the author conducted a series of tests on a 100-hp Stirling boiler with a Dutch-oven furnace, using partially dried ba-

gasse. The bagasse and the water were weighed. The average moisture of the material leaving the drier and being fed to the furnace was 46.2 per cent. The average efficiency of boiler and furnace in thirteen tests was 31.8 per cent, with an average of 80 per cent rating.

During 1914 and 1915 the author made thirteen boiler tests with bagasse as fuel on horizontal-return-tubular boilers at the Adeline, Vermillion, and Angola factories in Louisiana. In these tests the bagasse and the feedwater were weighed. In general these tests were made under better conditions and on better boilers and furnaces than the foregoing tests. The complete results of these tests, as well as those of 1909 and 1910, have been published.[1]

The tests at the Adeline factory were made on the unit shown in Fig. 4, which was designed by the Honolulu Iron Works, the boiler being rated at 250 hp. The efficiencies in the two tests were 52.8 per cent and 53.0 per cent, with ratings of 151.8 per cent and 102.7 per cent, respectively. The Vermillion factory tests were made on the unit shown in Fig. 1, which is a steel-encased boiler, rated at 250 hp, with asbestos lining, the furnace roof being flat. The boiler efficiencies were 60.4 per cent and 55.6 per cent, with ratings of 109.8 per cent and 105.9 per cent, respectively.

The tests at the Angola factory were made on a horizontal-return-tubular boiler, rated at 150 hp, having a furnace practically identical with that shown in Fig. 1, except that the setting was entirely of brick without the steel casing and with a sprung furnace arch. With ratings of 61.8, 103.3, and 125 per cent, the boiler and furnace efficiencies were 39.8, 47.7, and 50.1 per cent, respectively.

[1] "Report of Furnace Tests Using Bagasse as Fuel," Bulletin No. 160, Louisiana State Agricultural Experiment Station, October, 1916.

In 1922, the author conducted two tests on a Gilchrist furnace under a 1025-hp, four-pass Edgemoor boiler at Central Stewart in Cuba. The furnace was of the type shown in Fig. 2, although the boiler had four passes which gave a very low flue temperature. The efficiencies obtained were 61.32 per cent at 108.7 per cent rating and 60 per cent at 134.4 per cent rating. For purposes of comparison, a test also was made on a third boiler of the same size and make with a hearth, horseshoe-type furnace which, with a rating of only 88.7 per cent, showed an efficiency of 53.8 per cent. The efficiency would undoubtedly have been greater with a heavier load.

Special features in the Gilchrist furnace design are of interest, particularly the upward sloping roof and the wide floor extending back from the grate. In the Stewart furnace, the total distance from the front of the grate to the front of the bridge wall was some 18 ft. In order to clean the furnace, tools 20 feet long were required. Furthermore, the design necessitated a 20-ft firing pit in front. The construction cost as well as the operating inconvenience contributed to its discontinuance after five or six installations had been made, although the efficiencies were good. Another very reliable test on a furnace of the type shown in Fig. 2 was made at Central Florida, Cuba, by Professor Jesse J. Eames of the Massachusetts Institute of Technology in 1923. In this case, the boiler was an Edgemoor, 655-hp unit with three passes, which gave an efficiency of 56.8 per cent at 129.2 per cent of rating.

Fig. 3 shows a type of furnace which has probably been more widely adopted in recent years than any other design. The arch, which is of suspended construction and curved from front to rear, was developed by Messrs. Gregory and Ward of the Babcock & Wilcox Company in collaboration with the author, the first one

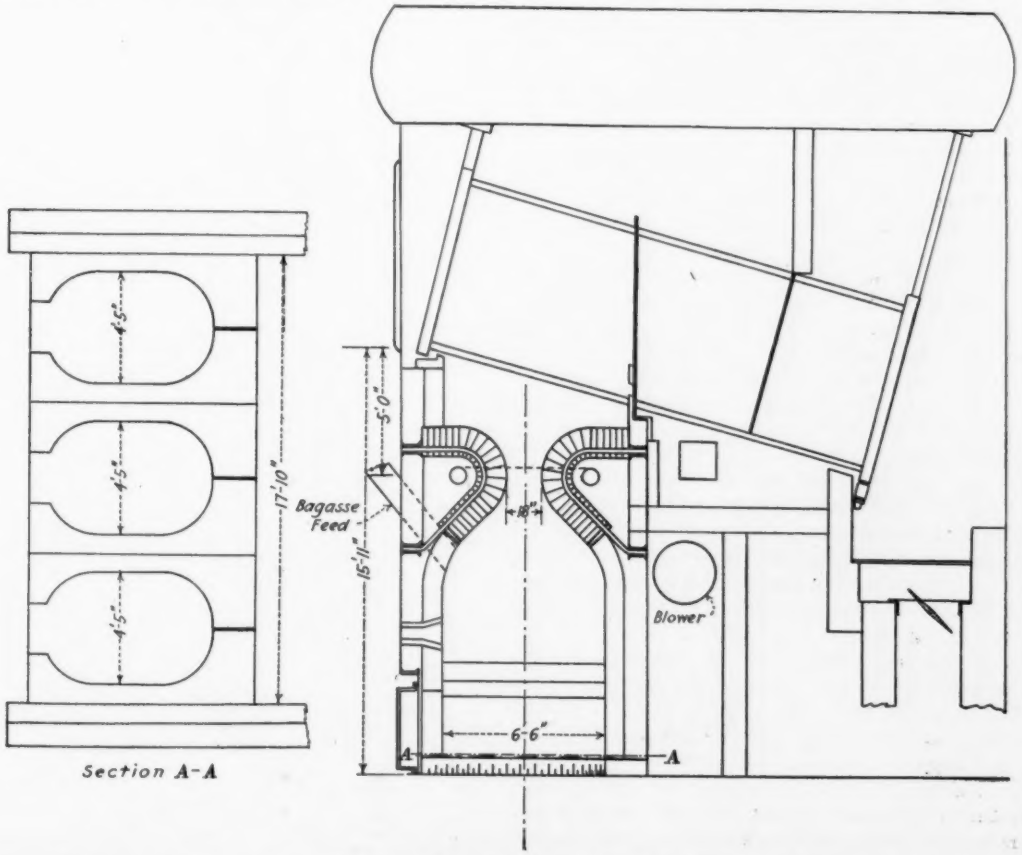

Fig. 8 Single-Pass Bagasse Furnace; a New Type With Reduced Radiation Loss; Also Less Time Lost for Cleaning

being installed at Central Perseverancia, Cuba, in one of the Cuba Sugar Cane Corporation factories. Since that time it has been adopted in many countries.

Fig. 7 shows a type of roof which, as already mentioned, was expensive to keep in repair and which the curved arch was designed to replace; the principal advantage of the curved arch being the reduced cost of up-keep and possibly somewhat less draft loss due to smoother flow.

In 1923 and 1924, a series of some sixteen tests was conducted at Central Baragua, Cuba, by Dr. N. E. Lewis, G. P. Ward, and the author on an 859-hp, Babcock & Wilcox, three-pass boiler in which the bagasse and water were weighed, all conditions being such as to make the results very reliable. The 1923 tests were made on the furnace shown in Fig. 7, which had a single horseshoe, whereas the 1924 tests were made with two horseshoes, each of somewhat smaller area. The ratings varied from 89.7 per cent to 155.4 per cent with efficiencies of 60.0 per cent to 54.3 per cent.

The latest and most revolutionary design of bagasse furnace, developed by the late G. P. Ward and known as the Ward furnace or single-pass furnace, is illustrated in Fig. 8, which shows a sectional view of a furnace under a straight-tube boiler, as well as a plan view through the furnace which has three hearths. The special features of this furnace are (1) the bottle shape narrowing to 18 in. at the neck; (2) cast-iron horseshoes through which air is admitted to the hearth by means of slots $^1/_2$ in. wide, and (3) the large air-insulated wall area. It will be noted that with this type of boiler the furnace is entirely underneath the first pass of the boiler and does not extend in front, thus eliminating a large area subject to radiation. The furnace can be and is used in connection with Stirling-type boilers. In this case, however, there is an extension of about 7 ft 6 in. in front of the boiler from the center of the front drum. Therefore, the reduction in radiation for Stirling boilers is not as great as for straight-tube boilers. The use of cast-iron wind boxes permits greater hearth area and lower air velocities through the tuyères. This, together with the high temperature at the neck, eliminates to a great extent the discharge of fly ash into the boiler.

Some twenty-two of these single-pass furnaces have been installed, one of them at Little Texas factory in Louisiana. They have given good satisfaction. Due to the large hearth area, etc., it is possible to operate this type of furnace at high ratings.

A test of a furnace of this type with a 450-hp watertube boiler was made by Mr. Ward at Central Preston in 1936. Complete data from the test are given in Table 1. The efficiency was 66 per cent with a developed rating of 165 per cent. Another test was made at Central Punta Alegre in which the developed rating was 165 per cent. Comparing this result with the Baragua tests, it will be noted that, with a rating of 155 per cent in two tests, the average efficiency was 55 per cent, which gives evidence of the increased efficiency with the single-pass furnace. Doubtless the greater part of this increase in efficiency is due to reduced radiation loss, although the elimination of fly-ash accumulation in the rear of the boiler is an important feature. It is claimed that even higher ratings, probably 200 per cent, are feasible with this furnace, which would give a heat release of some 60,000 Btu per cu ft of furnace volume per hr.

Fig. 5 illustrates a furnace developed in recent years which has been adopted extensively. The author was responsible for installing a furnace of this type under a 900-hp boiler at Central Moron, the first installation of its kind for bagasse. It will be noted that the bagasse is dropped onto an inclined refractory drying apron, sliding to cast-iron stepped grates, *a* to *b*, thence to plain grates having hand-operated pushers between them. Finally there is an ash dump, adjacent to the bridge wall, which is operated from the front. The furnace illustrated is actually composed of three furnaces with dividing walls between, the idea being to facilitate even feed and permit cleaning on the run. Air is admitted under the grate and through tuyères in the bridge wall. The arch is of the suspended type. The unit shown in Fig. 5 is a 750-hp Stirling boiler installed in a Louisiana factory.

A test was made on each of two 881-hp Casey & Hedges straight-tube boilers (watertube) with furnaces of this type at Reserve factory by Professor Wm. Whipple. A composite of the more significant data in these two tests is given in Table 2.

The efficiency of boiler and furnace was 58.8 per cent at a developed rating of 167 per cent. It will be noted that there is much cast iron in this furnace. The efficiencies in these tests were based on an average calorific value of 7980 Btu per lb, dry basis, which figure was the average of calorimeter tests made by two different laboratories. The calorific value for the five Baragua tests averaged 8200 Btu per lb dry basis.

The first hearth furnaces were designed and installed by Frederick Cook, who used heaters of cast-iron construction, employing flue-gas heat for raising the temperature of the air on its way to the furnace. In 1893 he ran a test on his "hot blast" furnace at Ingenio "Dos Hermanos," Cuba. The furnace was placed between two 640-hp Babcock & Wilcox boilers opposite the first pass. The gases divided, passing over the boiler heating surfaces in the usual way, then through individual tubular air heaters, thence to a common chimney. In this test he had to deal with bagasse of 58 per cent moisture. The test lasted 8 hours, one horsepower was developed with 13.25 lb of bagasse, the boiler operating at 76 per cent of rating. With a calorific value of 8000 Btu per lb of dry matter, this would be equivalent to an over-all efficiency of 57.5 per cent which for that time was exceptional.

In 1935 Mr. Ward conducted two tests on a 1290-hp Stirling boiler, equipped with a furnace of the general type shown in Fig. 3, but having a superheater and a vertical tubular air heater of modern design at the rear, together with forced- and induced-draft fans. Data covering these tests are given in Table 3. It will be noted that the efficiency of the boiler, air heater, and superheater was upward of 70 per cent at ratings of more than 200 per cent. In one test the gas temperature was reduced from 552 to 348 F by the air heater and 536 to 340 F in the other. The draft loss through the boiler and air heater was 2.65 in. water and 2.48 in. water, respectively. As far as the author knows these efficiencies are the highest ever obtained with bagasse fuel.

To complete the essential information concerning results obtained with bagasse fuel, Table 4 gives heat-balance data from the tests conducted at Centrals, Stewart, Baragua, Mercedita, Preston, and at Reserve factory.

The Effect of Preparation on Ash Fusibility as Revealed by a Study of Selected Illinois Coals

By L. C. McCABE[1] and O. W. REES,[2] URBANA, ILL.

The authors discuss the effect of sizing, and of sizing and specific-gravity separation on the softening temperature of the ash from ten representative coals mined in Illinois. The ash-softening characteristics of the sized coals fall into four groups. With the possible exception of two mines, there appears to be no grouping of ash-softening characteristics into specific-gravity fractions. Great differences in softening temperature were obtained in the ash of sized coals of narrow specific-gravity range. In general, the combining of ash of widely different fusion characteristics is to lower the high softening temperatures and to raise low softening temperatures of the individual portions.

STUDIES of the characteristics of the ash of coal have of recent years become increasingly common, such investigations being stimulated by the hope that they may provide criteria for establishing the particular suitability of the coal for specific uses. A variety of investigations have been made, but reference is necessary to only a few of these as examples. Ash-fusibility tests are being made in increasing numbers as part of the ordinary commercial analysis. Uncertainty as to the significance of these values has, in turn, stimulated investigations such as those of Nicholls, Selvig, and Ricketts (1)[3] into the relationship of fusibility determinations and clinkering tendencies. The relationship of ash composition to ash fusibility is also a problem that has received much attention recently (2). Some attention has been given to the bearing of the nature of the mineral components of the coal upon ash fusion (3). These and other investigations are providing a basis for a better understanding of the complicated relationship between ash composition and ash fusibility, and of ash fusibility to clinkering tendencies.

The investigation, the results of which are described in the present paper, was concerned with the effect of preparation upon the softening temperature of coal ash rather than with the relationship of ash composition to fusibility.

Few records of similar investigations have come to the attention of the authors. Ball (4) studied the amount and character of mineral matter of No. 6 bed coal from Franklin County, Illinois. Estep et al. (5) studied the effect of mixing coals on ash-softening characteristics of the mixture. Yancey and Fraser (6), in a report on some coal-washing studies, referred briefly to the effect of washing on ash fusibility. Selvig et al. (7), in discussing the relationship of ash fusibility to clinker formation commented on the effect of washing upon the fusibility and the clinkering characteristics of the coal. The only generalization of particular present interest that can be drawn from the last three papers referred to is that ash-fusion characteristics vary depending on the extent to which washing eliminates certain mineral substances. Furthermore, according to these authors, elimination of pyrite usually tends to raise the temperature of fusibility of the washed coal as compared with that of the raw coal.

This paper dealing with the effect of preparation on ash fusibility of coal screenings from Illinois mines is a part of an investigation of washability characteristics, size range, and petrographic and chemical nature of coal screenings, initiated by the Illinois Geological Survey in 1935. Ten mines were sampled so that each of the commercially important coal beds as well as the different producing districts in the state was represented, Table 1 and Fig. 1.

TABLE 1 LOCATION, COAL BEDS WORKED, THICKNESS OF BEDS, MINING METHODS, AND TONNAGES OF MINES SAMPLED

Mine	County	Coal bed number	Average thickness, ft	Average thickness, in.	Mining methods	Daily average, tons
A	Henry	1	4	1	Room-and-pillar, coal shot from solid, hand loading	450
B	Woodford	2	2	9	Long-wall, hand mining, hand loading	425
C	Peoria	5	4	2	Room-and-pillar, machine mining, hand loading	3000
D	Vermilion	Grape Creek	5	0	Room-and-pillar, machine mining, hand loading	3000
E	Sangamon	5 Springfield	5	9	Room-and-pillar, coal shot from solid, hand loading	1500
F	Christian	6	7	6	Room-and-pillar, coal shot from solid, hand loading	700
G	St. Clair	6	7	0	Room-and-pillar, machine mining, machine loading	1300
H	Marion	6	6	4	Room-and-pillar, machine mining, hand loading	1700
I	Williamson	6	10	0	Room-and-pillar, machine mining, mechanical loading	4000
J	Saline	5 Harrisburg	5	3	Room-and-pillar, machine mining, hand loading	2000

Increments of from 12 to 15 lb were taken from the loading chute at each mine throughout a day's run. One quarter of the gross sample of from 1000 to 1500 lb was sized and used in float-and-sink tests. Water solutions of zinc chloride were used in the float-and-sink tests of coal from $^3/_4$ to $^3/_8$ in. and larger, and organic solutions, carbon tetrachloride, benzene, and bromoform mixtures, in the sizes smaller than $^3/_8$ in. Results and details of procedure of the sizing and washability tests (9) have been published and will not be repeated here.

From the float-and-sink fractions, samples were taken which have furnished a fund of data on the ash-fusion characteristics and ash composition of these coals. Only the data pertaining to the effect of sizing and heavy-liquid separation on ash-fusion temperatures will be considered here; ash composition and its relation to ash-fusion characteristics will be treated at length in another publication.

FIG. 1 MAP OF ILLINOIS SHOWING LOCATION OF MINES WHERE SCREENINGS WERE SAMPLED

The screenings sample from each mine was sized as follows: $1^1/_4$ to $^3/_4$ in., $^3/_4$ to $^3/_8$ in., $^3/_8$ in. to 10 mesh, 10 to 48 mesh, and minus 48 mesh. Round-hole screens were used in sizing at $^3/_8$ in. and above and Tyler standard sieves for sizing below $^3/_8$ in.

Each size was separated by heavy liquids of 1.30, 1.35, 1.40, 1.50, and 1.70 specific gravities into the following fractions:

1.30 specific gravity, float
1.30 to 1.35 specific gravity, float
1.35 to 1.40 specific gravity, float
1.40 to 1.50 specific gravity, float
1.50 to 1.70 specific gravity, float
1.70 specific gravity, sink

The ash and sulphur values for the coals were obtained according to A.S.T.M. procedures (10). The ash-fusion data were obtained according to A.S.T.M. specifications (11) in a Barrett ash-fusion furnace. The ash analyses were made in accordance with procedures outlined by Hillebrand and Lundell (12) and Washington (13) for the analysis of silicate rocks.

Initial-deformation, softening, and fluid temperatures of the ash together with percentages of ash, sulphur, and weight of the gravity fractions are given elsewhere (14). Figs. 2 to 5 show the relationship between coal size and ash-softening temperature.

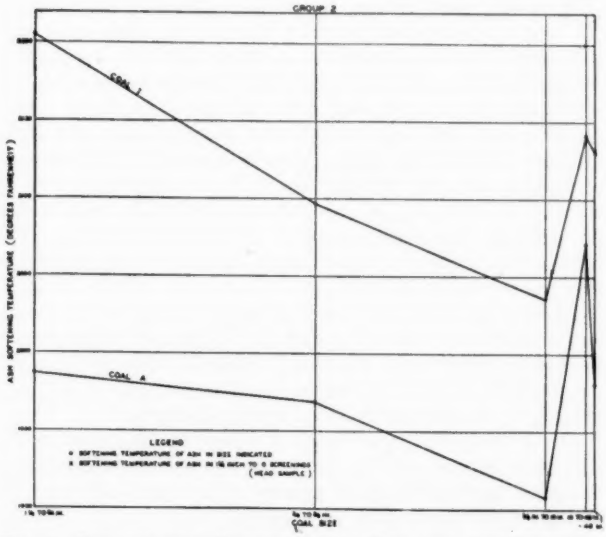

FIG. 3 RELATIONSHIP BETWEEN COAL SIZE AND ASH-SOFTENING TEMPERATURE, MINES I AND A

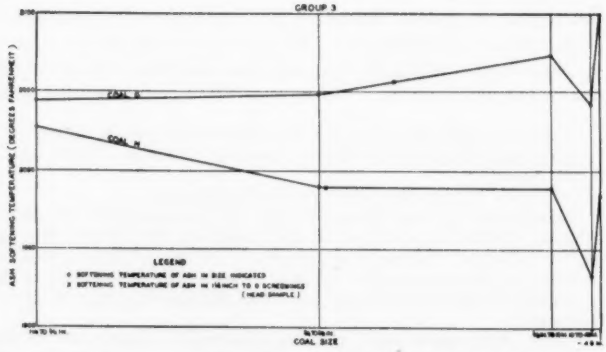

FIG. 4 RELATIONSHIP BETWEEN COAL SIZE AND ASH-SOFTENING TEMPERATURE, MINES G AND H

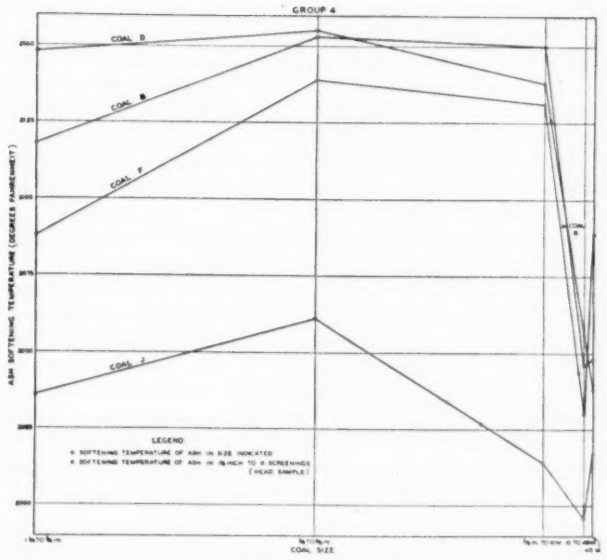

FIG. 5 RELATIONSHIP BETWEEN COAL SIZE AND ASH-SOFTENING TEMPERATURE, MINES B, D, F, AND J

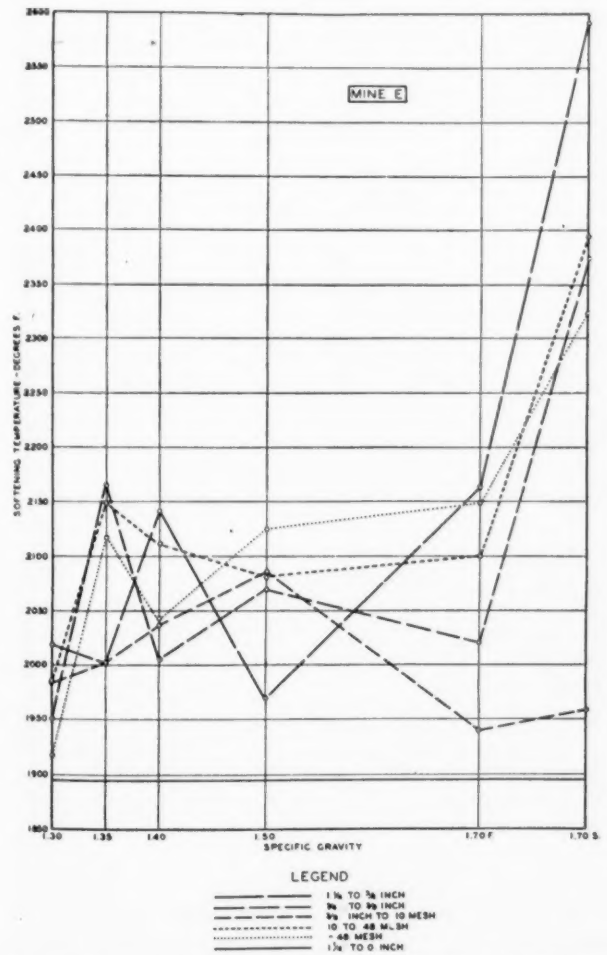

FIG. 6 RELATIONSHIP BETWEEN NARROW-RANGE GRAVITY AND ASH-SOFTENING TEMPERATURE, MINE E

sizes aids in comparing these values for the different sizes in the same mine and the curves formed by connecting the points make it possible to place the mines in characteristic groups.

The curves of ash-softening temperatures for the ten mines may be divided into four groups each containing two or more similar curves. In group 1 which includes coals from mines C and E (Fig. 2) the highest ash-softening temperature is in the minus 48-mesh size. The curves of group 2, representing coals I and A (Fig. 3) exhibit their lowest softening temperature in the $^3/_8$-in. to 10-mesh size, followed by an increase of from 100 to 150 F in the 10- to 48-mesh size with a reversal to a lower softening temperature for the minus 48-mesh dust. The group 3 curves, based on coals G and H (Fig. 4), show rather uniform ash-softening temperatures for all sizes except the 10- to 48-mesh size which is consistently lowest. The curves of group 4 representing coals B, D, F, and J (Fig. 5), show the highest softening temperatures to be in the $^3/_4$- to $^3/_8$-in. size. Three of these curves show the lowest ash-softening temperature in the 10- to 48-mesh size with a slightly higher softening temperature in the ash from the minus 48-mesh coal. In coal B no such reversal is shown.

While the number of mines represented is too small to be conclusive, with one exception there appears to be a relationship between the geographical location of the mines and the groupings indicated. The mines of group 1 are in No. 5 coal in the western part of the coal basin (Fig. 1). Mines of group 3 operate in No. 6 coal in the Belleville district of southwestern Illinois. Group 4 includes mines working the Grape Creek No. 2, No. 5, and No. 6 coals but all operating near the center or to the east of the center of the coal basin. Group 2 embraces two widely separated mines, mine A operating in No. 1 coal in northern Illinois and mine I producing from No. 6 coal in Williamson County.

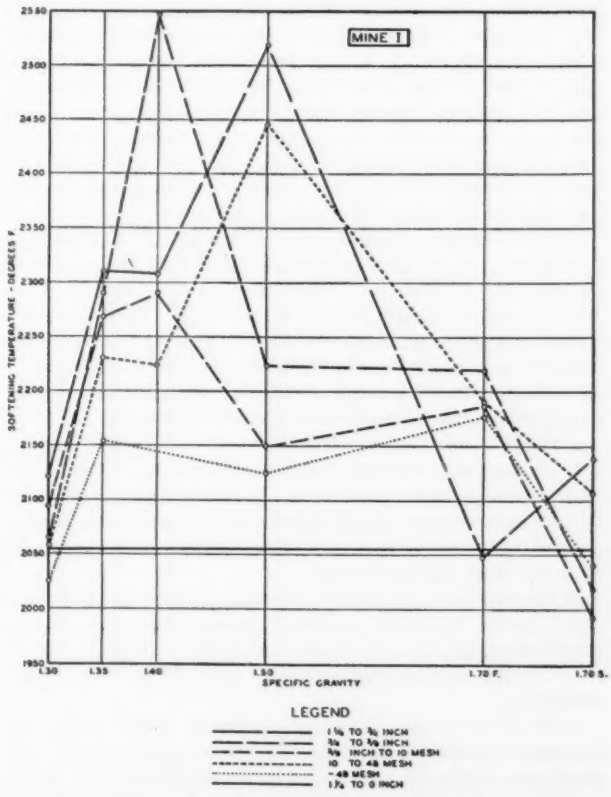

FIG. 7 RELATIONSHIP BETWEEN NARROW-RANGE GRAVITY AND ASH-SOFTENING TEMPERATURE, MINE I

Coals E and I were selected for an exhaustive study of ash composition in relation to ash-fusion characteristics because of the extremes of sulphur content. The sulphur content is 5.3 per cent for mine E 1¼ to 0 screenings and 1.9 per cent in screenings from mine I.

To investigate further the effect of preparation on ash fusion, samples of each of the five sizes of coals from mines E and I were separated by heavy solutions into fractions, 1.30, 1.35, 1.40, 1.50, and 1.70 float, and 1.70 sink. Chemical analyses of the ashes of the 1¼ to 0 samples of these coals appear in Table 2, while ash-fusion determinations as well as percentages of ash, sulphur, and weight of the specific-gravity fractions are given elsewhere (14).

TABLE 2 ASH ANALYSES OF SCREENING SAMPLES (1¼ IN. TO 0) FROM MINES E AND I

Ash constituents	Mine E, per cent	Mine I, per cent
SiO_2	40.15	46.94
TiO_2	0.77	0.93
Al_2O_3	11.81	20.19
Fe_2O_3	26.20	18.82
MgO	0.88	1.24
CaO	8.37	4.62
Na_2O	0.92	0.50
K_2O	1.35	2.12
P_2O_5	0.00	0.00
Total sulphur as SO_3	9.09	4.69
Total	99.54	100.05
Ash in coal (dry basis).....	13.8	10.4
Sulphur in coal (dry basis)...	5.3	1.9

Inspection of Table 2 shows the coal from mine E to be higher in ash and sulphur than that from mine I. The composition of the two ashes varies also; the SiO_2 and Al_2O_3 are lower in coal ash E while the Fe_2O_3, CaO, and SO_3 are considerably higher than in ash I.

These closely sized fractions of narrow specific-gravity limits cover a wide range of ash-softening temperatures but the curves (Figs. 6 and 7) show the ash-softening temperatures to be quite different for the two mines. In general the lowest ash-softening temperatures for mine E are in the fractions of low specific gravity and with the exception of the ⅜ in. to 10 mesh, the highest softening temperatures are in the minus 48-mesh size. The mine I curves show low ash-softening temperatures in both the low- and high-specific-gravity fractions and high ash-softening temperatures at intermediate specific gravities.

The ash-softening temperature of the mine I ¾- to ⅜-in. 1.40-specific-gravity fraction is 2547 F (14) and of the 1.70-sink fraction 2019 F, a range of 528 F between the maximum and minimum softening temperature in the size. The difference in softening temperature between the 1.50 (2518 F) and the 1.70 (2048 F) float in the 1¼- to ¾-in. size is 470 F. Mine E 1¼- to ¾-in. coal shows a range of 622 F in the ash-softening temperatures of the 1.50-specific-gravity-float fraction (1971 F) and the 1.70-sink fraction (2593 F).

It is noteworthy that the head sample for mine I has a lower ash-softening temperature than do most of the sizes prepared from it. All ash-softening temperatures of float and sink fractions derived from mine E head sample are higher than the softening temperature of the head sample.

It appears from the data for these two coals that sizing and close gravity separation produce products the ash-softening temperatures of which are usually higher than that of the original coal. It also appears that each coal possesses individual characteristics.

In Figs. 8 to 11 are presented ash-fusion data for sizes and cumulative gravity samples studied. The composite samples were made up according to percentages by weight obtained by gravity separations of each size. This procedure makes it possible to observe the effect on softening temperature of adding increments of high-ash coal to lower-ash coal or to determine the effect on softening temperature of washing at any given specific gravity.

It has been shown that the ash-softening temperatures of four of the high-specific-gravity fractions of mine E (Fig. 6) are considerably above the softening temperatures of the ash of the fractions of low specific gravity. It is apparent from an examination of the increment curves for this mine (Fig. 9) that the addition of increments of high-softening-temperature ash does not always raise the softening temperature of the composite; in most instances the effect is one of lowering the softening temperature of the whole. In the curve showing individual softening temperatures of the ¾- to ⅜-in. size (Fig. 6) fractions having specific gravities above 1.30 have higher softening temperatures than does the fraction floating at 1.30 specific gravity, yet when these fractions are combined in the proportion in which they occur in the coal, the effect of each added increment is to lower the softening temperature. The minus 48-mesh cumulative curve (Fig. 9) roughly follows the curve of individual softening temperatures (Fig. 6) in the first five increments but on the addition of the 1.70-sink fraction, which has a softening temperature 175 F

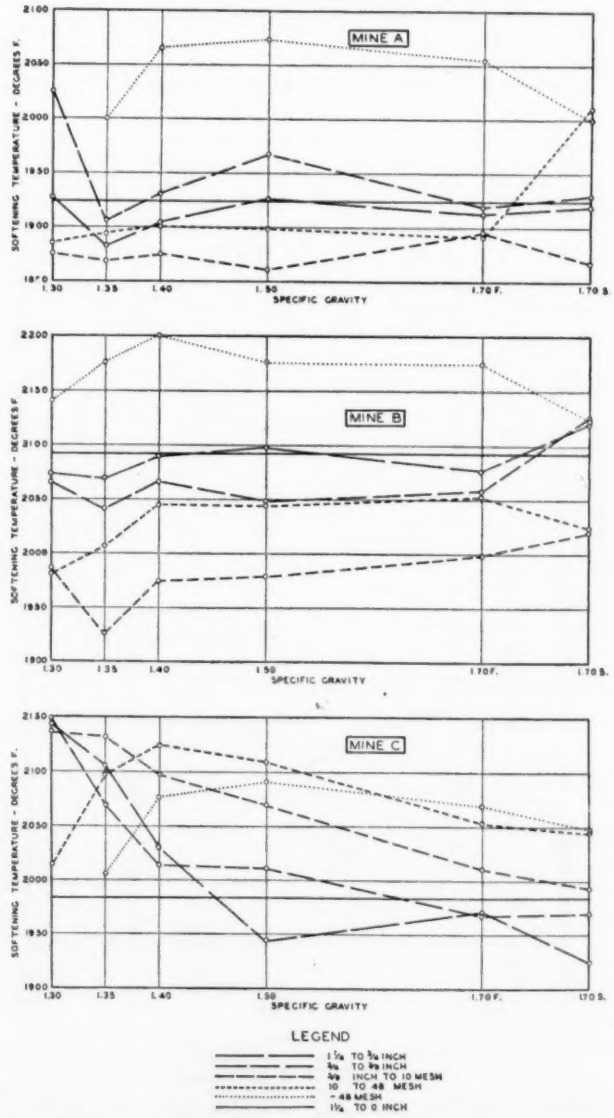

FIG. 8 RELATIONSHIP BETWEEN CUMULATIVE GRAVITY AND ASH-SOFTENING TEMPERATURE, MINES A, B, AND C

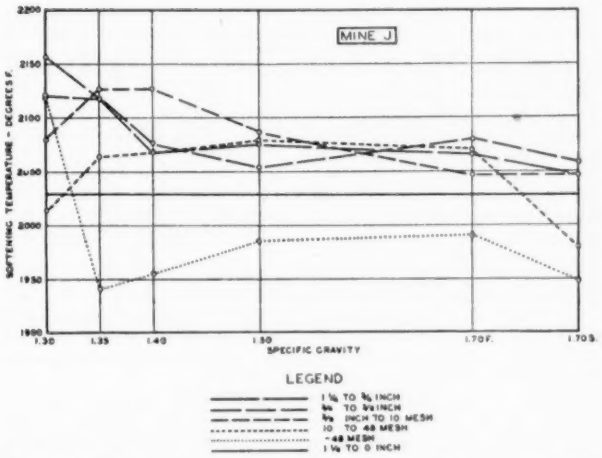

FIG. 11 RELATIONSHIP BETWEEN CUMULATIVE GRAVITY AND ASH-SOFTENING TEMPERATURE, MINE J

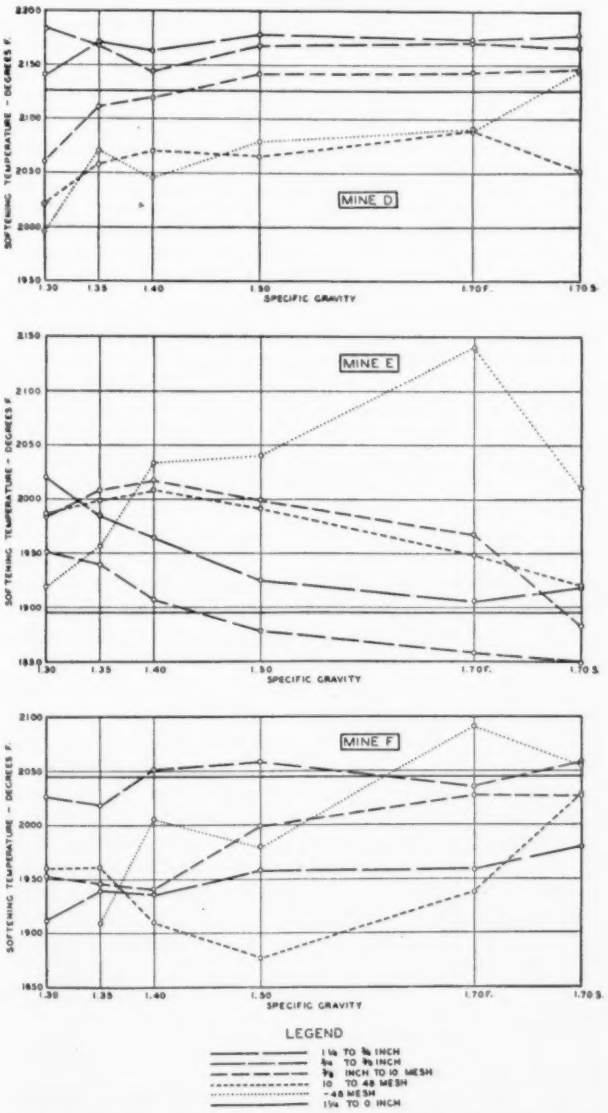

FIG. 9 RELATIONSHIP BETWEEN CUMULATIVE GRAVITY AND ASH-SOFTENING TEMPERATURE, MINES D, E, AND F

higher than that of the nearest increment (14), the softening temperature of the composite is lowered 129 F.

While the cumulative curves for mine I (Fig. 10) conform in a general way to the curves of softening temperature for individual fractions (Fig. 7) a modifying effect on both high and low points is apparent.

At 1.50 specific gravity (the washing gravity of most Illinois coals) the majority of sizes at all mines except B and F have higher ash-softening temperatures than the $1^1/_4$- to 0-in. head sample (Figs. 8, 9, 10, 11). However, it does not follow that, if these sizes were combined to form washed screenings, the fusion temperature would be higher than in the unwashed screenings. It might be higher or it might be lower.

The cumulative ash-softening curves for mines G and H (Fig. 10) are similar in shape and the curves for the various sizes occupy the same relative positions. These relations are not apparent for the coals of the other eight mines (Figs. 8, 9, 10, 11).

While sulphur values for all samples have been listed (14), no

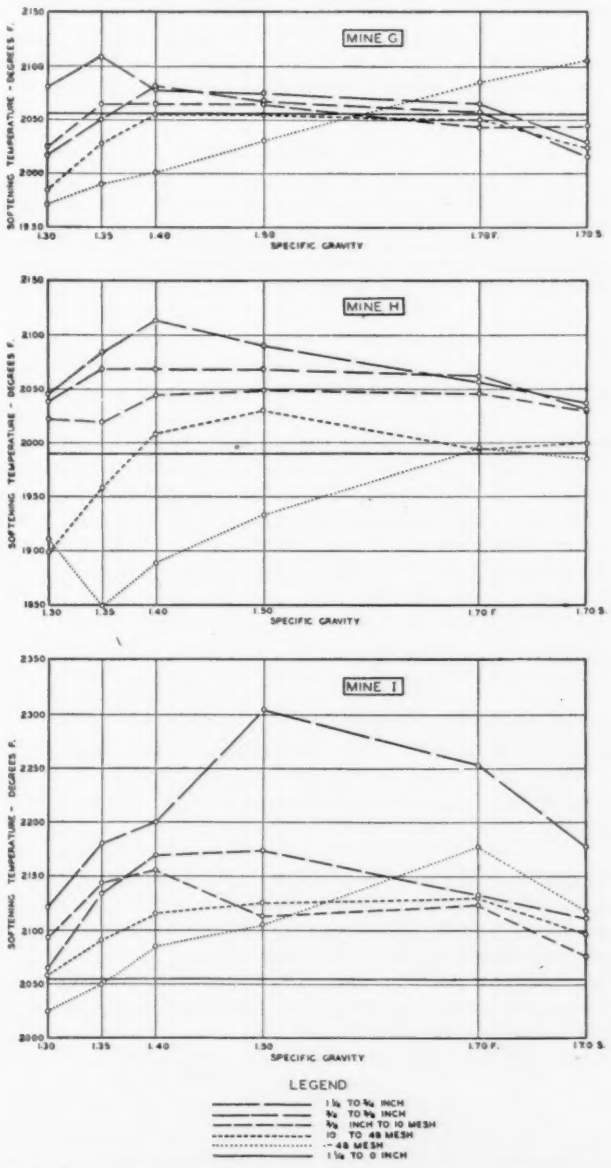

FIG. 10 RELATIONSHIP BETWEEN CUMULATIVE GRAVITY AND ASH-SOFTENING TEMPERATURE, MINES G, H, AND I

definite relationship of these values with ash-softening temperatures is apparent. Undoubtedly any such relationship depends on the nature and quantity of other minerals in the coal. These relationships will be discussed in a later publication.

Conclusions

Examination of the data presented in this paper leads to the following general conclusions:

1 On the basis of sizing alone the ten coals studied may be divided into four groups within which the ash-fusion relationships are similar.

2 With the possible exception of coals from mines G and H, the ash-fusion relationships of which are similar, no groupings similar to those derived from sizing appear possible on the basis of cumulative specific-gravity separations.

3 The greatest difference in ash-softening temperature was obtained in sized coals of narrow specific-gravity ranges. This may explain clinkering difficulties experienced with stoker coals when changes are made in sizing or washing procedure.

4 The effect, in general, of combining portions of narrow specific-gravity range is to lower high softening temperatures and to raise low softening temperatures of these component portions.

Burning Various Types of Oil-Refinery Fuels

By A. L. WILSON,[1] LINDEN, N. J.

The paper describes the various types of waste by-product fuels which are produced in an oil refinery and the burning of them in boiler furnaces. Composition and characteristics of these by-products are given together with the methods of handling and utilization. Burner design and the use of steam for atomization are considered and attention is called to the fact that combination burners have been developed to burn simultaneously five different fuels in liquid, gaseous, and solid form.

OIL REFINING requires the utilization of relatively large volumes of fuels, among which are nonmerchantable by-product fuels, as well as high-grade merchantable fuels. It is the purpose of this paper to deal mainly with the burning of these nonmerchantable fuels as economically as possible.

Industries that utilize by-product fuels were compelled to design and develop suitable burners and furnaces to meet their individual requirements. This problem is particularly difficult because, due to the changing heat content of these fuels, it is impossible to set up performance charts that would indicate their true efficiencies.

Each installation must be considered as a special problem and, therefore, no attempt is made in the scope of this paper to set up a code that will be a cure-all for the designing and operating of a fuel-burning system by other refineries.

A new industry, while in its early stages, is concerned chiefly with the efficient conduct of the operation which yields its finished product. The substances which are produced at the same time, and are known as by-products, receive increasing attention when competition or other economic circumstances make it necessary to reduce the cost of the manufactured article, or when the amount of these by-products has risen to such proportions that better means for their disposal must be found. Under such circumstances, the attention of the industry is concentrated on these by-products, to provide a more suitable means for their disposal.

In the following discussion, oil-refinery fuels will be classified as follows: (1) Merchantable fuels, such as gas, coke, and fuel oils, (2) sludges, (3) tars, and (4) tank cleanings.

In this classification, the first group can be considered as high-grade, merchantable fuels, which serve as the basis for the evaluation of all other refinery fuels. This group of fuels is burned only after all by-product or nonmerchantable fuels are disposed of. In refineries where coke production is in large volumes, the greater percentage of this coke is a merchantable fuel, demanding a premium, particularly because of its adaptability to metallurgical and other uses requiring a relatively pure carbon. The amount of coke which cannot be considered merchantable, and which may be classed as a waste fuel for burning within the refinery, is small in volume, representing at most a negligible percentage of the total fuel burned. The remaining fuels listed can be considered as by-product or waste fuels, and the rest of the paper will deal mostly with these fuels.

Sludges are by-product materials from a purification process which uses sulphuric acid to remove tarry or gummy constituents from oil. Compared to fuel oil, some sludges are slow-burning and require high ignition temperatures to produce a reasonable heat release. The sludges vary extremely in characteristics, depending upon the initial crude stock, method of treating, and requirements of the finished product. Some sludges are readily blended with various tars to form a smooth-working fuel. Some have a heating value as high as 17,500 Btu per lb while in others it is as low as 9000 Btu on the as-fired basis. This variation is largely due to varying moisture content.

Due to the higher percentage of sulphuric oxide and water vapors in the products from the combustion of sludges, superheater supports, gas by-pass dampers, and economizer tubes deteriorate rapidly unless the exit-gas temperature is kept above the dew point. Exit-gas temperature is not always a true indication of metal temperatures, particularly in the economizer section of the boiler where the actual shell temperature of the tube is considerably lower than the average exit-gas temperature. As is the case when using high-sulphur coals, problems still exist in connection with economizers and preheaters where high efficiencies are desired when sludges are burned.

"Tar" is not exactly defined in refinery terminology, and is a type of sludge from acid refining operations, or may consist of distillation residues. Its combustion characteristics are quite similar to those of sludges.

Nonmerchantable coke is usually a hard nonfriable substance containing a small quantity of volatile matter and varying percentages of sulphur and ash. If the small nonmerchantable portion of this coke is to be burned as pulverized fuel, it must be powdered to a high degree of fineness. If petroleum coke is not finely pulverized the small particles pass out of the furnace partly burned, and may be deposited in the soot hopper or duct of the stack, or may pass through the stack to the atmosphere. The characteristics of the merchantable portion of any coke which is produced are such that it burns more freely and in a manner comparable with pulverized coal.

Small amounts of light oils or tars of light gravity, which are a by-product of some treating operations, average about 19,000 Btu per lb, and may be successfully burned in a separate burner system. Great care, however, must be exercised in handling these fuels, as they usually have a low flash point and high volatility.

Tank cleanings, or "bottoms," consist of a considerable portion of oil of varying gravity and volatility, of dirt, water, salts, asphaltic and waxy semisolid materials, and often of iron scale. The heat value of this material will vary greatly, depending upon the proportion of its various constituents. Tank cleanings may be disposed of in liquid form through a grinding operation, which will be discussed later, or may be cooked up with fluxing oil, by means of which treatment, water, salts, and noncombustible solids are settled out and rejected as such.

The grades and amounts of these various by-product fuels depend upon the crude run and the type of processing, but are seldom available in sufficient quantities to meet the entire fuel requirement of the refinery. The changing character of the sludge which constitutes about 90 per cent of the liquid residuals burned,

Contributed by the Fuels Division and presented at the Spring Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, New Orleans, La., February 23–25, 1939.

Discussion of this paper closed March 25, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

is indicated in Table 1 which shows two typical laboratory determinations.

TABLE 1 SHOWING VARYING CHARACTER OF SLUDGE

Gravity	16.1 API	12.3 Bé heavy
Specific gravity	0.9587	1.092
Weight, lb per gal	7.984	9.105
Sulphur, per cent	4.03	7.43
Heat content, Btu per lb	17,219	13,555

While these analyses are given as typical, the predominating characteristic of the sludges is extreme variability. The moisture or weak acid content of some sludges burned varies through a range up to 50 per cent and on rare occasions goes even higher. Such variations in moisture content cause a wide variation in the consistency of the sludge and require special handling equipment and operating procedures.

Sludges may be classed in two groups: Those from treating gasoline and kerosene, and those from treating heating oils and other heavy petroleum products.

Sludges From Treating Gasoline and Kerosene

Light-oil sludges are produced in two ways: (1) The acid oil, lighter than acid tar, settles out from sludge in the kettle or storage tank before processing. (2) The sludge is pumped into a kettle containing hot water where reaction takes place, resulting in a three-layer separation of acid oil, acid tar, and weak acid. The acid tar, the largest percentage in this separation, has the highest acid content, and is more readily handled and atomized than the heating-oil sludge. It is the most corrosive of all the liquid residuals, due to the amount of water entrained during the separation of the tar from the weak acid.

Sludges From Heating-Oil Refining

These are distinguished from those of gasoline by their thick viscous consistency. Also they are not separated into two layers by the addition of water, as the separated acid is too high in impurities. This sludge is obtained from the purification of heating oil, and is pumped directly to the sludge storage tanks, from which it is pumped to the burners. It requires no agitation, fluxing, or heating for handling. It is not as corrosive as the lighter sludges, either because of the undiluted acid or the inhibiting action of the sludge itself.

Paraffine Sludge

This sludge is a by-product from paraffine-wax treating operations. In many cases this sludge causes considerable difficulty, as it becomes entirely solidified at atmospheric temperature. A large eastern refinery, however, has developed equipment for burning it that has proved satisfactory. The sludge is kept in agitation by steam jets and fluxed with a heavy viscous oil at the treating plant. It is then pumped to the boilerhouse into lead-lined storage tanks, which are equipped with closed brass heating coils located about six feet above the bottom of the tank. Agitation is effected by means of a mechanical mixer located below the heating coil. The storage tank is also provided with a ring of steam jets in the bottom that serves the dual purpose of heating and agitating the sludge. This sludge is burned in a separate fuel system similar to that employed for fuel oil. Burners, using steam for atomizing are employed successfully and the sludge is supplied to the burners at a temperature of from 200 to 220 F. The temperature required depends upon the characteristics of the particular batch of sludge burned.

Preparation Technique

The efficient burning of various sludges constitutes a problem that must be developed by each refinery to meet its particular conditions. Successful utilization of by-product fuels in one refinery is no assurance that it will be equally successful in another, even under similar conditions, as each separate method of processing produces its own variety of sludge. Since various operations produce different types of sludge, no definite rules can be given for its treatment. Frequently it may be processed as a common fuel without troublesome coke deposits. As to whether it is properly processed or agitated, only the experience of trained operators can determine.

Waste Fuel Ground Up as "Colloidal" Fuel

Additional waste fuels consist of all the wastes that have any combustible characteristics. These residues consist of gummy coke, heavy tank bottoms, muck, asphaltic residues, and slop, i.e., plastic solids or semisolid materials which are neither truly solids nor liquids, and cannot be pumped. Collected and dumped into a pit, they may be ground or processed by the wet-pan type of grinder. The product of this operation is a frothy liquid containing appreciable quantities of carbon particles up to $^1/_8$ in. or more in diameter. The quantities of these wastes are generally not sufficient at any one time to warrant continuous operation of separate burning equipment for their individual disposal. In many cases the cost of disposing of these wastes in any other manner is prohibitive.

Sludge Handling and Storage Equipment

The storage and handling of sludges and tars present no difficult problem when the usually accepted standards are maintained. Lead-lined tanks are used for receiving and storing the sludge. These tanks usually are equipped with steam jets to provide constant agitation and proper consistency for pumping and burning, although many sludges are burned without additional heating or agitation. With all fuel-burning equipment, constant flow through the supply and return lines must be maintained in order to prevent stoppage of the system. It is frequently necessary, when shutting down a sludge-burning system, to have the line thoroughly blown out with steam to purge it completely of coke particles which tend to solidify and plug the line. Otherwise the line may have to be dismantled for cleaning. Receiving and storage tanks may be equipped with an acid-fume arrester, if necessary, to collect and dissolve any objectionable acid fumes that may originate through blowing or agitating operations.

Pipes and cocks used for handling the acid sludges are made of brass. This material contains about 85 per cent copper and 15 per cent zinc and usually can be considered as satisfactory.

The pumping quality of sludge is good in most cases and offers no particularly difficult problem in winter or summer. Reciprocating pumps of the type in general use for handling liquid fuels are utilized and in most cases are satisfactory. Pump-valve construction is of various types, being spring-actuated or of the plain rectangular-block type, depending considerably upon the extent of repairs necessary for maintenance. Pistons, piston rods, and lines usually are of acid-resisting bronze of sufficient hardness to avoid excessive wear.

Fuel-Burning Equipment

When faced with burning a variety of liquids, semiliquids, and solid by-product fuels, a novel combustion problem presents itself. The furnace design usually follows the accepted standards for high rates of combustion and steam generation and serves as an efficient plant for the disposal of by-product fuels as well. See Fig. 1.

It is generally desirable to have a combined-type burner, Fig. 2, which is capable of burning a combination of gaseous, liquid, or pulverized solid fuels without changing burner parts, or which permits all of these fuels to be burned simultaneously.

One refinery operation has one of its three large boilers, each of

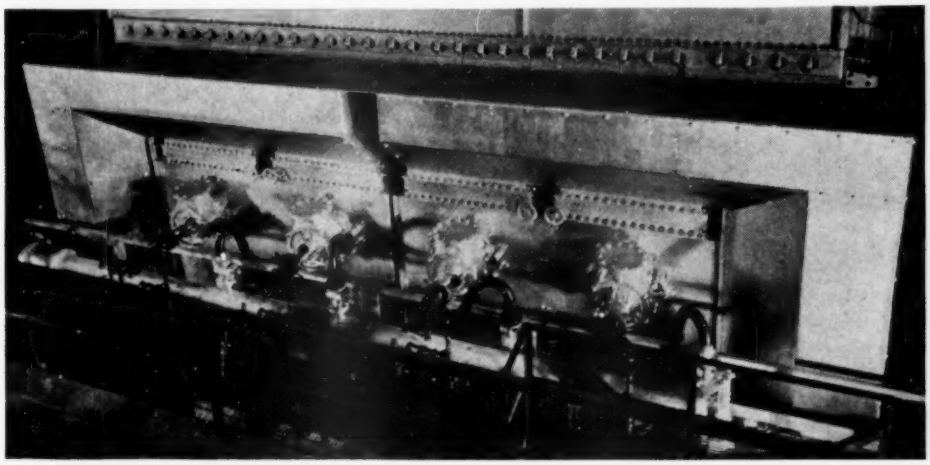

FIG. 1 UPPER PANEL OF FOUR COMBINATION BURNERS FOR BURNING PULVERIZED COKE, FUEL OIL, SLUDGE, AND GAS
(Another set of four is located below the platform, as shown in Fig. 3.)

which is designed to produce a maximum of 225,000 lb of steam per hr at 650 psi and 740 F, equipped to burn five separate fuels simultaneously, i.e., fuel oil, refinery gas, petroleum coke, acid sludge, and colloidal fuel. The other two boilers are equipped to burn refinery gas, bunker fuel oil, and sludge at the same time. Another boiler plant, consisting of four boilers, each with a capacity of 50,000 lb of steam per hr at 380 psi and 650 F, has twelve burners to each boiler. Seven of the burners may burn either fuel oil or sludge; the remaining five are for refinery gas. This boilerhouse generally is referred to as the waste-fuel disposal plant and burns waste fuels entirely when the supply is sufficient to carry the full load. Fuel oil is used only to keep settings warm when sludge is not available.

All boilers on which sludge is used as fuel are equipped with waterwalls and economizers. Induced and forced draft are used at the large plant, while induced draft is used at the smaller plant.

A full complement of indicating, recording, and integrating meters is advisable on high-pressure steam-generating units burning refinery by-products and sludges as fuels, as efficient burning of such fuels reduces the amount of commercial fuels required.

Combustion controls are usually operated manually due to the constantly changing heat content and varying amounts of the fuels.

Indicators are essential to detect instantly the presence of smoke. Smoke indicators used in conjunction with duplex gas recorders have been invaluable in securing maximum efficiency from the various fuels.

Due to the various fuels burned, a multiplicity of piping and valves introduces rather complex operating features, Fig. 3. Steam is employed in most cases to purge supply and return lines, headers, and burner connections, when it is necessary to change burners.

In the larger plant, four headers cross the front of each of the boiler burner panels—one for fuel oil, one for acid fuel, one for gas, with the fourth supplying steam for atomization and for purging lines. When it is necessary to purge an entire sludge system, steam or air is usually used in the parts of the system to be purged.

The large boiler equipped to burn pulverized coke has eight of the modern turbulent horizontal-type burners, and is fired from two levels of four burners each. Two ball mills, each having a coal capacity of 15,000 lb per hr, or sufficient to carry the boiler alone on full rating, comprise the pulverizer equipment. The exhauster of each mill has four ducts leading to one firing level so that one mill may be used at a time.

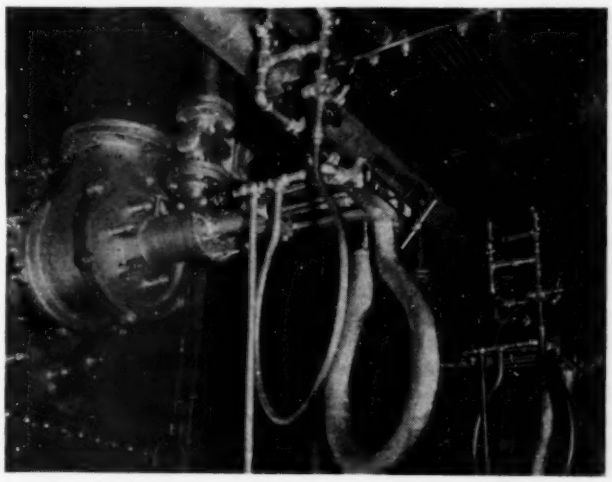

FIG. 3 COMBINATION BURNERS FOR PULVERIZED COKE, FUEL OIL, SLUDGE, AND GAS
(The large blank-covered top connection at the left is for pulverized fuel. The next vertical connection is from the gas header to the control cock. Steam, sludge, and fuel-oil headers are shown supported from the platform.

BURNER DESIGN

In firing various sludges, the most important factor is good atomization to reduce the sludge to a fine mist for its complete, combustion. Of the various approved methods of atomization, steam has generally been used for the liquid sludges, which often are of high specific gravity and contain a considerable amount of solid matter, carbonaceous or otherwise, in noncolloidal suspension. Due to these conditions, there has been much development in designing burners that would be successful in burning the various kinds and grades of refinery liquid sludges without deteriorating too rapidly.

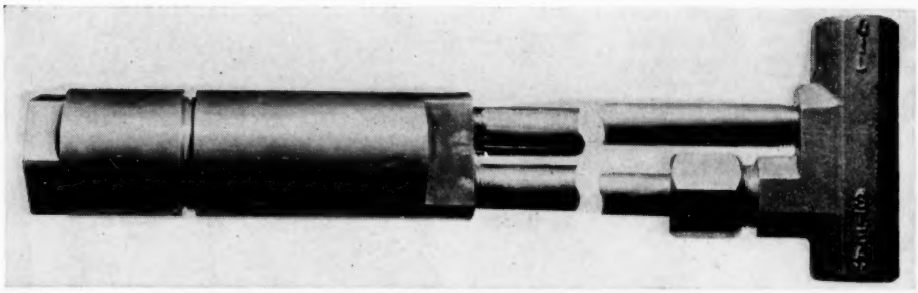

FIG. 4 BURNER FOR FUEL OIL AND SLUDGE

Factors that usually determine the selection of a burner are: (1) Simplicity of design; (2) low cost of installation; (3) thorough atomization of cold sludges; (4) low pump pressure; (5) flexibility and efficiencies on swinging loads; (6) capability of bringing a cold boiler on the line at short notice; (7) ability to burn extremely heavy oils and sludges; and (8) resistance to erosion and corrosion.

A burner, Fig. 4, in one refinery has been designed to burn successfully the different grades of sludge at a pressure of 50 psi and a temperature of 110 F. Effort was made at first to heat the sludge to lower its viscosity, but considerable plugging of the lines and burners resulted and it was finally decided to burn the sludges cold.

The burner in design conforms to the outside-mixing type. The assembly consists of a steam-and-sludge manifold arrangement on one end connected by about six feet of $^1/_2$-in. brass pipe to the burner at the other end. The burner is fastened to the ignition tube of the air register with a swinging yoke clamp for quick attachment. The same clamp attaches the sludge and steam-line connections to the burner manifold obviously avoiding many separate pipe connections. A by-pass valve is provided between the steam and sludge passages to blow the burner assembly clean before changing the burner or to remove solid particles in the burner which may temporarily shut off the sludge supply while in service.

The sludge and steam are admitted under pressure through separate valves and pipe arrangements into the burner tip before atomization takes place. The diffusing nozzle for atomization is located in the tip of the burner. This nozzle has a number of steam ports placed tangentially at the end of the nozzle in relation to the sludge stream and depends upon atomization off the burner tip. This arrangement avoids excessive burner wear. The burner tips are made of alloy metal that will withstand the strong erosive action as well as the corrosive attack of the by-product fuels.

The sludge is forced under pressure through the atomizer, past the steam ports which gives it a high velocity of rotation, breaking it up under the action of centrifugal force. The sludge leaving the burner tip is acted upon by three forces: Gravity, centrifugal force due to the rotating effect of the steam on the oil stream, and translation along the axes of the atomizer. In this manner the sludge is broken up in a fine fog-like mist which can be readily mixed with the secondary air admitted around the burner for complete ignition. The flame is a turbulent rotating cone that does not touch the rear wall tubes.

Regardless of the type of burner employed, satisfactory results cannot be obtained unless the furnace of the boiler is suited for the burning of by-product fuels. The design of the furnace must approach that suitable for good fuel oil by allowing sufficient furnace volume for maximum boiler requirements. The gas must be kept highly heated and afforded time and space in which to burn completely before reaching boiler heating surfaces.

Some important advantages of this type of burner are as follows:

1 Pulsation in the furnace is avoided by allowing sufficient mixture of air and sludge vapors for combustion.

2 There is no objectionable smoke to foul the boiler tubes with a carbon deposit and cause a serious loss of capacity and efficiency.

3 The admission of excess air to the furnace is avoided.

4 The required burning conditions, consisting of good atomization and burning in suspension, are obtained.

5 Low sludge temperatures and pressures are sufficient.

6 The plugging of burners, due to large sludge particles reaching the burner tips, is avoided.

The success of atomization with steam in many cases has been remarkable in that it has eliminated many of the objectionable features encountered in preparation and handling the heavy by-product fuels before they could be burned. The largest percentage of these by-product fuels is burned cold as it is received at the sludge storage tanks and is not fluxed with fuel oil to lower its viscosity.

Burning sludges cold has many advantages. It is difficult to obtain a metal with sufficient strength, corrosion resistance, and thermal transfer efficiency to heat the sludge in a closed heater. Agitating and heating by means of steam jets is necessarily accompanied by excessive steam costs and increase of moisture content in the sludge. Agitating in some cases causes the coke, held in a semicolloidal suspension in the sludge, to drop out in the tank, or in the lines and burners, thereby clogging them. When coke particles are precipitated through agitation and heating, they will not be absorbed again by the fluid even though boiled in heavy acid. This frequently makes it necessary to take the tanks out of service for cleaning and repairs to the heating and agitating system.

OPERATING RESULTS

In the refinery operation previously mentioned, the coke-pulverizing equipment is of standard make as applied to pulverizing coal. It has not been in service long enough to provide any definite data on wear or maintenance costs. The small portion of nonmerchantable coke, as it comes to the boilerhouse, has a high carbon content with a varying ash content as shown in Table 2.

TABLE 2 ANALYSES OF COKE

	Sample no. 1	Sample no. 2	
Oil (separately determined)	7.4	8.3	
Sulphur (separately determined)	3.24	2.4	
Volatile matter	12.61	14.12	Per cent by weight
Carbon	78.2	80.27	Per cent by weight
Moisture	0.77	1.21	Per cent by weight
Ash	8.42	4.4	Per cent by weight
Hardgrove scale	38	56	
Btu per lb	14,500	14,972	

The presence of part of the volatile matter may be explained by the surface oil which accumulates after the coke bed is formed.

In grinding, this oil naturally spreads over the fine particles of pulverized material and must be consumed by surface burning when injected into the furnace. While the surface burning is in process, the coke particle is traveling to cooler parts of the setting (see Fig. 5) where combustion is slowed up. In many cases, sufficient time has not been allowed to consume the particle of carbon itself, permitting it to pass through the furnace only partially burned.

FIG. 5 NEW BOILER UNDER CONSTRUCTION

(View looking vertically up from dry-slag hopper. This boiler will be fired by eight modern turbulent horizontal burners, capable of burning liquids, semiliquids, and solid by-product fuels. Capacity, 225,000 lb of steam per hr at 650 psi and 740 F; heating surface of waterwalls and boiler, 22,500 sq ft; economizer surface, 14,100 sq ft.)

Due to the mineral-ash content present in petroleum oils and removed by means of the acid treatment, which is finally deposited in the sludge, considerable slagging of an objectionable nature is often experienced on the boiler settings while burning these sludges. This slag, in many cases, adheres to the firebox row of screen tubes, the burner-panel water tubes, and particularly to the flat bottoms of the furnaces, when they are employed as sludge-burning units, thus lowering the boiler rating and efficiency to a considerable degree.

UTILITY AND HEAT VALUES

While each of these residues entails its own problem of disposal, much might be said about their utility value, as their true value when burned in a furnace cannot be determined on the basis of calorimeter indications alone.

It is difficult to allocate operating expenses, such as maintenance and repairs, to their proper location on steam-generating units that utilize varying proportions of these fuels. Burning by-product fuels may interfere with efficient evaporation from the heat-transfer surfaces, with a corresponding drop in over-all boiler efficiency and rating since the heating surfaces may be coated with a deposit of slag which is not present when standard fuels are burned.

It is practically impossible to secure a reliable heat-unit balance or true boiler efficiency on sludges that are burned as waste fuel. Due to slagging and fouling of the settings, maintenance and repair costs should be apportioned to the various grades of by-product fuels burned. This is accomplished best by establishing a reasonable operating efficiency for the basic fuel, and debiting or crediting any loss or gain against the waste fuels or the department that produces the by-product material. This method of accounting appears to be a fair means of arriving at or near the utility value of sludges burned, since any efficiency loss or excessive repair or maintenance cost will thus be properly charged.

Discussion

T. GARDNER.[2] The corrosion problem, resulting from the burning of sludges and coals of high-sulphur content, referred to by the author, is one of economic importance, in that boilers and auxiliary equipment attacked by active corrosion may fail and require replacement after only a few years of service.

Such corrosion, evidently, is activated by the accumulated deposits on the metal exposed to the flue gases and by the attendant moisture conditions. These deposits, which are hydroscopic, can become actively corrosive when the metal temperature at the point of corrosion is below the dew point of the surrounding gases. In practice, this condition frequently occurs in units while operating at low loads, while banked, or during outages. Even at higher loads, air-heater corrosion may occur when deposits on the gas side of the tube reduce the heat-transfer rate and lower the metal temperature.

In cases where active corrosion is anticipated, the practice of the writer's company is to advise the customer of the probable deterioration of the tubes, due to this cause, and to suggest that either tubes of heavier gage be used or that alternative designs be employed, to prolong the life of the equipment. One or the other of these suggestions is usually accepted.

G. F. GAST.[3] In general the writer's experience in the burning of nonmerchantable combustibles is in agreement with that of the author. However, the operation of the refinery with which the writer is connected is not comparable with that of the Bayway Refinery, is so far as the fuel situation is concerned. The only nonmerchantable fuels utilized at the Bayonne refinery are creek slop and high-viscosity bottoms. The proportion of water in the creek slop is not constant at all times. This difficulty is overcome, when the moisture content is too high, by burning good fuel along with the slop mixture.

The burning of high-viscosity bottoms is very simple, since the only question involved is that of heating the oil to the proper temperature in order to obtain the correct viscosity at the burner.

J. A. HAYES.[4] The introduction of the type of bunker-C fuel oil, as now produced by the principal petroleum-refining companies has presented a new problem both to users of bunker-C fuel oil and to oil-burning-equipment manufacturers. Cracked fuel oils require improved oil-burning equipment to prevent carbonization of the atomizers, as well as better methods of air introduction to permit faster and cleaner combustion. Present-day fuel oils are largely blends of residuum left in the still and a light product such as virgin gas oil, obtained from the early stages of the distillation, or a cracked gas oil, obtained from the pressure-stilling operation. Generally this blend contains solids in suspension. As the percentage of solids increases, the colloidal type of fuel is reached which requires the use of preheated air for rapid ignition and combustion.

Proceeding beyond the colloidal type of fuel we encounter the class of nonmerchantable fuels treated by the author. It is not

[3] Power Engineer, Tide Water Associated Oil Company, Bayonne, N. J. Mem. A.S.M.E.

[4] Todd Combustion Equipment, Inc., New York, N. Y. Member A.S.M.E.

impossible nor, in fact unlikely, that fuels now considered nonmerchantable will be offered in the future for industrial use. Since the demand or need of the overhead product from the distillation of fuel oil is such as to necessitate obtaining the maximum yield, the residuum may be of almost solid consistency at ordinary temperatures. It may not be economical to "cut back" with lighter fractions to produce the fuel oils now available. In that event, fuel oils approaching the nonmerchantable types discussed in this paper may have to be utilized.

Common difficulties met in the use of bunker-C fuel oil may be mentioned as follows:

(*a*) Tendency toward instability in storage; (*b*) similar tendencies if too highly heated before reaching the burners; (*c*) atomizer deposits; (*d*) stack solids and ash and slag formation. These difficulties are aggravated as the grade of fuel oil becomes poorer. The nonmerchantable oil-refinery fuels, mentioned in this paper, demand a storage and preparation technique entirely unfamiliar to the ordinary plant operator. It is of comforting interest to note that the conventional boiler and furnace design is satisfactory for the combustion of exceedingly poor grades of fuel. The changes necessary in the fuel-oil-burning equipment can be determined only by actual test. Fuel-oil-burning equipment has kept in step with the quality of fuel oil. There is every reason to expect that, should the occasion arise, efficient methods of burning the available fuel oils will be developed.

The author has pioneered in the field of by-product fuels. His methods for obtaining the maximum heat recovery from these fuels will no doubt be of great assistance to operators and fuel-oil-burning-equipment manufacturers.

Author's Closure

In closing, the author wishes to express appreciation for the interest shown by the commentators. Comment and criticism in subsequent meetings would, no doubt, be of further assistance to engineers faced with the disposal of waste fuels under discussion.

The petroleum industry in particular is continually striving to reduce production cost, therefore, utilization of all by-products is becoming more and more important.

Mr. Hayes's comments are especially valuable in showing the possible relation between industrial fuels of today and tomorrow. The study is of economic importance and should bring forth further research in methods of handling, preparation, and burning of heavier fuels.

The many plants that pioneered in burning waste fuels have contributed a vast amount of information, if this were not true, modern installations of waste-fuel-burning plants would be far behind their present state of development.

It is felt that there is still much to be achieved in the future development of equipment for handling and burning waste fuels, and that such progress can only be attained by further experimentation in the field where these fuels are available.

The Analogy Between Fluid Friction and Heat Transfer

By TH. VON KÁRMÁN,[1] PASADENA, CALIF.

The results of the modern turbulence research on velocity distribution near solid walls are applied to extend Reynolds' analogy between fluid friction and heat transfer to liquids. Discrepancies between the experimental results and the theory of Taylor and Prandtl are explained. A new theoretical formula which fits the experimental results more satisfactorily is suggested and compared with the empirical equations of Dittus and Boelter.

IN the year 1874 Osborne Reynolds published a remarkable paper (1)[2] entitled "On the Extent and Action of the Heating Surface for Steam Boilers." In this paper Reynolds suggested that momentum and heat in a fluid are transferred in the same way. He concluded that in geometrically similar systems a simple proportionality relation must exist between fluid friction and heat transfer. Suppose, for example, a flow parallel to the x-axis in which the mean velocity of the fluid is a function of the y-coordinate only. It is known from Reynolds' previous investigations that the shear stress τ occurring in an arbitrary plane perpendicular to the y-axis is equal to the total momentum transferred by the molecular and turbulent exchange and is given by

$$\tau = \mu \frac{du}{dy} - \rho\overline{v'u'} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where u is the mean velocity, u' and v' are the velocity fluctuations parallel to the x- and y-axes, μ denotes the coefficient of the molecular viscosity, and ρ the density of the fluid. If the temperature θ of the fluid varies with the y-coordinate, the heat flow in the y-direction, i.e., the amount of heat transferred by unit area across the same plane, can be expressed in a similar way. It consists of two parts: The molecular heat conduction and the turbulent heat transfer due to the fluctuations of velocity and temperature. The first contribution is equal to $-k\, d\theta/dy$, where k is the coefficient of the molecular heat conduction (thermal conductivity), and θ the mean temperature, which is supposed to be a function of the y-coordinate only. The second part is equal to the mean value of the product $c\rho v'\theta'$ where c is the specific heat per unit mass of the fluid (in the case of a compressible fluid the specific heat for constant pressure), and θ' is the fluctuation of the temperature. Because of the temperature gradient in the y-direction, a correlation exists between θ' and v'; therefore the mean value $c\rho\overline{v'\theta'}$ is different from zero and gives the amount of heat transferred by the turbulent fluctuations.

Hence, the total heat flow is given by the equation

$$q = -k\,(d\theta/dy) + c\rho\overline{v'\theta'} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

The second term in Equation [1] is called the contribution of the eddy viscosity, the second term in Equation [2] the contribution of the eddy conductivity. The analogy suggested by Reynolds amounts to the following statement: If the mean value $\overline{v'u'}$ is expressed in the form $\epsilon\, du/dy$, the mean value of $\overline{v'\theta'}$ is equal to $\epsilon\, d\theta/dy$, where ϵ has the same numerical value in the two expressions, and is called the coefficient of the turbulent exchange.

Introducing the kinematic viscosity $\nu = \mu/\rho$ and the thermometric conductivity $\kappa = k/c\rho$ one obtains the following fundamental equations

$$\left.\begin{aligned} \tau/\rho &= (\nu + \epsilon)du/dy \\ q/c\rho &= -(\kappa + \epsilon)d\theta/dy \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

It follows from Equations [3] that direct proportionality between shearing stress and heat transfer can be expected

(a) if ν and κ are negligible compared to ϵ,
(b) if ν and κ are numerically equal.

In the case of turbulent flow in pipes or around submerged bodies the condition (a) is generally satisfied with the exception of a relatively narrow range near solid walls. Consider two planes $y = y_1$ and $y = y_2$ in the turbulent region, and assume first that τ and q are independent of y. Then it follows by integration from Equations [3]

$$(u_2 - u_1)/\tau = c(\theta_1 - \theta_2)/q \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

This is the analytical expression of Reynolds' analogy. It is evident that the same relation prevails if τ and q vary with y according to the same law. In most cases, for example in a flow in a channel or a pipe, the law of variation of τ and q is not exactly identical. Between parallel walls or in a circular pipe τ varies linearly with the distance from the wall, whereas the variation of q is determined by the balance between the heat carried by the fluid in the flow direction and the heat flow across the stream, and therefore depends on the velocity distribution. However, the influence of the deviation between the distribution of τ and q is not very significant, and Equation [4] can be generally applied in the fully developed turbulent region.

Condition (b) is approximately satisfied by gases, since the kinematic viscosity and the thermometric conductivity of gases are of the same order of magnitude. However, for liquids ν is very much larger than κ. The ratio $\sigma = \nu/\kappa$ is for some liquids as high as $\sigma = 200$. Hence, Reynolds' analogy cannot be applied directly to the heat transfer between solids and liquids. The present paper is concerned mainly with this case. For completeness the case $\sigma = 1$ will also be discussed. However, in the next section the coefficients of friction and heat transfer will be defined first.

Coefficients of Friction and Heat Transfer

The quantity τ/ρ which occurs in the first Equation [3] has the dimension of the square of a velocity. Hence $\tau/(\rho/2)U^2$, where U is a velocity of reference of the physical setup, is a dimensionless quantity. In general, the ratio $\tau/(\rho/2)U^2$ is used as the coefficient of friction; it will be denoted by the symbol C_f. The choice of the reference velocity is more or less arbitrary. For

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

flow through a pipe the velocity at the center or the average velocity over the cross section may be chosen. In the case of a body submerged in a fluid, U is suitably taken equal to the relative velocity between the solid and the undisturbed region of the fluid.

The quantity $q/c\rho$ which occurs in the second Equation [3] has the dimension of velocity times temperature. Hence, if Θ denotes a reference temperature, $q/c\rho U\Theta$ is a dimensionless quantity. The reference temperature Θ is in general the temperature difference between two suitably chosen points of the system, or between temperatures averaged over certain regions. The ratio $C_H = q/c\rho U\Theta$ is a dimensionless quantity and will be called in this paper the *heat-transfer number*.

Introducing the coefficients C_f and C_H the shearing stress and the heat flow appear in the form

$$\left.\begin{aligned} \tau &= (C_f/2)\rho U^2 \\ q &= C_H \rho c U \Theta \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

It is seen that C_f is the ratio between two stresses, namely, the shearing stress τ and the dynamic pressure $U^2\rho/2$. The heat-transfer number C_H is the ratio between two heat flows: the heat flow q across the stream and the heat carried per unit cross-sectional area by a fluid of temperature Θ and velocity U, which is obviously equal to $\rho c U\Theta$. Since the shearing stress is equal to the momentum transferred across the stream, and the quantity ρU^2 can be considered as the momentum carried by the fluid in the direction of the stream, the concept of the coefficients $C_f/2$ and C_H appears analogous.

Another conception of the heat-transfer number is, however, commonly used in engineering practice. In the case of molecular heat transfer the heat flow is equal to $q = -k\, d\theta/dy$ (cf. Equation [2]) or if the distribution of the temperature is linear between two surfaces at the distance d, and $\Theta = \theta_1 - \theta_2$

$$q = k\Theta/d \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

Now in the general case of molecular and turbulent heat transfer one can write the second Equation [3] in the analogous form

$$q = k'\Theta/d \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

where $k' = c\rho(\kappa + \epsilon)$ can be interpreted as an increased value of the coefficient of the thermal conductivity k and d is a suitably chosen characteristic length of the physical setup. Then the ratio k'/k is a dimensionless quantity which expresses the rate of increase of the heat transfer due to turbulence. This ratio is sometimes called the *Nusselt heat-transfer number* and denoted by the symbol Nu. The equations

$$q = C_H \rho c U \Theta \ldots\ldots\ldots\ldots\ldots\ldots [8a]$$

and

$$q = Nu\, k\Theta/d \ldots\ldots\ldots\ldots\ldots\ldots [8b]$$

are two equivalent expressions for the heat flow, based on two different conceptions of the transfer mechanism.

The film coefficient or heat-transfer coefficient h generally used in practical calculations is equal to the heat flow per unit time and per unit surface per unit temperature difference between solid and fluid.

Hence, from Equations [8a] and [8b]

$$h = q/\Theta = C_H \rho c U = Nu\, k/d \ldots\ldots\ldots\ldots [9]$$

It is seen that the use of the Nusselt number is somewhat simpler for calculation, but the number C_H has the great advantage that it is directly linked to the coefficient of friction. The relation between the two numbers is the following

$$Nu = C_H \frac{\rho c U d}{k} = C_H \frac{\rho U d}{\mu} \frac{\mu c}{k} \ldots\ldots\ldots [10]$$

Now the expression Ud/ν is known as the Reynolds number Re, the ratio $\mu c/k = \nu/k = \sigma$ which already was mentioned in the introduction is called Prandtl's number, and the reciprocal of the latter is sometimes called Stanton's number. From Equation [10] one obtains

$$Nu = C_H Re\, \sigma \ldots\ldots\ldots\ldots\ldots [11]$$

The dimensionless number $\rho c U d/k = Ud/\kappa$ is called Peclet's number Pe; obviously $Pe = Re\, \sigma$. Hence, if Re and σ are given, Peclet's number is not an independent parameter.

The heat-transfer numbers C_H or Nu are functions of two of the three parameters Re, Pe, and σ. In this paper Re and σ are used as independent parameters.

Reynolds' Analogy for $\sigma = 1$

For an ideal gas both the kinematic viscosity ν and the thermometric conductivity κ are proportional to the product of the mean free path and the mean velocity of the molecules of the gas. According to the kinetic theory of gases the ratio ν/κ depends only on the number of degrees of freedom. Eucken (2) has suggested an empirical relation between σ and the ratio $\gamma = c_p/c_v$ of the specific heats of the gas

$$\sigma = 4\gamma/(9\gamma - 5) \ldots\ldots\ldots\ldots\ldots [12]$$

According to this equation $\sigma = 0.66$ for monatomic and $\sigma = 0.74$ for diatomic gases. Since σ is not very much different from unity the original Reynolds analogy can be applied to obtain an approximate value of the heat-transfer number between a solid and moving air.

For $\sigma = 1$, Equations [3] become, by replacing κ by ν

$$\left.\begin{aligned} \tau/\rho &= (\nu + \epsilon)du/dy \\ q/c\rho &= -(\nu + \epsilon)d\theta/dy \end{aligned}\right\} \ldots\ldots\ldots\ldots [13]$$

Assume first that τ and q are constant. Then if u_0 and θ_0 denote the velocity and temperature at the wall, and u and θ correspond to an arbitrary point in the fluid, it follows from Equations [13] by integration, that

$$\left.\begin{aligned} u - u_0 &= \frac{\tau}{\rho}\int_0^y \frac{dy}{\nu + \epsilon} \\ \theta - \theta_0 &= -\frac{q}{c\rho}\int_0^y \frac{dy}{\nu + \epsilon} \end{aligned}\right\} \ldots\ldots\ldots\ldots [14]$$

Hence, if velocity and temperature are measured relative to the wall, their laws of distribution are similar. This will be approximately correct also if q and τ are not constant, but vary approximately in a similar way. It follows that if U is the mean velocity of the fluid relative to the wall, and Θ is the difference between the mean temperature of the fluid and the temperature of the wall

$$U/(\tau/\rho) = -c\Theta/q \ldots\ldots\ldots\ldots\ldots [15]$$

or (cf. Equation [5])

$$C_f/2 = C_H \ldots\ldots\ldots\ldots\ldots [16]$$

This relation implies important conclusions:

(*a*) If the friction τ is proportional to the nth power of the velocity U, the heat transfer q is proportional to the power $(n - 1)$.

(*b*) Roughness increases the friction and heat transfer in the same ratio.

It must be emphasized that Equation [16] has an approxima-

tive character, first because of the assumption $\sigma = 1$, and second, because of the deviation in the laws of variation of the shearing stress and the heat flow over the region involved.

Extension of Reynolds' Analogy to Liquids. Approximations of G. I. Taylor and L. Prandtl

It was mentioned that for most liquids Prandtl's number σ is large compared to unity. Hence, Reynolds' analogy can only be applied directly to the fully developed turbulent region in which the kinematic viscosity ν can be neglected compared to the eddy viscosity ϵ. G. I. Taylor (3) and L. Prandtl (4) extended Reynolds' analogy to the case of liquids flowing through a pipe by subdividing the fluid into two regions: The turbulent region in which ν is negligible, and a laminar region in which ϵ can be neglected compared to ν.

If the thickness of the laminar layer is δ, the velocity at the wall is equal to zero, the temperature at the wall is Θ_0, and the velocity and temperature at the boundary between the laminar layer and the turbulent region are denoted by U_δ and Θ_δ, respectively, it follows from Equations [3] that

$$\left.\begin{aligned} U_\delta &= \frac{\tau}{\rho}\int_0^\delta \frac{dy}{\nu} \\ \Theta_0 - \Theta_\delta &= \frac{q}{c\rho}\int_0^\delta \sigma\frac{dy}{\nu} \end{aligned}\right\} \quad [17]$$

and therefore

$$\sigma\frac{\rho U_\delta}{\tau} = \frac{c\rho(\Theta_0 - \Theta_\delta)}{q} \quad [18]$$

Reynolds' analogy applied to the turbulent region gives the relation

$$\rho(U - U_\delta)/\tau = c\rho(\Theta_\delta - \Theta)/q \quad [19]$$

where U and Θ are the mean values of the velocity and temperature taken over the cross section of the pipe. Eliminating Θ_δ one obtains

$$\frac{c\rho}{q}(\Theta_0 - \Theta) = \frac{\rho U}{\tau} + (\sigma - 1)\frac{\rho U_\delta}{\tau} \quad [20]$$

or introducing $C_f = 2\tau/\rho U^2$ and $C_H = q/c\rho(\Theta_0 - \Theta)U$

$$\frac{1}{C_H} = \frac{2}{C_f}\left[1 + \frac{U_\delta}{U}(\sigma - 1)\right] \quad [21]$$

This result was obtained by G. I. Taylor in 1919. Nine years later L. Prandtl further developed the theory by computing the ratio U_δ/U by means of the semiempirical formulas which at that time were used for the expression of the velocity distribution. Prandtl found that for the case of the flow in a smooth pipe U_δ/U is proportional to $Re^{-1/8}$, where Re is Reynolds' number. Then Equation [21] gives the following relation for the heat-transfer number C_H (β is a universal constant)

$$C_H = \frac{C_f}{2}\frac{1}{1 + \beta Re^{-1/8}(\sigma - 1)} \quad [22]$$

In general, it can be assumed that $U_\delta/(\tau/\rho)^{1/2}$ is a universal constant for smooth surfaces. On the other hand, $U/(\tau/\rho)^{1/2} = (2/C_f)^{1/2}$; therefore $U_\delta/U = \text{const}\sqrt{C_f}$ and from Equation [21] it follows that

$$1/C_H = (2/C_f) + \text{const}\,(2/C_f)^{1/2}(\sigma - 1) \quad [23]$$

The experimental evidence has shown that Equation [22] or Equation [23] holds only for relatively small values of $(\sigma - 1)$, perhaps up to $\sigma = 2$; for larger values of σ there is an increasing discrepancy between the experimental results and Equation [23]. To obtain better results the transition between the laminar and turbulent region must be taken into account.

Extension of Reynolds' Analogy to Liquids. The Author's Analysis

Assume that in the region near the wall, i.e., for $y < \delta$ neither ν nor ϵ can be considered small, i.e., the molecular and eddy viscosity might be of the same order, however, δ is so small that τ can be considered constant for $y \leqq \delta$. This condition is in general well satisfied. Then from Equations [3]

$$\left.\begin{aligned} U_\delta &= \frac{\tau}{\rho}\int_0^\delta \frac{dy}{\nu + \epsilon} \\ \Theta_0 - \Theta_\delta &= \frac{q}{c\rho}\int_0^\delta \frac{dy}{(\nu/\sigma) + \epsilon} \end{aligned}\right\} \quad [24]$$

It is known from theoretical and experimental results of turbulence research (cf., for example, the excellent treatise (5) of Bakhmeteff) that in the vicinity of a smooth wall the ratio $u/(\tau/\rho)^{1/2}$ is a universal function of the dimensionless distance parameter $y^* = (\tau/\rho)^{1/2}y/\nu$, or denoting that universal function by $f(y^*)$

$$u/(\tau/\rho)^{1/2} = f(y^*) \quad [25]$$

It follows that

$$\frac{du}{dy} = \left(\frac{\tau}{\rho}\right)^{1/2} f'(y^*)\frac{(\tau/\rho)^{1/2}}{\nu}$$

and

$$\frac{\tau}{\rho du/dy} = \nu + \epsilon = \frac{\nu}{f'(y^*)} \quad [26]$$

In other words, the ratio ϵ/ν is a function of y^* only. Substituting

$$\epsilon = \nu\left(\frac{1}{f'(y^*)} - 1\right) \quad [27]$$

and introducing y^* as variable into Equations [24], one obtains

$$U_\delta = \left(\frac{\tau}{\rho}\right)^{1/2}\int_0^{y_\delta^*} f'(y^*)dy^* \quad [28]$$

and

$$\Theta_0 - \Theta_\delta = \frac{q}{c\rho(\tau/\rho)^{1/2}}\int_0^{y_\delta^*}\frac{dy^*}{\frac{1}{\sigma} - 1 + \frac{1}{f'(y^*)}} \quad [29]$$

The value of y_δ^*, i.e., the value of y^* which corresponds to the boundary of the fully turbulent region might be somewhat arbitrary, but is certainly the same for geometrically similar flows. Hence, the definite integral in Equation [28] represents a numerical constant A, and the definite integral in Equation [29] represents a function of σ only, say $B(\sigma)$. Then from Equations [28] and [29]

$$\frac{c\rho(\Theta_0 - \Theta_\delta)}{q} - \frac{\rho U_\delta}{\tau} = \left(\frac{\rho}{\tau}\right)^{1/2}[B(\sigma) - A] \quad [30]$$

Reynolds' analogy applied to the turbulent core yields the relation

$$\frac{\rho(U - U_\delta)}{\tau} - \frac{c\rho(\Theta_\delta - \Theta)}{q} = 0 \quad [19]$$

By subtraction of the two equations, one obtains

$$\frac{c\rho(\Theta_0 - \Theta)}{q} - \frac{\rho U}{\tau} = \left(\frac{\rho}{\tau}\right)^{1/2}[B(\sigma) - A]$$

or

$$\frac{1}{C_H} = \frac{2}{C_f} + \left(\frac{2}{C_f}\right)^{1/2}[B(\sigma) - A] \quad [31]$$

and

$$C_H = \frac{C_f}{2}\frac{1}{1 + (C_f/2)^{1/2}[B(\sigma) - A]} \quad [32]$$

In order to determine the function $B(\sigma) - A = g(\sigma)$ Niku-

radse's experimental results can be used. In Fig. 51 (p. 79) of Bakhmeteff's treatise (5), $u/(\tau/\rho)^{1/2}$ is represented as function of y^* in a semilogarithmic diagram. There are no experimental values for $y^* < 10$. However, for small values of y^* it can be assumed that the velocity distribution is linear and $u = (\tau/\mu)\, y$ or $u/(\tau/\rho)^{1/2} = y^*$. For $y^* > 30$ the logarithmic law which is considered a characteristic distribution law for the fully turbulent region is fairly well satisfied. Hence, $y_\delta^* = 30$ is chosen. The points between $y^* = 10$ and $y^* = 30$ can be approximated by a straight line which joins the curve $u/(\tau/\rho)^{1/2} = y^*$ tangentially at $y^* = 5$. The equation of this straight line is

$$u/(\tau/\rho)^{1/2} = 5[1 + \log_e(y^*/5)] \quad \ldots\ldots\ldots\ldots [33]$$

Substituting $f'(y^*) = 1$ for $y^* < 5$ and $f'(y^*) = 5/y^*$ for $5 < y^* < 30$ and carrying out the integrations, one obtains $A = 5(1 + \log_e 6)$ and $B = 5[\sigma + \log_e(1 + 5\sigma)]$. With these values Equation [31] becomes

$$\frac{1}{C_H} = \frac{2}{C_f} + 5\left(\frac{2}{C_f}\right)^{1/2}\left\{\sigma - 1 + \log_e\left[1 + \frac{5}{6}(\sigma - 1)\right]\right\}. \quad [34]$$

It is seen that

(*a*) for $\sigma = 1$, $1/C_H = 2/C_f$, according to Reynolds' analogy,

(*b*) for small values of $\sigma - 1$, by expansion of the logarithmic term

$$1/C_H \cong (2/C_f) + \text{const}\ (2/C_f)^{1/2}(\sigma - 1)$$

in accordance with the theory of Taylor and Prandtl.

Fig. 1 shows schematically the approximate velocity distribution used for the calculation. Fig. 2 shows the values of the exchange coefficient resulting from this assumed velocity distribution. The assumptions corresponding to the Taylor-Prandtl theory are indicated in both figures by dash-dot lines. The improvement introduced into the theory consists essentially of the elimination of the abrupt change of the exchange coefficient. There remains a discontinuity at the boundary between the transition layer and the fully turbulent region. However, it is believed that this discontinuity has no large effect on the result, since in the calculations (cf. Equations [24]) only the reciprocal values of the quantities $\nu + \epsilon$ and $\kappa + \epsilon$ appear. Therefore, the accuracy depends chiefly on the correctness of the assumptions in the region where these quantities are small.

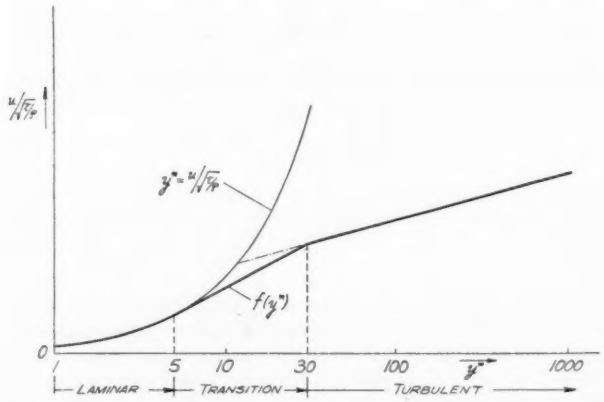

FIG. 1 VELOCITY DISTRIBUTION IN THE VICINITY OF A SOLID WALL

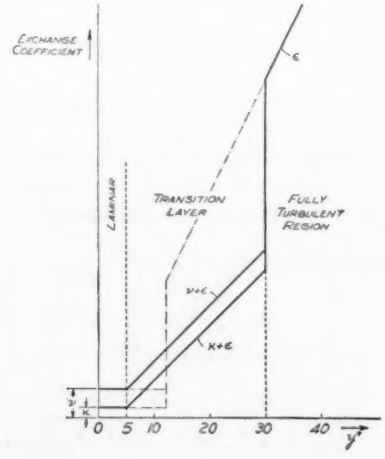

FIG. 2 EXCHANGE COEFFICIENTS IN THE VICINITY OF A SOLID WALL

COMPARISON BETWEEN THEORY AND EXPERIMENT

The theoretically computed values of the heat-transfer number can be compared with experimental data on the amount of heat transferred in smooth-walled pipes between the walls and the fluid at different rates of flow. However, an exact comparison is difficult for the following reasons:

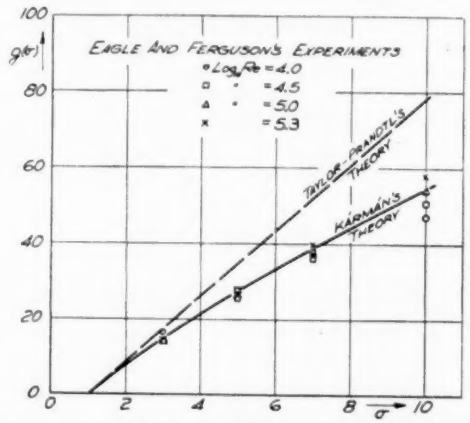

FIG. 3 COMPARISON BETWEEN THEORY AND THE EXPERIMENTS OF EAGLE AND FERGUSON

(*a*) Some experimenters use relatively short pipes, whereas for the application of the theory the pipe should have a long entry section, so that the velocity and temperature distributions can reach their final shapes.

(*b*) The physical properties vary with the temperature and, therefore, the heat-transfer coefficients depend on the rate of heat flow and are especially different for the case of heating and cooling of the fluid by the walls.

(*c*) Due to the variation of the physical properties over the cross section of the pipe, it is uncertain which values of the coefficients of viscosity and thermal conductivity are to be used for the evaluation of the transfer numbers.

(*d*) The value of the transfer numbers depends on the interpretation of the mean temperature, namely, whether the temperature is simply averaged over the cross-sectional area or is weighted according to the flow of matter passing through the elements of the cross section.

The difficulties mentioned under (*a*), (*b*), and (*c*) can be properly eliminated only by a careful extrapolation of the measured experimental results for an infinitesimal rate of heat flow, i.e., infinitesimal temperature difference between pipe and fluid. Such an extrapolation has been carried out by the British researchers, Eagle and Ferguson (6), for the heat exchange between smooth-walled pipes and water at different temperatures. Both Prandtl's and the author's formula can be reduced to the form

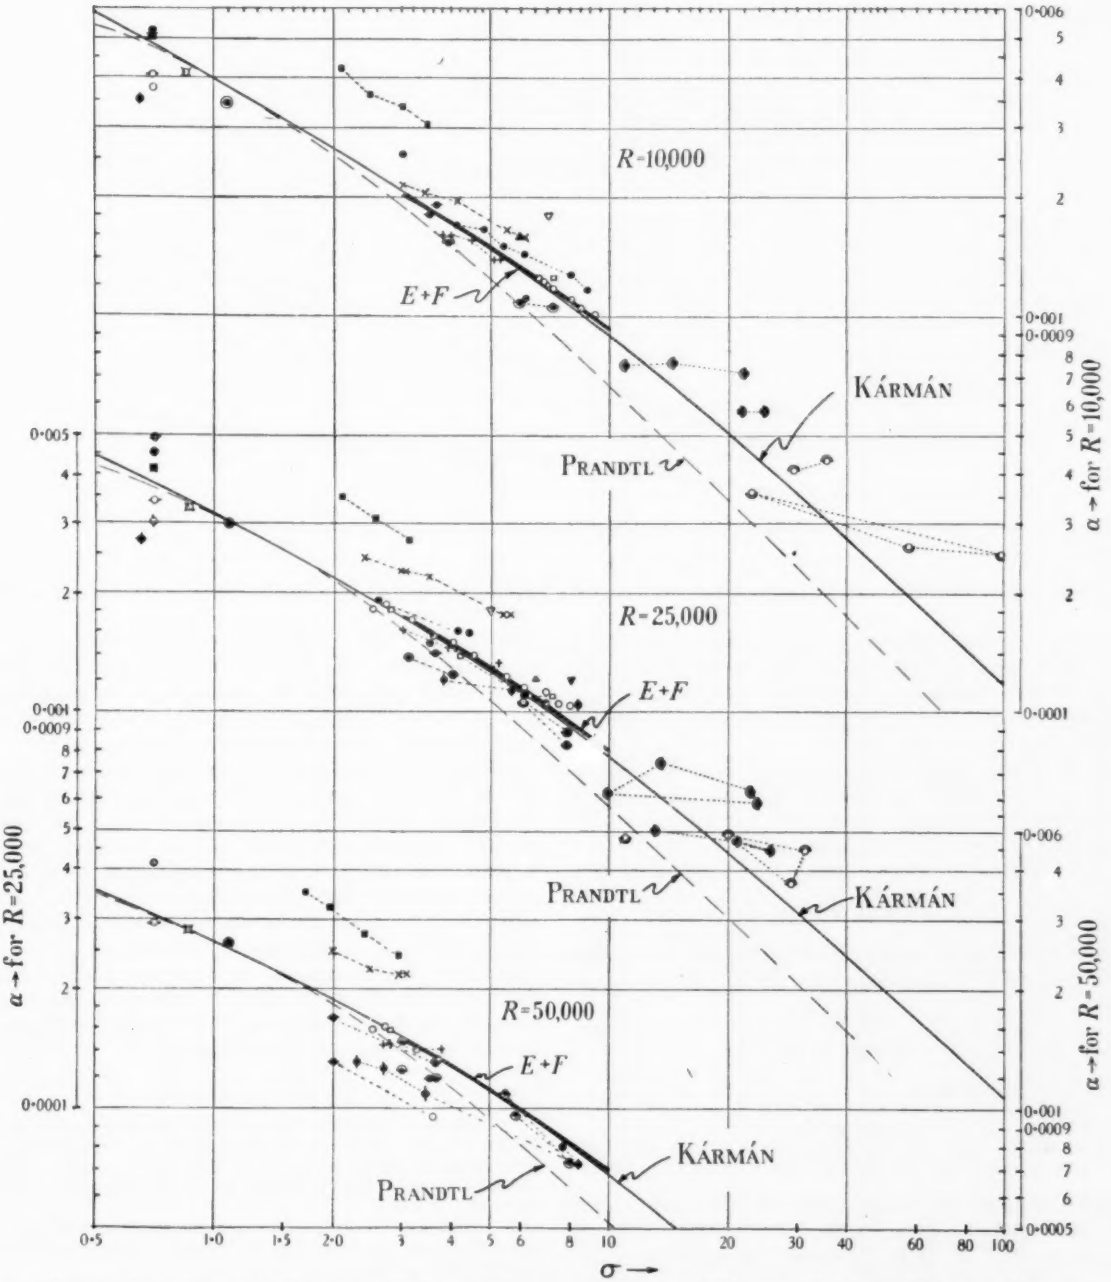

FIG. 4 HEAT-TRANSFER NUMBER IN PIPES FOR DIFFERENT REYNOLDS' NUMBERS COMPARED WITH THE THEORY
(α is equivalent to the symbol C_H used in this paper.)

$$\frac{1}{C_H} - \frac{2}{C_f} = \left(\frac{C_f}{2}\right)^{1/2} g(\sigma) \quad \ldots\ldots\ldots\ldots [35]$$

Prandtl uses for $C_f/2$ the approximation $C_f/2 = 0.04\ Re^{-1/4}$. With this value his theory leads to the expression

$$g(\sigma) = 8.7(\sigma - 1) \quad \ldots\ldots\ldots\ldots [36]$$

whereas according to the author's analysis

$$g(\sigma) = 5\{(\sigma - 1) + \log_e[1 + (5/6)(\sigma - 1)]\} \quad \ldots\ldots [37]$$

Fig. 3 shows the comparison of the two expressions [36] and [37], and the values of $g(\sigma)$ computed from the experiments of Eagle and Ferguson for $\log_{10} Re = 4$, 4.5, 5, and 5.3 for the range $3 < \sigma < 10$. It is seen that the accordance between the author's theory and the experimental results is very satisfactory. The results are not corrected for the error caused by the different interpretation of the mean temperature, item (*d*). G. I. Taylor made an estimate of this error for the case $\sigma = 1$, $Re = 10{,}000$ and found that it amounts to 3 or 4 per cent. However, for large values of σ the temperature distribution over the cross section becomes more and more uniform, so that the error is likely to be smaller than this value.

A great number of experiments have been carried out on heat exchange between pipes and different kinds of oils, petroleum, benzene, and so on. For these fluids σ varies from about 10 to 200. The results of these experiments show an extraordinary

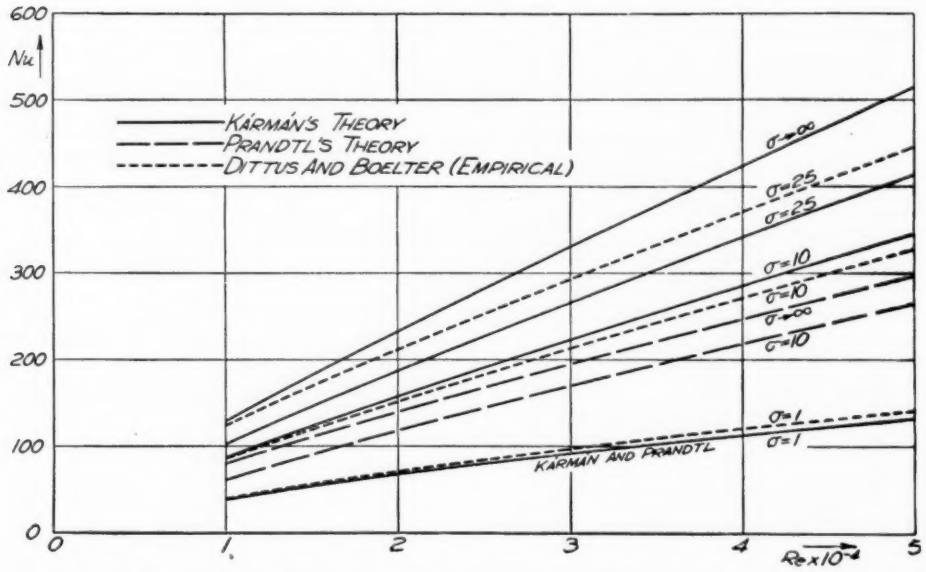

FIG. 5 COMPARISON BETWEEN THE THEORY OF PRANDTL AND THE AUTHOR WITH THE EMPIRICAL EQUATION OF DITTUS AND BOELTER

scatter, due to the great difficulties of experimentation and interpretation of the results. Fig. 4 shows the comparison between the heat-exchange numbers C_H computed from the results of different experimenters by H. Lorenz (7) and the values predicted by Prandtl's and the author's formula.

Dittus and Boelter (8) obtained two simple empirical formulas for the Nusselt number by averaging the scattered results of many experimenters: one equation for the case of the fluid's being cooled, the other for the fluid heated by the walls. The average of these two cases can be expressed approximately by the equation

$$Nu = 0.0254\, Re^{0.8}\sigma^{0.35} \quad \ldots\ldots\ldots\ldots\ldots [38]$$

On the other hand Prandtl's theory gives for the Nusselt number with $C_f/2 = 0.04\, Re^{-1/4}$ the expression

$$Nu = \frac{0.04\, Re^{3/4}\sigma}{1 + 1.74\, Re^{-1/4}(\sigma - 1)} \quad \ldots\ldots\ldots\ldots [39]$$

and the theory of the author

$$Nu = \frac{0.04\, Re^{3/4}\sigma}{1 + Re^{-1/8}\{\sigma - 1 + \log_e[1 + (5/6)(\sigma - 1)]\}} \quad [40]$$

The values corresponding to expressions [38], [39], and [40] are compared in Fig. 5 for the range $10{,}000 < Re < 50{,}000$. For very large values of σ Prandtl's theory gives the limiting form

$$Nu = 0.023\, Re^{7/8} \quad \ldots\ldots\ldots\ldots\ldots [41]$$

and the author's theory

$$Nu = 0.04\, Re^{7/8} \quad \ldots\ldots\ldots\ldots\ldots [42]$$

If the empirical formula of Dittus and Boelter is considered as representative for the averaged experimental values, it is seen that Prandtl's values are entirely too low, the author's values are very exact for $\sigma \leqq 10$, and give a fair approximation up to $\sigma = 25$. For larger values of σ the theory does not follow the increase of Nu with increasing σ. If σ is very large, there is a considerable drop of temperature in the laminar layer, and it is hard to expect that the hydrodynamic theory developed for constant viscosity can represent correctly the conditions. Moreover, the heat exchange in this case is determined chiefly by the thickness of the laminar layer, and, therefore, a small deviation in the function $f(y^*)$ used for the velocity distribution influences the results much more than in the case of moderate values of σ. Since the experimental values show an extraordinary scatter, more experimental research is necessary to furnish reliable data so that the theory can be extended to liquids with high viscosity.

It appears from the results of this paper that the fundamental idea of Reynolds' analogy can be applied with success to the problem of friction and heat transfer between fluid and solid. However, it must be mentioned that recent experiments make it doubtful whether the same idea is applicable to exchange phenomena between fluids flowing with different velocities. It seems that in this case the exchange of heat occurs at a relatively higher rate than the exchange of momentum. At the present time the number of experiments is still too small to draw final conclusions. It is believed that the exchange mechanism of friction and heat transfer for the case "fluid versus fluid" is one of the most important topics for future research.

Mechanical Purification of Steam Within the Boiler Drum

By M. D. BAKER,[1] SPRINGDALE, PA.

The paper is a report of tests run on new high-pressure high-temperature boiler installations to determine a baffle arrangement for the steam drums that would prevent objectionable carry-over during normal operation.

The arrangements of three types of baffle are illustrated and the results are given in tables and graphs as conductivity measurements on condensed steam samples taken from eight different points in the drum.

The cyclone-separator baffle finally developed will deliver steam containing solids approximating 0.5 ppm with boiler-water concentrations up to 1600 ppm, and will permit a large range of load change and water-level variation.

THE OBJECT of this paper is to present a description and discussion of the development work that was required to produce satisfactory steam purity under all normal operating conditions on the 1400-psi boilers recently installed at the Springdale Station of the West Penn Power Company.

The new boilers consist of three Babcock & Wilcox cross-drum sectional-header boilers equipped with return-bend economizers and superheaters within the boiler setting, and two-stage furnaces. A cross section of the boiler is shown in Fig. 1. The inside diameter of the boiler drum is 54 in. and the length is 30 ft 1 in. Fourteen 4-in. tubes connect the boiler drum with the superheater inlet header. The boilers were guaranteed to deliver a maximum steam output of 500,000 lb per hr with a boiler-water concentration of 1275 ppm. Under these conditions, they were guaranteed to deliver steam containing not over 1 ppm total solids. This is equivalent to a conductivity of about 1.5 micromhos.

In order for a steam purifier in the drum to be satisfactory from an operating standpoint it should deliver high-quality steam and prevent priming with reasonably rapid changes in rating, with reasonable variations of the drum water level above normal, and with the allowable boiler-water concentration sufficiently high so that the control of concentration is not a major operating factor requiring constant vigilance.

The production of steam free from impurities and entrained boiler water has always been a problem of major importance in central stations. With concentration and other conditions equal, the height of foam produced upon the water surface in the boiler drum becomes greater as the pressure increases. This is caused principally by the fact that the ratio of the specific weight of water to the specific weight of the steam decreases as the pressure increases. In the older boilers at the Springdale Station, which operate at 340 psi, this ratio is 69 to 1 whereas in the new boilers described here, which operate at 1350 psi, it is about 13 to 1. As this ratio decreases, the rate at which the foam disintegrates becomes slower thereby producing a greater height of foam for equilibrium, if other conditions remain the same. The weight of this foam is so small that it has little effect on the height of the water in the gage glass; in one case in a boiler operating at 1300 psi with a boiler-water concentration of 350 ppm, it was found that the foam level in the drum was more than 20 in. above the water level shown in the gage glass. It is evident, therefore, that although the water level in the gage glass may be showing two or three inches below the center line of the drum the so-called steam space in the drum may be actually filled up with foam which, of course, would produce severe carry-over.

Test Procedure

Before describing the three types of drum baffles which were tried and the results obtained from them, a description of the method used for determining the steam purity will be given.

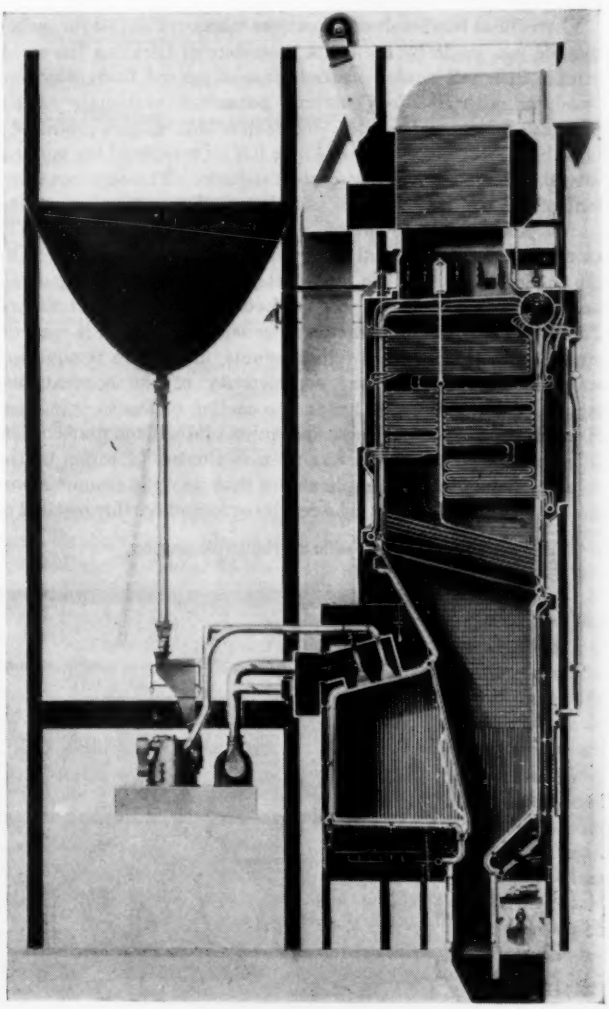

Fig. 1 Cross Section of Boiler

[1] Chief Chemist, Springdale Station, West Penn Power Company.

Contributed by the Power Division and presented at the Spring Meeting of The American Society of Mechanical Engineers, New Orleans, La., February 23–25, 1939.

Discussion of this paper closed March 25, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

There are two methods of determining steam quality in general use, namely, the conductivity method and the throttling-calorimeter method. The calorimeter method has been found inadequate where low moisture contents are being measured and where it is important to measure the entrained solids directly. The conductivity method of steam-purity determination is now used almost universally for this class of work. In its application a sample of the steam is condensed, sometimes deaerated to remove dissolved gases, and then the conductivity of the condensate is

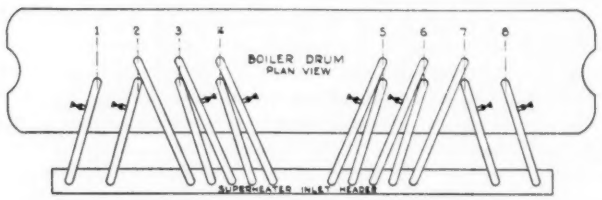

FIG. 2 SAMPLING POINTS FOR SATURATED STEAM

determined by means of a sensitive bridge and standardized conductivity cell. Rummel (1),[2] Hecht and McKinney (2), and Powell, Bacon, Jr., McChesney, and Henry (3) have fully outlined and described this method of determining steam purity, and the principles and the methods advocated by them were used in the tests reported in this paper.

Corrections for dissolved gases were made. The test for carbon dioxide was made by the usual procedure of titrating the steam sample in a tall narrow-necked glass-stoppered flask, with one two-hundredth (0.005 N) normal potassium carbonate to the phenolphthalein end point. One drop of this reagent produced a faint but positive color change in a 100 ml sample of the condensate showing an absence of carbon dioxide. The ammonia content of the condensed steam sample was determined by nesslerization and color comparison with a Hellige comparator. The ammonia content was not determined on all samples, especially the earlier ones. On the later tests, the following method was used to check the comparator method of determining ammonia. The condensed steam sample was boiled slowly until it was approximately one fifth its original volume, in order to remove any ammonia present, and the conductivity of the concentrated sample was measured. During the cooling of the sample great care was needed to prevent readsorption of dissolved gases. The difference in conductivity was then evaluated in terms of the volume of the original sample and in that way the ammonia correction was determined. The results obtained by this method of

determining the effect of ammonia on the conductivity were in close conformity with the conductivity-correction curve obtained by Rummel in 1934.[3]

Samples of the steam delivered from the boiler drum to the superheater were obtained by installing standard A.S.M.E. sampling nozzles in the saturated-steam tubes connecting the boiler drum to the superheater inlet header. As stated before, there are 14 of these tubes on each boiler arranged in pairs, except for the end ones, as shown in Fig. 2. It was originally thought that the two end and the two middle points, locations 1, 4, 5, and 8, would give a representative value of the steam purity, but it was found during the testing of the first baffle design that the center sampling nozzles showed higher conductivity values than the end ones, hence additional sampling nozzles were installed at locations 2, 3, 6, and 7. After the first six tests, samples were obtained at all eight locations on all subsequent tests. The steam from each sampling nozzle was delivered to its individual water-

[3] "Effect of Ammonia Content on Conductivity of Steam Condensate." Copies of this curve have been distributed by The Babcock & Wilcox Company, New York, N. Y.

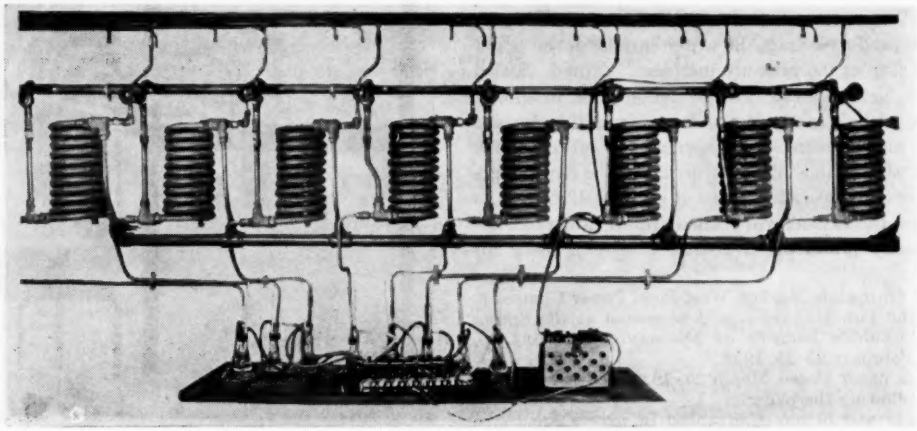

FIG. 3 CONDUCTIVITY APPARATUS AND STEAM CONDENSERS

cooled condenser and the condensate passed directly to its individual conductivity cell. Deaeration of this condensate was considered unnecessary because only occasional small amounts of ammonia were found, and all tests showed a complete absence of carbon dioxide. The individual condensers were placed at a convenient central location and connected by suitable piping to their corresponding sampling nozzles. Fig. 3 shows the arrangement of condensers with the cells, switches, and bridge in place ready for testing.

The condensers were not of sufficient capacity to condense the entire delivery capacity of the sampling nozzles, so throttling was necessary. This was done at the nozzle valve rather than at the condenser, since the sampling piping was not designed to withstand full boiler pressure. Tests were made to determine whether this throttling was detrimental to securing a representative sample. The sampling nozzle valves were throttled until the condensate temperature was reduced to 90 F with all available cooling water flowing through the condensers and the conductivity was determined. Readings were then taken with the sampling-nozzle valves wide open but with the additional steam above the condenser capacity escaping to the atmosphere. No appreciable difference in conductivity was noted, so it was concluded that the throttled samples were representative of the steam delivered by the boiler at the point of sampling. Table 1 presents data taken during this test.

Riser-Extension Baffle

The first steam-drum baffle installed is illustrated in Fig. 4.

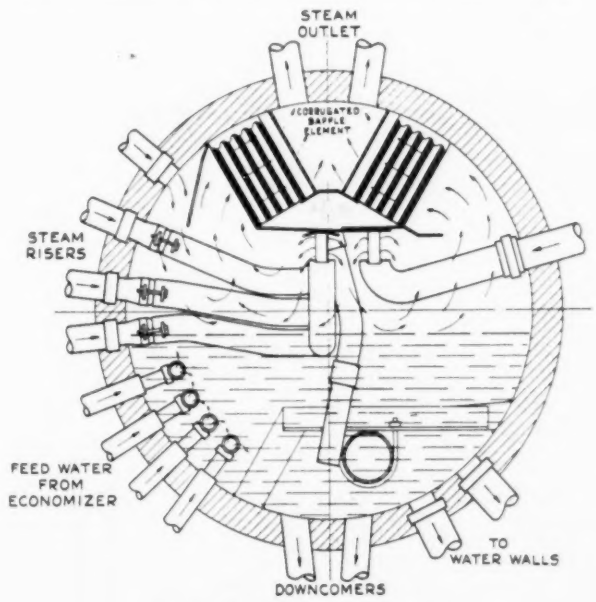

Fig. 4 Riser-Extension Baffle

The risers from the uptake headers of the boiler section and the waterwall headers were extended inside the drum to the vertical center line, and were so arranged that the steam and water were discharged from them vertically upward against deflector plates. These plates deflected the entrained water downward toward the water surface in the drum and the steam passed upward through the corrugated baffle elements located in the upper portion of the drum. The theory behind this design was to discharge all of the steam and the circulating water above the water level in the drum, and prevent the water and steam from impinging directly on the water surface at the discharge velocity. The corrugated steel plates were so arranged that the free-flow area for the steam was a large percentage of the total entrance area to the element, and they were so spaced that all the steam had to come in contact with some portion of the metal surface, thereby removing the moisture and returning it below the water level in the drum through the gravity drains. These corrugated baffle elements were retained and made a part of all three of the steam-drum

baffles tried. The feedwater was discharged from the economizer tubes through tees so placed that the water surface would not be agitated and the metal in the drum would not receive a thermal shock.

The purity of steam delivered by this baffle is indicated by the data presented in Fig. 5. The first increase in carry-over occurred during a burner change but with other conditions remaining constant. The steam flow at this time was approximately one half of the maximum rating of the boiler and the boiler-water concentration was 536 ppm. As will be seen in Fig. 5, severe priming took place a short time later when the gage-glass water level was raised to approximately $2^1/_2$ in. below the center line of the drum. Table 2 presents the data obtained during seven tests conducted on two boilers equipped with this steam purifier. With low boiler-water concentrations and with the gage-glass water level remaining constant, the steam delivered through this baffle had a conductivity of from 2 to 3 micromhos. Increases of the water level caused either by the feedwater regulator or by sudden changes in rating, resulted in excessive carry-over. In some instances the moisture carry-over was sufficient to reduce the superheat as much as 100 F.

The data obtained proved quite conclusively that this design of

steam-drum baffle would not meet the guarantee and imposed operating restrictions too stringent for satisfactory operation.

IMPACT-BOX BAFFLE

The second design of steam-drum baffle tried is shown in Fig. 6. Over each vertical row of riser tubes, there was placed a box with openings on either side above the drum center line and also at the bottom. The object was to dissipate the high velocity of the steam and water leaving the riser tubes and prevent impingement on the surface of the water. In addition to these boxes, the washing principle was also introduced by collecting the incoming feedwater into a manifold and spraying it into the upper part of the drum just below the scrubber baffle. Although this design was an improvement over the original design, it was not acceptable because a critical water level existed which was too low for satisfactory operation. As long as the water level in the gage glass was not above $3^1/_4$ in. below the center line of the drum, steam with a conductivity of 1.5 micromhos could be delivered, but with water levels $^1/_2$ in. higher than this, severe carry-over occurred; in some instances it was sufficient to increase the conductivity of the condensed steam to 129 micromhos and to reduce the steam temperature 120 F. Seventeen tests were made using this baffle and the significant data are shown in Table 3. The tests were made with boiler-water concentrations slightly above 1000 ppm. Fig. 7 illustrates the effect on the conductivity of the steam caused by raising the water level above the critical point.

CYCLONE-SEPARATOR BAFFLE

The third and final baffle design is shown in Figs. 8, 9, and 10.

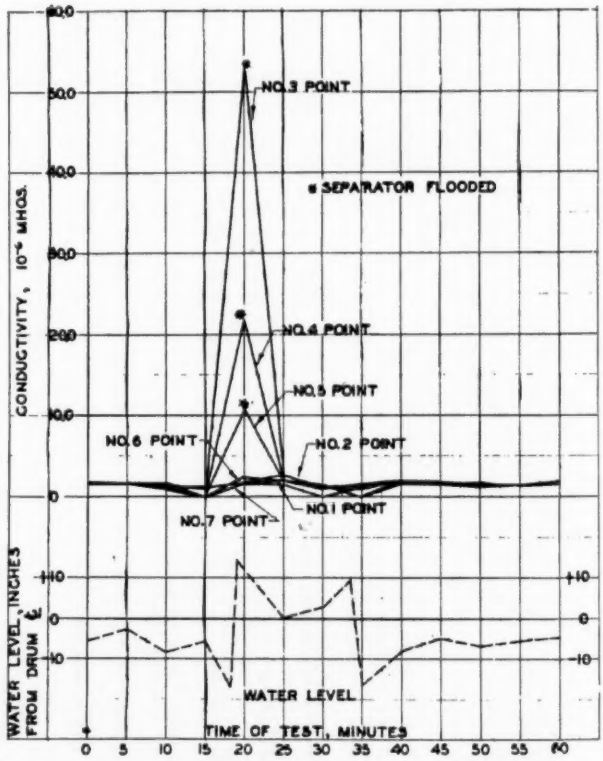

FIG. 11 STEAM QUALITY WITH CYCLONE-SEPARATOR BAFFLE AND VARIABLE WATER LEVEL

Steam	Boiler-water analysis		Steam analysis

	PO_4,	287 ppm	
	SiO_2,	36 ppm	
	Cl,	45 ppm	
	Saponifiable,	15 ppm	

The essential difference between this design and those previously tried is that the steam and the circulating water delivered by the risers are discharged into the individual cyclones and the water and steam separated before being released into the main portion of the boiler drum. As will be noted from these figures, an individual cyclone is connected to a single riser or to a small group of risers. The steam and water enter the cyclone tangentially and the water flows downward and out of the cyclone at the bottom periphery of the cylinder, while the steam leaves through the opening at the top. The cyclones are placed vertically and are so located that the openings at the bottom are normally below the water level in the drum and the top openings are well above the usual water level. The small differential pressure and the centrifugal energy of the water within the cyclone are sufficient to keep a water level from forming within the cyclone, but are not great enough to break the seal and permit steam to leave the bottom of cyclone. In this way the steam is prevented from bubbling up through the water in the drum, which would cause foam. The steam leaves the top of the cyclone in such a way that it does not impinge upon the surface of the water in the drum, thereby preventing the formation of foam from this cause. It has been found that the actual water level in the drum is within from 1 to 2 in. of the water level indicated in the gage glass under all conditions. The corrugated elements placed on top and made a part of the cyclones act as a straightening medium to change the centrifugal motion of the steam to a linear one. The number and size of the cyclones were so determined that the velocity of the steam leaving the top of them is too low to carry an appreciable

amount of moisture with the boiler delivering its maximum steam output. The corrugated elements used on the previous designs were retained in order to remove the final traces of moisture from the steam before leaving the drum.

This cyclone separator delivered steam having a conductivity of 1.5 micromhos until the water level in the gage glass was raised above the top of the cyclones. No appreciable effect on the amount of carry-over has been noted throughout a range of boiler-water concentrations up to 1573 ppm. Table 4 gives the data of five tests conducted on No. 6 boiler and three tests conducted on No. 2 boiler with this type of baffle. Corrections to the conductivity for dissolved ammonia were made only on the tests on No. 2 boiler.

The test data illustrated in Figs. 11 and 12 were obtained under abnormal conditions but present some interesting information. During these tests extreme changes in water level occurred; in one instance a 27-in. change in the gage-glass water level took place within one minute. The maximum gage-glass water level reached was $14^1/_2$ in. above the center line of the drum. After the cyclones had been flooded and the water level again lowered to their top, which is $6^1/_2$ in. above the center of the drum, the conductivity of the steam immediately decreased to 1.5 micromhos. The boiler-water concentration at the time this occurred was 1272 ppm. A high-rating test during which the water level was purposely varied was conducted. The results of this are shown in Fig. 12. With a steam flow averaging 500,000 lb per hr and a boiler-water concentration of 1215 ppm, the water level in the gage glass was raised as high as 5 in. above the center line of the drum and the average conductivity of the eight sampling points did not change from a value of 1.5 micromhos.

Fig. 13 presents data that were obtained on No. 2 boiler during normal operation. Under these conditions, after making corrections for pure water and for 0.07 ppm dissolved ammonia, the average conductivity of the steam during this test was 0.29 micromhos.

All of these tests have proved quite conclusively that the cyclone-separator baffle gives satisfactory results and permits a large operating leeway in rate of load change, in water-level variation, and in boiler-water concentration without jeopardizing satisfactory operation by increased carry-over or priming.

CONCLUSIONS

1 The importance of correct sampling and the use of a sufficient number of sampling points cannot be overemphasized. The variation in the conductance of the steam obtained from the eight sampling points, showed that the steam was not of uniform purity along the length of the drum at all times.

2 Determining of the dissolved-ammonia content in a condensed steam sample by nesslerization and comparison with a Hellige comparator, and correcting the conductivity of the steam sample by Rummel's correction curve were proved to be satisfactory methods of procedure.

3 The cyclone-separator baffle will deliver steam containing solids approximating 0.5 ppm with boiler-water concentrations up to 1600 ppm provided the drum water level is not raised above the top of the cyclones.

4 The cyclone-separator baffle permits a large operating leeway in rate of load change, in water-level variation, and in boiler-water concentration without jeopardizing satisfactory operation by increased carry-over or priming.

Discussion

MAX HECHT[4] AND D. S. MCKINNEY.[5] It appears that a highly efficient apparatus has been developed to accomplish a practically complete removal of the boiler water carried over in steam. It is gratifying to note that the author confirms the theory and principles which were presented by the writers[6] before the A.S.M.E. in 1930, as well as the independent work of J. K. Rummel.[7]

Inasmuch as it is obvious that the electrical conductivity testing procedure will replace the calorimeter method, and that there will be need for the preparation of a standard test code, it would be desirable for the author to present in his closure more complete detail of the testing procedure followed. The supplemental information desired should include the relative quantities of dissolved solids obtained by evaporation of both boiler water and steam to be used for comparison with the conductance of these

two fluids; complete analyses of the boiler water; chemical treatment, if any, of the boiler feedwater; blowdown of the boiler water, continuous or intermittent, and what per cent of feed; point of sampling of boiler water; and finally, comparisons of the Rummel and Powell procedures, if these were made during the extensive test runs. The writers pointed out in their paper[6] the necessity of correcting the conductance of condensed steam for the conductance conferred by CO_2, NH_3, and H_2S. They also discussed in detail the CO_2 and suggested a similar procedure for other conducting gases. (The technique of correcting for the conductance of gases has been patented by the writers.)

It is assumed that the boiler-water concentration is the result of chemical treatment. Furthermore, in this treatment, if sodium sulphite were employed for oxygen cleanup, the author might advise whether or not tests on the condensed steam showed the presence of sulphite. The ratio of sulphite in steam to that in the boiler water might help decide the question as to whether sodium sulphite is entrained as such in the steam, or whether it is evolved as the gas SO_2. If SO_2 is produced, this has conductance characteristics and the total conductance of the condensed steam must be corrected.

In the Colfax tests reported in 1930, sulphite was not used. With no evidence of ammonia in the steam at that time, the conductance was corrected for pure water and CO_2. Prior to 1933, the same procedure was employed at another station where, in addition to CO_2, NH_3 was found in the condensed steam. The NH_3 was eliminated from the samples under test by boiling as mentioned in the present paper.

If the relationship of conductivity to concentration has been determined by test, it would be most desirable if the author would furnish details of the evaporative procedure. Does the author conclude that the conductivity is a measure of the soluble ions or has he secured data to show that the silica, iron, and aluminum oxides have conducting characteristics?

The author stresses, as have the writers previously, the necessity of exact sampling. In 1924 while conducting tests at Colfax, data were secured throughout the length of a drum, showing conclusively that different concentrations existed along the drum.[8] After the 1930 tests at Colfax and before starting test work at other stations, it was recognized that the available sampling facilities required improvement. The late E. G. Campbell of Pittsburgh designed and installed sampling nozzles (patented) for securing representative steam and boiler-water samples from various points along the length of the drum. The inlet nozzle of the sampler offers a minimum resistance to the flow of steam. The various nozzles of either the steam or water sampler are connected within the drum to a single pipe via an orifice plate and thence to a single opening in the drum, the steam or water discharging into a cooling coil. This arrangement overcomes the reluctance of boiler manufacturers to provide sampling openings in the equipment. In the past this reluctance has caused the operators much grief in their attempts to diagnose water and steam conditions both with regard to carry-over and water conditioning.

In the present paper, the author has made a rather elaborate sampling setup for securing steam samples, but it is not clear whether the same extensive setup was made to secure boiler-water samples. To secure the correct ratio of conductance of steam to boiler water, it seems essential that the dependence should not be placed on a sample of boiler water taken from a single point in the drum or from the blowdown line connection, for it will be recognized from reference to Fig. 104[8] that the boiler-water concentration varies across the drum.

[8] "Corrosion, Causes and Prevention," by F. N. Speller, second edition, McGraw-Hill Book Company, Inc., New York, N. Y., 1935, Fig. 104, p. 423.

With the acceptance of the conductivity method by the operators as a test for determining carry-over accurately, it would appear that continuous records of steam quality are desirable. With the development of sampling equipment, it is possible to record the average of numerous points across the steam space of the boiler drum for both steam and boiler water. It is also possible to record the conductivities, respectively, on a conductivity recorder and to make the necessary corrections for the gases having conductance characteristics.

W. H. Rowand.[9] Cyclone separators similar to those described by the author have been installed in 21 boilers of the writer's company and are performing to the complete satisfaction of the operators. In every case they are giving results which confirm those of the author.

Several of the 1400-lb per sq in. pressure installations have been tested up to 1700 ppm boiler-water concentration. Two units in the 500 to 700-lb pressure range have been tested over 3000 ppm. Up to the present time, in no case has a limit of boiler-water concentration been reached. During the tests, the concentrations were not carried higher because the values attained were well above those generally expected to be encountered during operation. It was decided not to run the risk of possible damage to the superheater or to the turbine from carry-over or to the boiler tubes from scale.

As pointed out by the author, tests show that the actual water level in the drum is within 1 to 2 in. of that in the gage glass. The writer's tests indicate that the cyclone separators will deliver high-purity steam and prevent priming until they are practically submerged below the water level. This means that the gage-glass water level may be carried 5 in. or 6 in. above the center line of the drum without increased carry-over or priming.

Referring to Mr. Gurney's question as to whether cyclone separators increase the circulation of the boiler, the writer has had no direct experience as yet in this connection on cross-drum, sectional-header boilers. However, circulation tests have been conducted on one open-pass boiler and on one radiant-type boiler which show that the separators increase the circulating flow more than 40 per cent. This result is due to the action of the cyclone separator which not only separates the water from the steam but also the steam from the circulating water, thus furnishing "solid" water for the downcomers and producing the optimum circulating head. It is safe to say that, when a boiler design is such that steam is recirculated down through supply tubes or pipes, the installation of cyclone separators will increase the circulation by preventing the recirculation of steam in the downcomers.

M. C. Schwartz.[10] Similar work to that of the author has been carried out at the Louisiana Station of the Gulf States Utilities Company.

The problem may be divided as follows: (1) Design of steam-purifying equipment to prevent priming or excessive carry-over, with variations in operating conditions as drum water level, boiler-water dissolved-solids concentration, and boiler load; (2) design or comparison of steam-purifying equipment to improve the quality of the steam being delivered.

The pursuit of a solution to such a problem depends upon methods of estimating steam quality or carry-over. At present the most useful method, and the one followed by the author, is the determination of the electrical conductivity of the condensed steam, correcting for the presence, if necessary, of any soluble gaseous substances, as carbon dioxide, or ammonia, which form

[9] Service Department, The Babcock & Wilcox Company, New York, N. Y.

[10] Research Chemist, Louisiana Station, Gulf States Utilities Company, Baton Rouge, La.

electrolytes in solution. Thus far to the writer's knowledge, no method of collecting the condensed steam is available which will secure an ammonia-free sample. The correction for ammonia is troublesome. Its magnitude is likely to be such, in some instances, as almost to equal the total electrical conductivity of the sample.

However, the change in electrical conductivity of the condensed-steam sample, which is collected during priming, is so great that, under these conditions, the corrections for carbon dioxide or ammonia are quite small. The measurement of the carry-over which takes place during normal "satisfactory" operation is, on the other hand, very difficult, since it is likely to be minute. The solution of this latter problem to a satisfactory degree of accuracy is yet to be attained. Because of its commercial importance it should be pursued.

Author's Closure

The chemicals used for conditioning the boiler feedwater at the Springdale Station are disodium phosphate, caustic soda, and sodium sulphite. Boiler-water samples are obtained from two locations on each boiler; the supply line to the recirculating pump, and the center of the top waterwall header in the front of the boiler. The recirculating-pump supply is taken from the downcomer supplying the furnace walls which in turn takes water at points throughout the length of the drum. Consequently, a sample from this location is representative of the water in the boiler drum.

The steam-quality guarantee specifies that the impurities in the steam, as determined by the conductivity method, will not exceed 1 ppm of dissolved solids. The following procedure was used to obtain the conductance of 1 ppm of dissolved solids in the steam. The conductance of condensed steam was first determined; boiler water, equivalent to 0.5 per cent by volume, was added and the conductance of the mixture determined. The difference in micromhos of the two readings, after applying gas corrections, was the increase caused by the dissolved solids present in the added boiler water. This difference was divided by the number of ppm increase in concentration and the result was the conductance of 1 ppm. The conductance of 1 ppm as determined from each of the two boiler-water samples never varied more than 0.05 micromhos, in any one test, which confirms the correctness of the boiler-water-sampling procedure. The concentration of the boiler water was determined by evaporation in platinum.

The quantity of treated boiler water handled by the recirculating pump conditions the feedwater to give full economizer protection. Sodium sulphite has been used as an oxygen scavenger of boiler feedwater by the West Penn Power Company at intervals since 1923. The excess sodium sulphite in the boiler water is maintained at between 5 and 10 ppm. A special test to determine whether or not the sodium sulphite decomposed in the boiler was made as follows: The total boiler-water concentration was 451 ppm and the sodium sulphite content 5 ppm. Sodium sulphite was added in two charges by means of a chemical bottle located in a by-pass on the recirculating-pump discharge. It required 5 min to empty the bottle; the elapsed time for feeding both charges was 45 min. After the second addition of chemical, the boiler-water concentration was 699 ppm and the sodium sulphite was 169 ppm. Conductivity readings taken at each of the eight sampling points at 5-min intervals, before, during, and for 2 hr after adding the chemicals, showed no increase, not even the increase which normally would be expected from the higher concentration of boiler water.

The amount of ammonia present in the steam was seldom in excess of 0.10 ppm and in most of the tests it was between 0.02 and 0.05 ppm. At first there appeared to be no correlation between the amount of ammonia found and the gas correction as determined but, after extreme care was taken in making the Nesslers solution and in avoiding ammonia contamination from the atmosphere during the determination, reproducible results were obtained.

Fundamental Relationships in the Design of Cooling Towers

By G. RUSSELL NANCE,[1] LOS ANGELES, CALIF.

This paper presents a few theoretical considerations encountered when an attempt is made to correlate actual tower performance with that which may be predicted from thermodynamic considerations alone. The results of observed tests are correlated by means of empirical equations and sufficient material has been presented to enable the reader to check the performance of different types of towers with a fair degree of accuracy. A discussion follows in which information relative to the merits of various types of cooling systems is presented and suggestions are made as to the most economical type of tower to install.

THE USES OF cooling towers in conjunction with industrial cooling problems of all types have become so general that engineers are becoming more familiar with their importance in both old and new fields of industry. The body of this article deals primarily with a few of the more practical considerations relative to the selection of a tower and the determination of its principal dimensions. It is the author's hope that sufficient material will be presented to enable the prospective purchaser to analyze carefully his specific problem and to enable him to make an intelligent decision regarding the engineering and economics of selecting a tower.

When water is cooled atmospherically, one of the two following conditions exists:

(*a*) $t_w > t_{db}$

(*b*) $t_w < t_{db}$

where t_w = tower-water temperature; t_{db} = dry-bulb air temperature

Under nearly all conditions the wet-bulb temperature of the air t_{wb} is less than t_{db}, and represents the lowest value which t_w can approach. When the temperature of the water is greater than the temperature of the ambient air, as in condition (*a*), cooling occurs both by the evaporation of some of the water being cooled and by a heat transfer through convection, conduction, and radiation from the water to the air. Heat exchange by any or all of the last three processes is usually spoken of as sensible-heat transfer. When the temperature of the water being cooled is less than that of the ambient air, as in condition (*b*), cooling takes place by evaporation only, since the sensible-heat transfer is from the air to the water. Water may be cooled under condition (*b*) because the amount of heat extracted by evaporation is much greater than that which is added by sensible-heat transfer.

In order to predict the performance which may be expected under various operating conditions, several methods have been proposed for aiding the engineer in the coordination of the initial and final water temperatures and the wet-bulb temperature. The problem resolves itself into a measurement of the so-called "cooling head," or the atmospheric cooling effect, under a given set of conditions.

An interesting method of coordination has been derived from the Ferrel psychrometric equation by means of which the total cooling head H relative to a datum condition is expressed as

$$H = (P_t - P_{wb}) + 0.0115\,(t_t - t_{wb}) \quad [1]$$

where t_t is the water temperature, F
t_{wb} is the wet-bulb temperature, F
P_t is the water-vapor pressure at condition t_t, in. Hg
P_{wb} is the water-vapor pressure at the wet-bulb temperature, in. Hg

Physically, this equation represents the sum of the vapor-pressure difference between any two conditions of water and wet-bulb temperatures, or the evaporation effect, and the temperature difference for the same condition, or the sensible-heat effect. It is also representative of the relative cooling proportions between the evaporative and sensible-cooling effects.[2]

The cooling performances of similar towers may be compared by a factor representing the cooling efficiency E defined as

$$E = [(S_i - S_f)/(S_i - S_{wb})]100 \quad [2]$$

in which $S = P - 0.0115t$, the subscripts i and f refer to the initial and final water temperatures, respectively, and wb refers to the wet-bulb temperature. Increasing values of E represent closer approaches of the final water temperature to the wet-bulb temperature. The following values of E are obtained for water cooled under the conditions shown:

Case	t_i, F	t_f, F	t_{wb}, F	E, per cent
A	100	80	70	73.5
B	100	80	60	60.4
C	90	70	60	73.2

Cases *A* and *C* are conditions in which the temperature differences and approaches are equal. The approach is defined as the difference between the final water temperature and the wet-bulb temperature. In case *B* the temperature drop is equal to that of either *A* or *C*, but the approach is twice as large. Under actual test conditions it has been found that conditions *A* and *C* are harder to obtain than *B*, which would indicate that higher efficiencies represent cooling conditions more difficult to obtain.

As the wet-bulb temperature decreases, the efficiency relative to a fixed temperature range also decreases with a corresponding increase in the ease of cooling. Under such conditions it would appear that the lower the wet-bulb temperature, the greater would be the quantity of water which could be cooled atmospherically through a given range, or the lower the final water temperature which could be obtained if a constant quantity of water were circulated. This is not strictly true, for in practice it appears that in spite of the larger cooling potentials attendant with lower wet-bulb temperatures there is a portion of this energy difference which is not available for cooling. Thus the efficiency concept must be somewhat modified for operation in the lower wet-bulb ranges.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] "Water Cooling System Efficiency," by V. J. Azbe, *Mechanical Engineering*, vol. 46, 1924, p. 799.

Procedure in actual practice may be simplified by expressing the amount of cooling available under a given set of conditions as a function of the allowable water concentration per unit of deck (or tower) area which will produce these temperature conditions in actual tower performance. This empirical concentration factor may be expressed as a function of the cooling head after suitable modifications have been made to take into account physical characteristics of the tower and certain cooling discrepancies such as those noted in the preceding paragraph, although its use as a concentration factor is more convenient.

Fig. 1 illustrates a typical relation between concentration and temperature range. The curves represent constant approaches or values of $t_f - t_{wb}$. The differences between the initial and final water temperatures are expressed as ordinates, and values of the allowable water concentration C are shown as abscissas. These curves have been based on a 70-F wet-bulb temperature, but they may be referred to other wet-bulb temperatures by multiplying the values of C by K_{wb}, the values of which are shown in Fig. 2. A Fluor tower 12 ft wide and 35 ft high having 12 equally spaced horizontal decks was used in obtaining these curves.

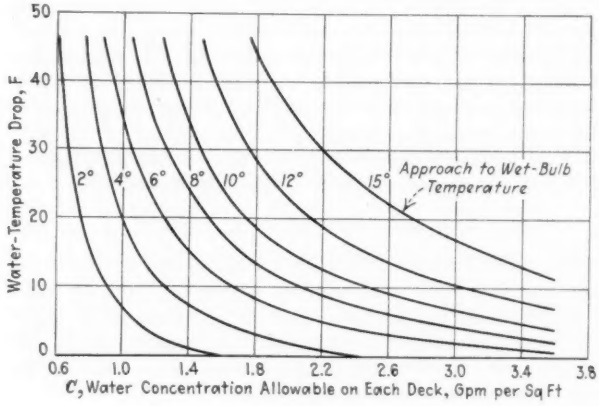

FIG. 1 COOLING-CAPACITY CURVES

(Values of water-concentration factor C plotted against drop in water temperature for various values of approach to wet-bulb temperature. Based on 12-deck tower, 12 ft wide × 35 ft high; wet-bulb temperature of 70 F; and wind velocity of 5 mph.)

An empirical method of determining the size of a tower is to consider the length L as

$$L = QDW/CA \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

in which Q = water circulated per unit of time, gpm
D = a design factor which varies with the physical characteristics of the towers
W = a factor which takes into account variations in wind velocity
C = water concentration, gpm per sq ft, Fig. 7
A = horizontally projected deck area corresponding to a unit of tower length, sq ft

A check on Equation [3] shows that it balances dimensionally since D and W are dimensionless factors.

The design factor D is used to correlate the relative effectiveness of towers of different widths, heights, and deck spacing. For a tower 12 ft wide and having a deck spacing of from $2^1/_2$ to 3 ft the factor varies with tower height approximately as shown in Fig. 3. Changes in width also affect the design factor, but not in any direct relation.

Fig. 4 shows the relation between tower length and wind velocity. It is at once apparent that it is quite important to select a wind velocity which is representative of the actual conditions existing at the proposed tower site. If too high a value is used, the tower will not be sufficiently large to cool the imposed heat load, while if the value is unnecessarily low, a tower larger and more expensive than actually warranted will be indicated.

For unobstructed locations and average conditions a 3-mph wind velocity is a safe figure to use, although Weather Bureau reports will usually show a 5-mph average. The values of C shown in Fig. 1 may be corrected to a 3-mph wind velocity by changing the abscissa scale by the ratio 1/1.25 as obtained from Fig. 4. The circumstances under which the plant is operating

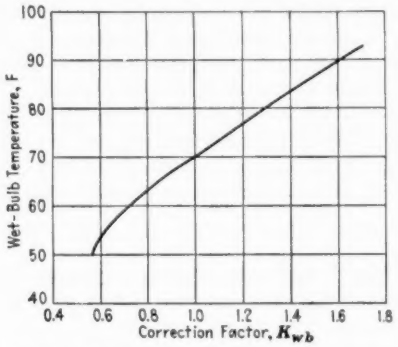

FIG. 2 WET-BULB CORRECTION FACTOR

(K_{wb} is used to correct the value of C in Fig. 1 to a wet-bulb temperature other than 70 F, $C_{wb} = C \times K_{wb}$.)

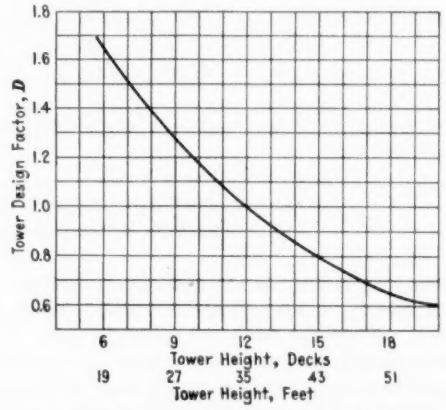

FIG. 3 DESIGN FACTOR, HEIGHT RELATION

(D is used to correct the values of C in Fig. 1 to tower heights other than 12 decks. Based on tower section 12 ft wide, having single-batten decks.)

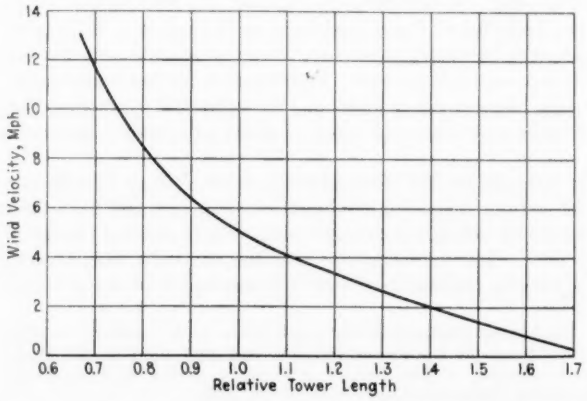

FIG. 4 VARIATION OF TOWER LENGTH WITH WIND VELOCITY

[Values of C in Fig. 1 can be corrected for other values of wind velocity by multiplying by (1/relative tower length).]

will in the last analysis decide whether an increase in tower size is justified by the savings resulting from a supply of lower-temperature water. Changes in wind velocity result in corresponding changes in the temperature range, providing the circulation remains constant.

The method of rating shown in Equation [3] is not only useful in determining the size of tower required for a given condition but also may be applied in other ways. Thus, if a tower of known size is available, the performance for a given water rate can be calculated. It is also useful in deciding whether a tower is meeting its guaranteed performance. It is very difficult to find the temperature ranges and wind velocities mentioned in tower specifications all occurring simultaneously. By this method suitable values are chosen for the atmospheric conditions, and the tower length, circulation, or temperature range can be checked against either of the other two variables. Solutions which satisfy the equation constitute a satisfactory check.

Fig. 5 has been included as a matter of interest to show the variation of temperature with height in a 20-section 12-deck tower. These data represent actual test conditions, and are indicative of the amount of heat removed from the water during various stages in the cooling cycle.

In specifying tower operating ranges, there should be borne in mind certain points, the application of which will result in more economical installations.

The size of a tower required to handle a given heat load varies with the performance required and care should be used in specifying the wet-bulb temperature, the approach of the final water

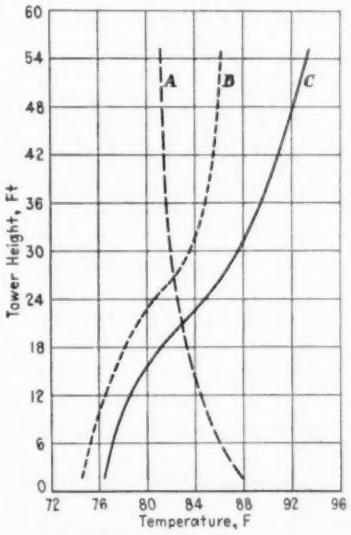

FIG. 5 TEMPERATURE RELATIONS BETWEEN AIR AND WATER AT DIFFERENT HEIGHTS IN A COOLING TOWER

(Curve *A*, temperature of entering air; curve *B*, temperature of leaving air; curve *C*, temperature of water in tower. Test on 12-deck vertical-louver (aerator) tower, 54 ft high. Wet-bulb temperature 73 F, wind velocity, 1.6 mph.)

temperature to the wet-bulb temperature, the quantity and temperature range of the water being circulated, and the wind velocity.

Plant operation is often dependent upon the maintenance of a fixed minimum water temperature, and care should be exercised in selecting the most economical vacuum to maintain, or temperature at which to operate equipment, if such flexibility is allowable.

It is generally preferable to base operation upon the worst atmospheric conditions experienced during the year in order that plant operation will not be impeded during the summer months when the wet-bulb temperature is the highest. This results in the selection of a larger tower than is necessary for operation during the winter months, but during this time the circulation may be decreased and a compensating economy effected.

Fig. 6 shows the relation between tower size and approach of the final temperature to a given wet-bulb temperature. It is apparent that as large an approach as is feasible should be used in order to keep the size of the tower within reasonable limits. In specifying operating conditions, an approach not less than 5 and preferably greater than 10 deg is recommended, depending upon the type of tower service.

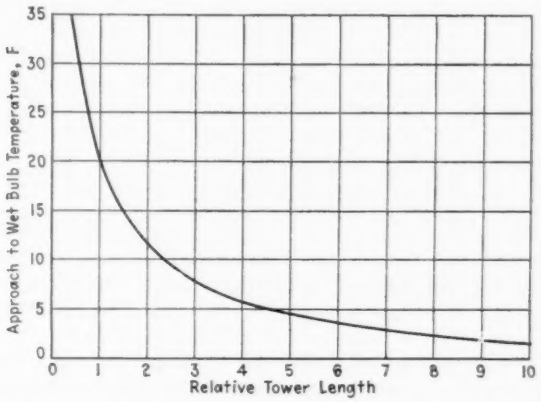

FIG. 6 VARIATION OF TOWER LENGTH WITH APPROACH TO WET-BULB TEMPERATURE

A calculation for a constant thermal load of 10,000,000 Btu per hr follows. Operating conditions make it undesirable to have more than a 25-deg or less than a 10-deg temperature drop.

The following selections could be made

$$\text{Gpm} = \frac{\text{Heat load, Btu per hr}}{\text{Temperature drop, F,} \times 8.33 \times 60}$$

Case	Solution	Gpm
1	10,000,000/25 × 8.33 × 60 =	800
2	10,000,000/20 × 8.33 × 60 =	1000
3	10,000,000/15 × 8.33 × 60 =	1333
4	10,000,000/10 × 8.33 × 60 =	2000

Table 1 shows the lengths of tower, 12 ft wide and 35 ft high, which would be required to handle these quantities, with the approach to the wet-bulb temperature and the wind velocity being constant.

TABLE 1

Case	Length, ft	t_i, F	t_f, F	Temp drop, F	t_{wb}, F	Approach, F	Projected area, sq ft	Wind velocity, mph
1	55.0	94	69	25	60	9	660	5
2	60.5	89	69	20	60	9	725	5
3	68.5	84	69	15	60	9	822	5
4	77.0	79	69	10	60	9	924	5

If the wet-bulb temperature were 65 F, the approach to the wet-bulb temperature would be decreased to 7 deg, making the final water temperature 72 F, and if the wet-bulb temperature were 70 F, the approach would be decreased to 6 deg, making the final water temperature 76 F. Fig. 7 further illustrates the relation between capacity, range, and tower size. These curves have been computed for conditions in which the wet-bulb temperature, approach of the final temperature to the wet-bulb temperature, and the wind velocity have been held constant. With the exception of the broken-line curve, these values have not been based on constant heat loads. In general, it may be

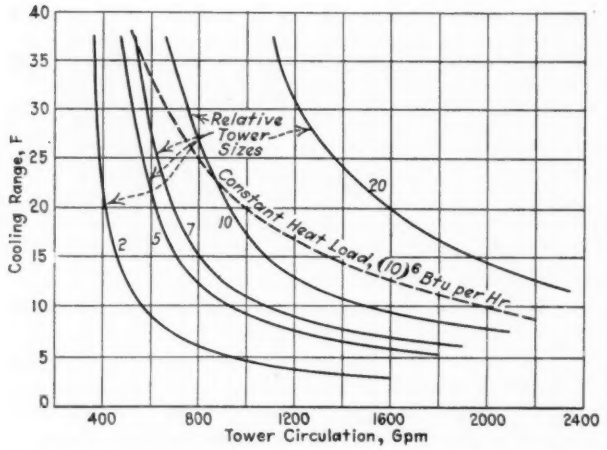

FIG. 7 COMPARATIVE TOWER SIZES RELATIVE TO WATER CIRCULATION AND COOLING RANGE
(Wet-bulb temperature, approach, and wind velocity constant.)

concluded that for the same heat load less tower is required for cooling a small quantity of water through a large temperature range than is required to cool a large quantity of water through a small temperature range.

In arriving at a final decision on a cooling system, it would be worth while to consider the relative economies of cooling ponds, spray ponds, and atmospheric and mechanical-draft towers.

Cooling ponds are generally economical to use only when a natural pond is available. If the required capacity is large, the initial cost will be high if any extensive excavation work is required, and since the cooling capacities of ponds are low per unit area, a more economical type of cooling system could be installed.

Spray ponds have a larger capacity per unit area than cooling ponds and frequently are used when a large amount of space is available and the temperature range through which the water is being cooled is small. As in the case of a cooling pond, the initial cost of a spray pond will usually exceed that of any type of cooling tower. In comparing a spray system with an atmospheric tower, it should be remembered that the pumping charges for the former will be about one half of those for a tower, and the prevailing power rates probably will determine which installation is the more suitable to install and operate over a given period of time. If a large temperature drop is required, respraying will be required, and the pumping charges will then be comparable to those of a tower. Modern mechanical-draft cooling towers have practically the same total pumping head as spray ponds when a low-head pressure-distributing system is used.

In the majority of cases an atmospheric tower will be an economical installation since its performance is dependable over a large range of conditions and the cost of maintenance is low. In selecting a site it will be necessary to place the tower broadside to the prevailing winds if the best performance is required.

As far as water cooling is concerned, tower height has little

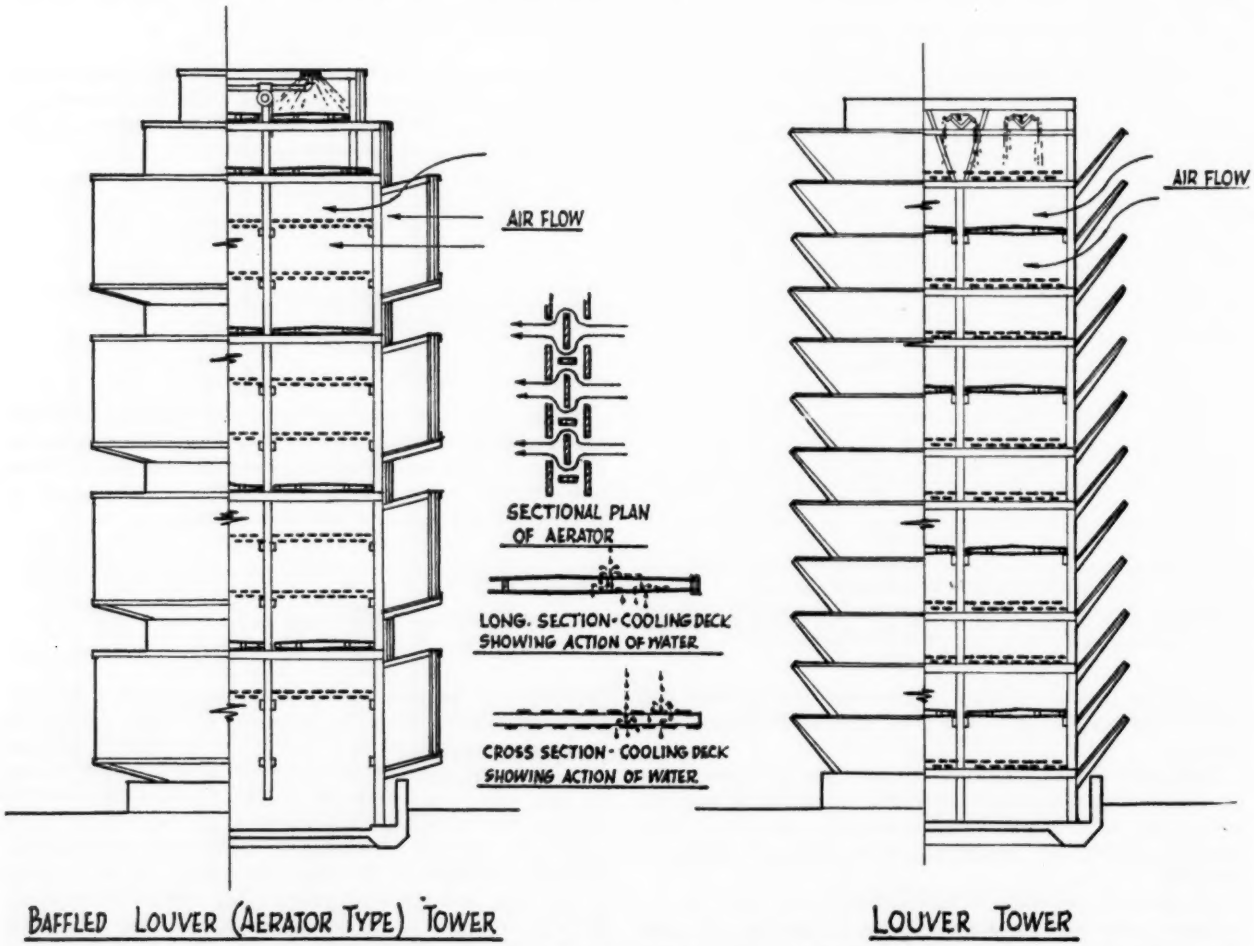

FIG. 8 SECTIONAL VIEWS OF TWO TYPES OF ATMOSPHERIC COOLING TOWERS

TABLE 2 COST COMPARISON OF ATMOSPHERIC COOLING TOWERS

No. of decks		12	15	18
Tower size, ft	length	108	84	66
	width	18	18	18

a Cost per 1,000,000 gal of water pumped.

effect, since the length is correspondingly increased according to the curve of Fig. 3 for towers having a given capacity.

In selecting the economical size of tower to install, a check should be made of the initial cost of towers and basins in comparison with the costs of pumping water over the towers.

Table 2 outlines a suggested method of comparison. In this study atmospheric towers of various heights have been selected to cool 3000 gpm from an initial temperature of 120 F to a final temperature of 90 F based on a wet-bulb temperature of 73 F and a wind velocity of 3 mph. An arbitrary power rate of 1 cent per kwhr has been selected, and it is assumed that the initial cost of the tower and basin will be depreciated over a ten-year period.

The values are applicable only in this case, and will vary for different cooling ranges, tower prices, and power rates. The cost of the make-up water required to replace that lost by evaporation and windage and the cost of chemically treating this water have not been included in the total cost per million gallons circulated since they would be approximately the same for each tower. The property value of the tower site has not been included because of the difficulty in assigning a reliable value. The conclusion may be drawn that high towers are most economical in so far as the initial installation is concerned, but that low towers are more economical to use over a period of years.

If water is very expensive, it would be worth while to select a type of tower from which little water is blown out by the wind. A windage loss as small as 0.5 per cent of the water being circulated will often exceed in value the original price of the tower within a few years. The water lost by evaporation is of course the same for any tower cooling water under the same conditions.

Forced- and induced-draft towers have a greater unit concentration than atmospheric towers, and because of this find a great application under conditions in which space is limited. A positive cooling effect is assured by the use of fans which force air through the tower, and when the wind is not blowing this is often of paramount importance in plant operation.

In comparing mechanical-draft towers with atmospheric towers, a tabulation of the same general type as shown in Table 2 may be used. In order to obtain a satisfactory comparison, the atmospheric tower should be based on a wind velocity of from 0 to 2 mph, since it is assumed that if the wind velocity were greater, an atmospheric tower would be less expensive to install and operate, providing the space were available.

In this comparison, it will be necessary to take into consideration the power requirement of the fan as well as that of the pump. Generally, the pumping head on a mechanical-draft tower will be less than on an atmospheric tower, so that the over-all power consumption on the former will not be as large in comparison as it would appear to be on casual inspection. Another compensating factor is that the price of a mechanical-draft tower is usually less than that of an atmospheric tower for the same capacities and cooling conditions.

An installation should be selected which will give the least total annual cost including both operating cost and fixed charges, and only a careful study of all the factors involved will show whether an atmospheric tower or forced-draft tower should be installed.

A sectional view of a 12-deck atmospheric type of tower is shown in Fig. 8 in which the arrangement of the distribution system, decks, and louvers has been outlined as in a typical installation. The performance of the louver and baffled-louver tower is the same in so far as cooling properties are concerned. The baffled-louver (aerator) tower, however, has a much lower windage loss than the plain-louver tower.

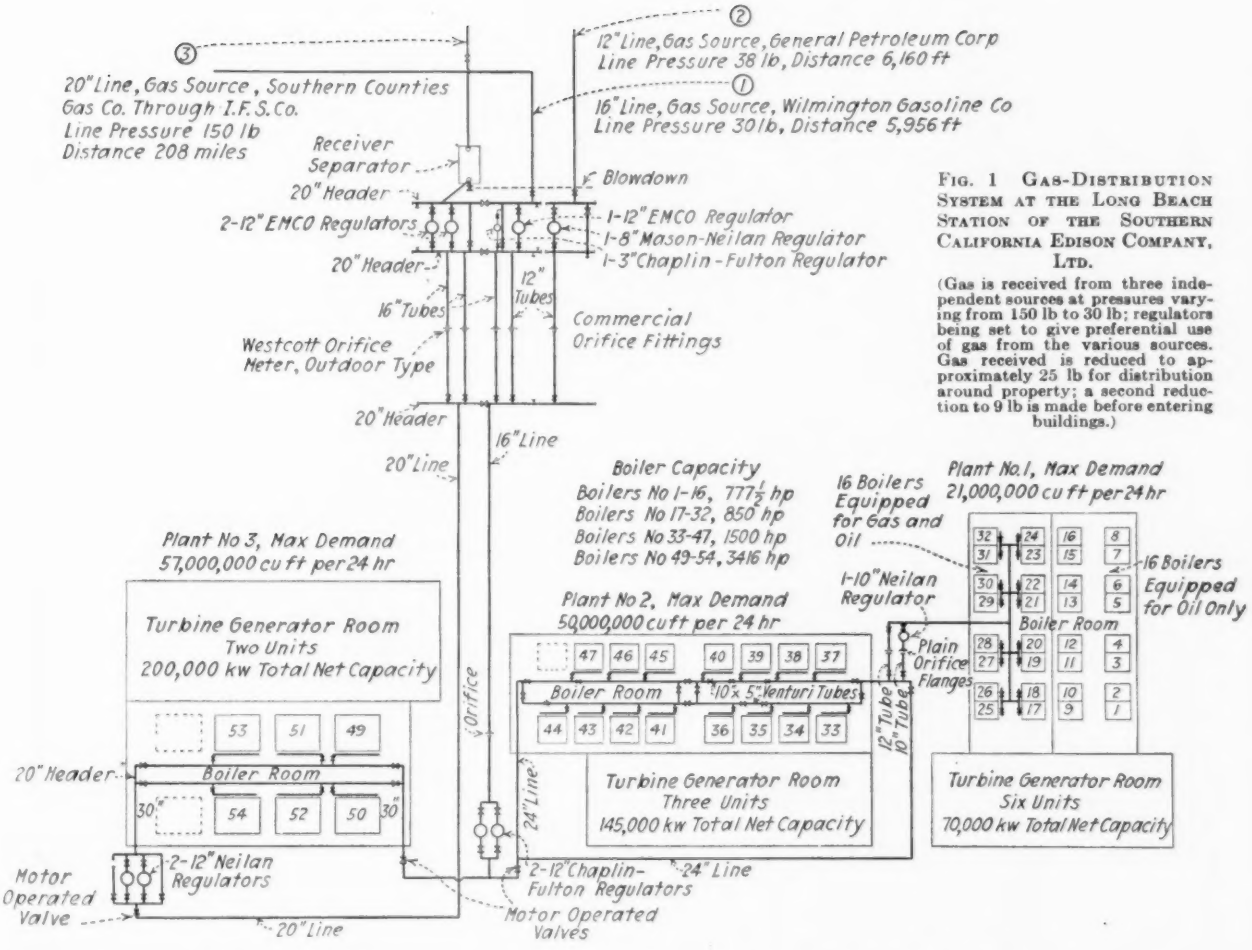

FIG. 1 GAS-DISTRIBUTION SYSTEM AT THE LONG BEACH STATION OF THE SOUTHERN CALIFORNIA EDISON COMPANY, LTD.

(Gas is received from three independent sources at pressures varying from 150 lb to 30 lb; regulators being set to give preferential use of gas from the various sources. Gas received is reduced to approximately 25 lb for distribution around property; a second reduction to 9 lb is made before entering buildings.)

Boiler-Plant Performance With Natural-Gas Firing

BY F. G. PHILO,[1] LONG BEACH, CALIF.

With its diversified operations, the Long Beach Steam Station of the Southern California Edison Company, Ltd., using natural gas as fuel has been required to solve many problems. The author presents the boiler-plant performance obtained with this fuel and outlines the methods and equipment adopted to give economic operation. A feature of this paper is the detailed instruction chart developed for the guidance of the boiler-plant operators. During the last fifteen years 120,000,000,000 cu ft of natural gas from three main sources have been burned in the installation. It is the author's opinion that a properly designed gas-piping system in the hands of competent operators probably presents fewer problems and no greater hazard than does the use of liquid or powdered fuels.

THE Southern California Edison Company, Limited is one of the world's largest consumers of natural gas as power-plant fuel. Beginning in 1922, considerable pioneer work was carried out at the Long Beach Steam Station and today 385,000-kw capacity at this station is equipped to utilize natural-gas fuel. The entire station capacity of 415,000 kw is equipped also for burning oil.

For many years base-load operation was customary. The economic depression of the last decade and the advent of Boulder Dam power made it highly desirable to operate as stand-by for emergency capacity. This change in basic function indicated certain alterations to be desirable in equipment and methods of operation, the most important being a method of burning minimum quantities of gas while being ready instantaneously to pick up and retain maximum station loads. Therefore, with its diversified operating requirements, the Long Beach Steam Station may be considered especially suited for study of the

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 1 LONG BEACH STEAM STATION, PLANT NO. 3; PROCEDURE FOR BRINGING UP THREE BOILERS FROM COLD STAND-BY CONDITION WITH GAS FUEL

(Crew, four experienced operators; time, 3 to 3½ hr)

Head fireman	Assistant head fireman	Third operator (fireman or fan man)	Fourth operator (fuel-oil or gas man)
1 Received request to fire up for load from both the switchboard operator and watch engineer at least 3 hr before steam is needed for turbine.			
2 Check boiler-header gas pressure. Water level in boiler glass should be 2 to 4 in. Close following switches for combustion control on rear of boiler panel: (*a*) Fuel drive; (*b*) DC for combustion control; (*c*) Interrupter switch.	If boiler is filled to vent, open main boiler blowdown valves to blow down tank until water is down to firing level. Open cold-air doors.	Open stack dampers; open induced fan dampers; close forced-fan dampers; water to induced-fan bearing; close switch on induced-fan combustion-control box. Check oil level in fan and motor bearings. Check oil glass in combustion-control box.	Constantly watch gas pressure to maintain 18 to 30 lb intermediate pressure and 9 lb boiler-header gas pressure by making necessary regulator adjustments and using proper orifice to give desired reading on charts. Check chart for operation, time, setting, and ink.
3 Start induced fan—allow to run 10 sec to vent furnace. Set chronometer valve at 2 by pointer.	Open burner register on Nos. 3, 7, 13, and 17 burners. See that all gas plug valves are closed. Light torch and insert in burner front; open plug valve.	See that: Nonreturn valve stem is up; all inspection and explosion doors on boiler and preheater are closed; all superheater drains are open; high-pressure drip valve at superheater outlet is open; boiler-drum vent is open; water-glass, water-column, and feedwater regulator drains are closed; check all boiler blowdown valves.	
4 Open main gas valve to ½ lb at burner. Open main gas valve and adjust gas pressure with chronometer valve. Note: When furnace is very cold from cold stand-by service, it may be necessary to run induced fan until temperature is raised in furnace and stack.	Light one burner at a time with torch.		Watch gas pressures and regulators.
5 See that boiler steam header and feedwater header valves are open and that steam header lines are drained. Notify watch engineer of boiler-room condition and ask him to take care of steam receiver drains on pump floor. Open auxiliary steam valve to fuel-oil system.	Watch fires and water in boiler.	When steam starts to blow from boiler-drum vents, close drum-vent valves and superheater drains. The high-pressure drip valve is to be left open. See that steam-inlet valve to Fisher reducing valve in steam line to fuel-oil room is closed. Inspect high-pressure traps of this line in sub-basement to see that condensate is being taken care of.	Watch gas pressure and regulators.
6 When steam pressure is sufficient to lift the nonreturn valve, and send steam to receiver, close boiler-header drain and check with watch engineer for receiver draining.	Watch fires and water in boilers. Check charts and instruments for operation, time, setting, and ink.		
7 Watch fires and water in boilers. Note: Notify pumpman when water is needed.	Assisted by third and fourth operators blow all Bailey walls about 1 min each to start circulation and to prevent water hammer.	Help assistant head fireman.	Help assistant head fireman.

8 Gradually put in 20 fires per boiler with induced-draft fan only and fuel at 1/2 lb pressure.	Close cold-air doors. Help head fireman.	Open forced-draft-fan dampers; start motor in forced combustion-control box; close preheater-hopper drains; check fan and motor bearings for oil level, ring movement, and water flow from jackets. Help assistant head fireman.	Watch gas.
9 Watch fires and water in boilers.	At 75-lb and 300-lb steam pressure, check over boiler equipment for leaks and tighten up on boiler-drum manheads.		
10 Watch fires and water in boilers.	Blow all water-glass, water-column, and feed-water-regulator drains. Watch fires and water in boilers.		
11 Supervision. Note: After unit is rolling, the fires are to be regulated according to steam demand and the pressure increase required to be at 410 lb gage when unit goes on line.	Watch fires and water in boilers. Open oil-inlet and oil-return valves on oil headers at boiler front. Regulate oil pressure and temperature by equalizing oil circulation on boilers.	Routin nspection of fan floors.	Prepare one fuel-oil pump to circulate oil through one heater on No. 10 side and one heater on No. 11 side by: Open suction valve at oil-service tank to be used; set return oil valve in position to return oil to tank or oil-suction line of tank being used; open pump suction to tank to be used; open pump discharge valves; open oil inlet to heater; open oil outlet from heater; open oil inlet and outlet valves on oil heat exchangers; open division valves between No. 10 and No. 11 fuel-oil rooms; see that main strainer valves are in proper position; open fuel-oil header-line valves at pipe gallery; start pump by push button (if pump does not pick up the suction, start the booster pump and let it run 2 min and cut out). Check air pressure for temperature control; open steam valve at heater; open steam valve at Fisher reducing valves and set low-pressure side at 50 to 75 lb; check over heater traps and see that trap discharges are turned to heat exchangers; see that water from detector tank goes to sewer until there is no evidence of oil leaks; then turn condensate to distilled tank. Adjust oil temperature to about 220 F at heater for oil circulation and at about 250 F for oil-burning operation. For oil-burning operation maintain 220 lb pressure at pumps. This is done at present by regulating with the low-pressure relief valve at oil-pump discharge. Note: Temperature adjustment is made by turning pointer on controller to right or left as directed on dial. Steam pressure is regulated by adding or taking off weights at Fisher reducing valve.
Note: Standard operating conditions for boiler output of 250,000 lb per hr or more should be approximately as follows: Water level 6 to 10 in. in glass; gas-header pressure, 8 to 9 lb; burner-gas pressure, 1 to 3 1/2 lb; CO_2, 9 to 11 per cent; steam-flow, air-flow pens should be together; steam temperature, 775 F maximum; boiler drum pressure, 455 lb maximum. All pressures and temperatures will vary as boiler output varies and approximate standard conditions may be determined from curve charts made from tests of boiler No. 50.	Note: When picking up load from natural draft conditions, feedwater supply and the boiler control should be operated manually until boiler reaches at least 225,000 lb of steam per hr. Amount of air used for combustion should be determined from amount of gas-fuel input rather than from steam output or air-flow-steam-flow pen relation on boiler meter, until boiler and furnace temperatures become sufficiently high to insure proper combustion at established ratios.	Routine inspection.	

general problems of boiler-plant performance with natural-gas firing.

Gas is received at the station from three independent sources; one from Kettleman Hills approximately 208 miles distant; and two additional sources from the Wilmington field directly adjacent to the plant. Due to price and contractual obligations, it is necessary to establish and maintain a definite priority of use from these three sources.

The schedule is automatically carried out by means of differentially set gas-pressure regulators as shown in Fig. 1. Regulator No. 1 is set to maintain downstream pressure at 30 lb per sq in.; regulator No. 2 at 23 lb per sq in., and regulator No. 3 at 18 lb per sq in. Thus, when all gas is being taken from source No. 1, regulator No. 1 will be wide open. As the plant demand increases the pressure will be reduced to 23 lb per sq in., at which point

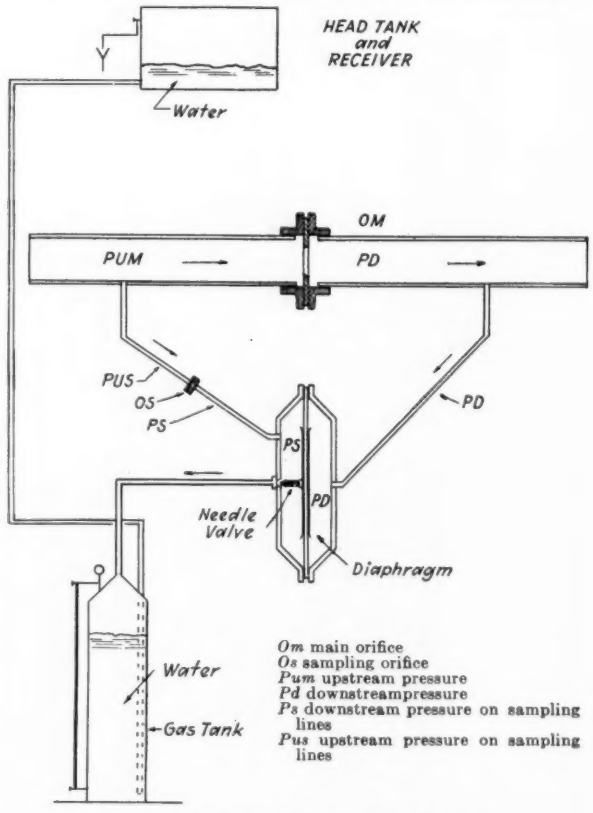

FIG. 2 THOMPSON PROPORTIONAL SAMPLER

(Sampler collects gas samples proportional to rate of use; samples used to determine specific-gravity and heating values which represent weighted average of fuel used.)

regulator No. 2 will open and gas will be taken from source No. 2. Similarly, when the full amount available from sources Nos. 1 and 2 is being used, the pressure will be reduced to 18 lb per sq in., and all additional requirements taken from source No. 3. These regulators are pilot-operated. With systematic care and maintenance they give accurate and dependable regulation. Before entering the boiler-room header, the pressure is further reduced to 9 lb per sq in. Each boiler is equipped with an individual header of its own branching off the main loop header below the boiler-room floor. Gas pressure in these individual boiler headers, Fig. 1, is regulated in plant No. 3 by chronometer valves which are operated automatically by a combustion-control system or manually if so desired. Plants Nos. 1 and 2 are controlled by manual operation only.

The standard procedure for firing these boilers is given in Table 1. This table is shown exactly as it appears in the "Station Standard Operating Methods" in order to illustrate the definite segregation of duties and the detailed instructions given. It has been found that detailed instructions of this kind tend to give a better understanding of operating problems to all concerned. They also, as illustrated, synchronize the duties of the various members of the operating personnel, each operation being done in its proper sequence, and each member of the crew having a thorough knowledge of what the others are doing. Careful preparation of such instructions and thorough drilling in their execution avoid confusion and enable the work to be done safely and with a minimum of supervision. The particulars of oil circulation for stand-by fuel are included, since it is felt that maintenance of a secondary fuel is a vital part of competent boiler operation with gas firing.

Natural gas is being purchased on a basis of heat content. This necessitates the measurement of the gas consumed in standard cubic feet and determination of the average Btu per standard cu ft. The gas volume measurement is carried out in accordance with the standard specifications and data based on results published in Gas Measurement Committee Report No. 2 of the American Gas Association. This report with its appendix gives a complete and authoritative summary of all the work in deriving the various factors involved and is universally accepted as standard throughout the gas industry. Consequently, although involving considerable detailed computations, the measurement of gas in standard cubic feet is clear-cut and well-defined. However, the translation into total Btu has presented some interesting complications. The station loading varies greatly during the day, and the heat content per cubic foot from the three independent sources is markedly different. In addition, the Btu per cu ft from any one source may fluctuate from hour to hour as much as 20 per cent.

In order to obtain the true weighted average Btu per cu ft for 24 hr of changing percentages of the different gases being used at widely different rates throughout the day, it has been necessary to build a proportional sampler. This sampler, based on a design by H. E. Thompson, is placed across an orifice through which the mixture of the three gases flows. It is constructed, as schematically shown in Fig. 2, to take a sample directly proportional to the flow through the main orifice.

The regulator is set to maintain *Ps* equal to *Pd*. Since the upstream pressures, *Pum* and *Pus*, are the same on the two orifices *Om* and *Os* and the downstream pressure on *Os* is maintained the same as *Pd*, the two orifices are subject to the same differential, and the flow of gas through orifice *Os* will be a constant small proportion of the flow through the main orifice *Om*. This small proportionate flow as it enters the sampler causes a displacement of the diaphragm which opens the needle valve and allows it to escape to the gas tank. This causes no change in pressure *Ps*, since the diaphragm is not restricted in its motion.

Samples are taken from the sampling tank by means of a rubber gas bag every 24 hr and run through the Thomas recording calorimeter, thus establishing the true average Btu per cu ft for the period. Proper care should be taken in this connection to include corrections for moisture in the fuel. Natural-gas calorimeters generally give Btu per cu ft of saturated gas. The gas as received and burned in the boilers is only partially saturated. The same sampling device is applied to the determination of true-average gravities for varying gas mixture. With these data and the steam pressure, steam and feedwater temperatures, and steam flow the station statistician is enabled to figure the true boiler performance and efficiency. Apparatus required for the determination of these quantities includes a recording calorimeter, recording thermometers, recording gravity balance, proportional samplers, orifice meters for gas, venturi meters for feedwater.

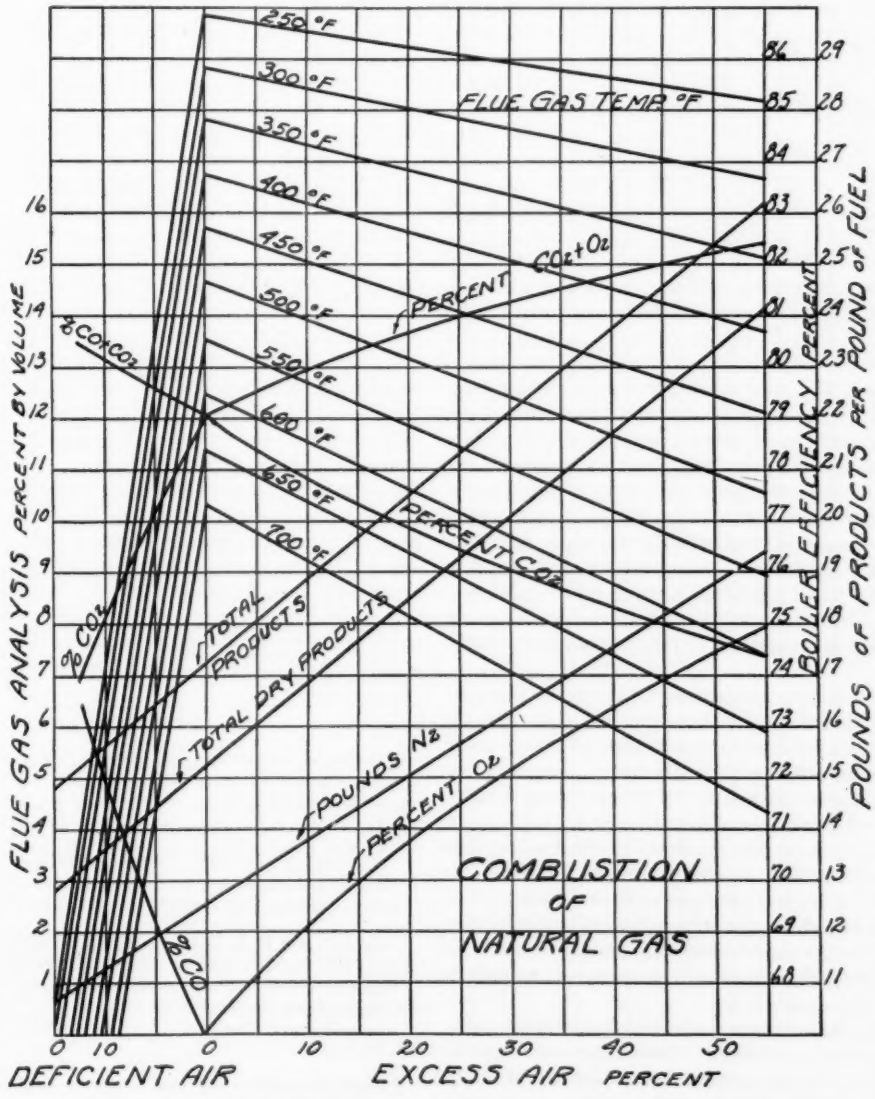

FIG. 3 COMBUSTION OF NATURAL GAS—PRODUCTS FORMED AND BOILER EFFICIENCY

(Analysis, per cent by volume: CH_4 = 79.230, C_2H_6 = 18.314, N_2 = 1.942, O_2 = 0.514; air temperature 70 F; higher heating value 22,458 Btu per lb, 1131 Btu per cu ft at 60 F and 14.696 psi; specific gravity 0.6584.)

In order accurately to evaluate the results thus obtained, it is necessary to give due consideration to the chemical constituents of the gas burned and their resultant combustion products and losses. Table 2 gives the analysis and combustion characteristics of a representative natural gas. Having these quantities and the specific heats of the various gases, it is possible to construct a graph such as Fig. 3, wherein the various known losses are subtracted from 100 per cent to give the theoretical heat-balance efficiencies for various values of excess air and flue-gas temperature. Such a set of curves permits an analysis of the relative importance of excess or deficient air and flue-gas temperature. It also establishes a standard with which reported efficiency may

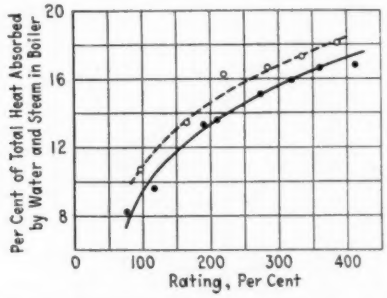

FIG. 4 COMPARISON OF TOTAL HEAT ABSORBED IN SUPERHEATER WHEN USING GAS AND OIL FUELS

be readily compared. Experience at Long Beach Steam Station has indicated actual efficiencies about 1 per cent lower than heat-balance efficiencies.

It should be noted in studying Fig. 3 that with the low flue-gas temperatures (300–350 F) that exist with the use of economizers and air preheaters that considerable increase in excess air has little effect on heat transfer efficiency. On the other hand, a deficiency of air causes losses to mount rapidly as shown on the left side of Fig. 3. Excess air losses however rise rather sharply when using the boiler alone without heat recovery equipment. Hence, although it is entirely possible with gas fuel to run with almost zero excess air and still attain complete combustion, it is considered good practice to operate with approximately 15 per cent excess air. This virtually obviates the possibility of slipping over into the deficient air range and CO in the flue gas with its resultant large losses.

Fig. 4 gives an interesting comparison of the percentages of total heat absorbed in the superheater when using gas and oil fuels. This boiler has a convection superheater. Consequently the heat absorbed is affected only by gas temperature and velocity passing the superheater tubes. With gas firing, at any rate of firing, there will be a larger volume of combustion products and, due to lower flame luminosity, relatively less heat absorption in the waterwalls and first bank of tubes than when firing fuel oil. Thus, flue-gas temperatures and velocities at the superheater will be higher with gas fuel and the quantity of heat absorbed in the superheater, as well as the superheated-steam temperature, will be higher. Obviously this relation will be reversed in boilers employing radiant-type superheaters.

Flexibility of performance and ease of control are two inherent advantages in the gas firing of boilers. These have been capitalized in the stand-by features of the plant No. 3 boilers at the Long Beach Steam Station. These 3416-hp boilers are operated with all twenty burners lighted, at outputs just sufficient to carry 1 per cent load on the main unit, and with the combustion-control mechanism in the "emergency" position. This emergency position requires manual starting of the forced- and induced-draft fans and selection of the "completely automatic" position on the control. The balance of bringing combustion up to full fire is entirely mechanical and requires 24 sec. Under test conditions, with two boilers being handled by each fireman, all boilers reached maximum fan speed and maximum fuel flow in 45 sec. The main turbogenerator units[2] accepted 85 per cent full load instantaneously, reaching full load in 5 min.

As shown in Table 1, the regular crew in plant No. 3 boiler room consists of only four men. These four men handle six boilers and related equipment furnishing steam to two 100,000-kw main units.

Operation of soot blowers is not required for gas fuel as burned in the stations described. However, soot blowers are installed and are used when burning oil.

Series 150 steel fittings, back-welded, are recommended for use in gas-piping systems.

The present installation is an outgrowth of a period in which gas from a source of very low line pressure, 15 lb per sq in., was available. In view of the present delivery of high-pressure gas only, future installations would be made delivering gas to the boiler room at not less than 25 lb per sq in., with consequent savings in size and cost of valves and fittings.

It is felt that orifices in the individual burner lines would allow the use of burners of ample gas-outlet areas and still restrict gas flow to a safe value in case of failure of local boiler gas-pressure controls. This control would be an individual reducing valve at each boiler, the setting for which would be regulated by the automatic-combustion-control system. Experience at Long Beach indicates the use of pilot-operated reducing valves of ample diaphragm area. The pilot mechanism may be located at a considerable distance from the reducing valve proper. It is highly desirable with parallel operation of reducing valves to have reducing-valve flow-pressure characteristics similar for all valves operating in conjunction with each other. These data are now available from the leading manufacturers of gas-control equipment. During the last fifteen years 120,000,000,000 cu ft of gas have been burned in the installation described above. A properly designed gas-piping system in the hands of competent operators probably presents fewer operating problems and no greater hazard than does the use of liquid or powdered fuels.

Power and Steam Plants for Oil-Refinery Service

By C. E. STEINBECK,[1] SAN FRANCISCO, CALIF.

This paper describes the general layout of the oil-company power plants, the various major items which will be used in their design, and the economy of the arrangement for both the Pacific Gas and Electric Company and the oil refineries.

THE DISCOVERY of oil in the lower San Joaquin Valley and in other sections of California approximately 40 years ago led to the establishment of oil refineries on the shores of upper San Francisco Bay. Some companies built pipe lines and others used ships and rail to transport the crude oil to the refineries, and the products of the refineries were shipped to all parts of the world by water and rail. As new and more efficient processes were developed and as demand for petroleum products increased, it became necessary to enlarge the refineries. This has required, from time to time, an increase in electricity for power and steam both for power and heat.

The increasing demand for steam and power at the refineries, together with the desire to increase operating efficiencies, led to a study of the question of whether to purchase these services or to build their own plants to supply them. It was found that the economies were in favor of purchased services and, hence, contracts which are similar for all companies, were made between the Pacific Gas and Electric Company and each of the following companies: Tide Water Associated Oil Company, Shell Oil Company, and Union Oil Company of California.

The Pacific Gas and Electric Company is constructing a steam-electric generating plant at the refinery of each company for the supply of steam and electric power. Since the steam plants are connected to the power company's transmission lines, no difficulty is presented due to unbalance in the electric and steam loads of the refineries. The quantities (for the three refineries) involved are approximately 20,000 kw maximum power demand, 120,000,000 kwhr per year, 875,000 lb per hr maximum steam demand, and 4 billion lb of steam per year. The power is delivered at 2300 volts and the steam at 160 psi with 50 F superheat.

The feedwater to the evaporators will be deaerated so that steam delivered to the refineries will be free of oxygen and CO_2. All water is furnished by the refineries with an allowance for blowdown depending upon the quality of the water.

A large natural-gas field has been developed a comparatively short distance from the sites of these plants and this supply, together with that from Kettleman Hills, will probably make natural gas the principal fuel.

Payment by the refineries for electric energy and steam will be made partly in cash and partly in fuel. This fuel may be fuel oil or refinery wastes such as sludges. The furnaces are suitable for the burning of petroleum coke as the use of this fuel is a future possibility.

Plant Design

Except for circulating-water supply, foundation conditions, and a few minor items, all plants will be the same. This will greatly reduce the engineering, construction, and operating costs. There are only a few miles separating the stations and as the Shell Oil plant at Martinez is centrally located between the Tidewater Associated plant at Avon and the Union plant at Oleum, the company's central office and plant shops will be located there.

Fig. 1 shows the general arrangement of the plant. Brick buildings will be erected to house the turbine, switch house, and control room. The boilers, evaporators, fans, water-softening equipment, and contact and deaerating heaters will be constructed for outdoor operation. The hot-air duct between the air heater and the burner front forms a roof over the firing aisle and by roofing over corresponding space between boilers, an enclosed firing aisle is obtained. The operating floors of the boiler firing aisle, the turbine operating platform, and that of the control room are all on the same level.

All panels necessary for operation of individual units, such as boilers, turbines, and pumps, will be located in the control room so that complete operation of the entire plant will be at one point. Automatic equipment will be installed wherever possible so that the operating personnel may be reduced to a minimum.

The design is such that changes which may be required by possible future conditions can be made. For example, should oil-refining processes change so that steam would no longer be required, a condensing unit would be installed to take the steam which is now extracted from the high-pressure unit for operation of the evaporators. On the other hand, should more steam be required, additional boiler, turbine, and evaporator capacity can be added.

Boilers

The nine radiant boilers to be installed, three at each station, are so called because, essentially, all the boiling or addition of latent heat is accomplished by the radiation of heat to the furnace walls. There is no conventional boiler convection bank, as the tubes between the furnace and the superheater are risers from a portion of the furnace waterwalls.

The units will have a maximum continuous capacity of 200,000 lb of steam per hr each, and a 24-hr overload capacity of 230,000 lb per hr. They are designed for a pressure of 1525 psi and a total steam temperature of 950 F at the maximum continuous steam flow.

The furnaces will be fired by natural gas, oil, and acid sludge through three combination burners arranged in a vertical row. Provision has been made for future firing with pulverized petroleum coke. Space has been allowed for pulverizers and piping to the burners which can be installed when necessary. The burners are so arranged that more than one of the fuels can be used simultaneously. For instance, when burning sludges, natural gas will be burned to support combustion and light the burners should some incombustibles be pumped to the burners.

[1] Assistant Engineer in charge of Steam Plant Design, Pacific Gas and Electric Company. Mem. A.S.M.E.

Contributed by the Power Division and presented at the Spring Meeting of The American Society of Mechanical Engineers, New Orleans, La., February 23–25, 1939.

Discussion of this paper closed March 25, 1939, and is published herewith directly following the paper.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

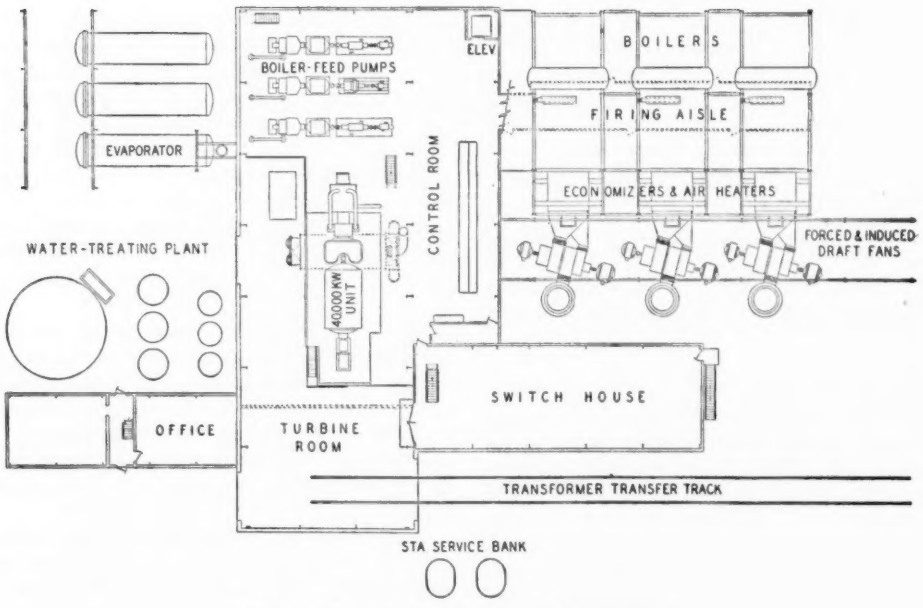

FIG. 1 GENERAL POWER-PLANT ARRANGEMENT

The furnaces are completely water-cooled and of stud-tube construction. The floors and the lower parts of the four walls are of fully studded tubes, and the upper portion of the furnaces of partially studded tubes. The fuels to be burned have so little ash that it was possible to design the furnaces with much simpler bottoms than is possible with coal-fired units for which special designs are necessary to provide for ash removal.

Each boiler has one forged steam-and-water drum, 60 in. ID, fitted with a steam scrubber to reduce the total solids carry-over in the steam to not over 1 ppm at all loads up to the designed capacity of the units, with a concentration in the boiler water of 1000 ppm

The boilers are designed to have just sufficient heating surface ahead of the superheaters to give them proper protection. The superheaters are pendant-type units and have sufficient surface to give 950 F total steam temperature at 100,000 lb output with gas fuel and 950 F at 150,000 lb with oil fuel. The metal in the superheater is grade C medium-carbon steel in the cooler section with special metal for the tubes and outlet header in the hotter portion to reduce the rate of oxidation and to provide the necessary creep strength for the pressure and temperatures involved. A gas by-pass of sufficient size to keep the superheat temperature down to 950 F at the top loads is provided along one side of the superheater. Automatic controls connected to dampers located in the gas stream behind the economizers will control the superheat temperature by causing gas to by-pass the superheater at the high loads. Quicker and safer starting up of the units will also be obtained by by-passing the superheaters to prevent overheating of the elements during the time no steam is being generated.

The by-passes around the superheaters are continued through the economizers. That section of the by-passes which parallels the superheater is formed by studded-tube water-cooled baffles. Economizer tubes with studs and plastic chrome ore form the baffles above the economizers.

The economizers are conventional horizontal water-tubular units, with gas flowing down across the tubes and the water entering at the bottom and flowing up through the tubes, and are designed so that they can steam at the high loads. The by-pass baffles cross all the economizer tubes so that the temperature of the water leaving all the tubes is as nearly uniform as possible. This insures good distribution.

Tubular air heaters have been located back of and below the economizers to permit washing the economizers, if necessary, and to provide better operating room between the air heaters and the burners.

These steam-generating units are designed to operate at 81.0 per cent efficiency and 9.0 in. draft loss through boiler, superheater, economizer, and air heater with natural-gas firing; 85.6 per cent efficiency and 12.8 in. with oil, and 88.3 per cent efficiency and 14 in. draft loss with pulverized petroleum coke at 200,000 lb of steam per hr at 1450 lb and 950 F total steam temperature at the superheater outlet. The efficiency given for petroleum coke does not include carbon loss. When the boiler is operating at a steaming rate of 200,000 lb per hr with gas fuel, the heat input per foot of furnace width is 23,000,000 Btu per hr. The equivalent release is 33,500 Btu per cu ft of furnace volume per hr. Fig. 2 shows the arrangement of boiler elements.

CONDENSER

The condensing equipment is designed to condense 300,000 lb of steam per hr with a heat surrender of 280,000,000 Btu per hr, giving a back pressure of 1.89 in. mercury abs when 37,500 gpm of water is circulated at 70 F, and 3.26 in. when inlet cooling water is 90 F.

The main condenser will have 18,000 sq ft of surface composed of $^{7}/_{8}$-in. OD, 18BWG tubes of 26 ft 0 in. over-all length. The water flow is single-pass and the water boxes and covers are divided so that half the tubes may be cleaned while the other half are in service. The tubes are roller-expanded at both ends. The tube sheet at the water-outlet end of the condenser is secured to the shell through a flexible-diaphragm expansion joint.

The tube-sheet layout of the condensers is of the double-folded type, each half an inverted U with a central exit lane to an air cooler, thus a short steam-flow path of low resistance is provided. Through the center of the entire length of the condenser shell is a V-shaped steam inlet passageway extending downward into the hot well and separated from the exit lanes by water seals between baffle plates. This arrangement permits accumulation

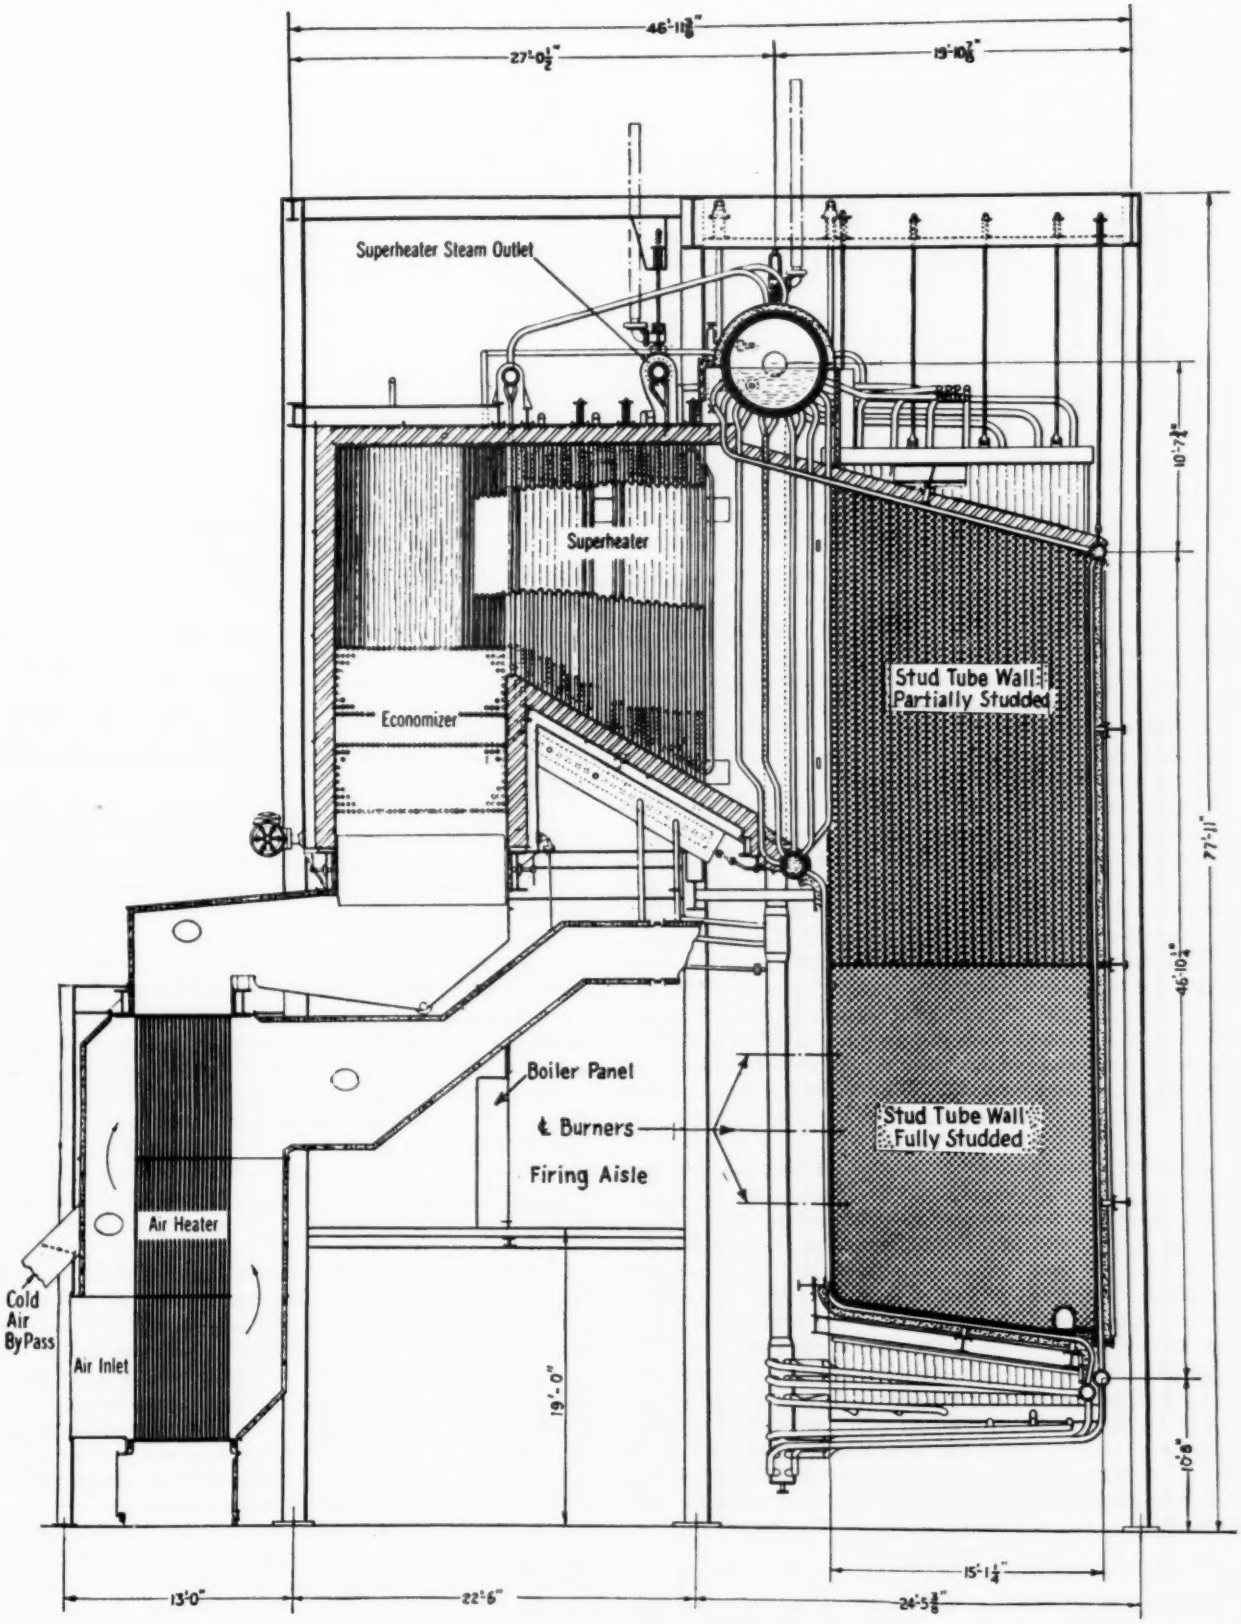

FIG. 2 BOILER ARRANGEMENT

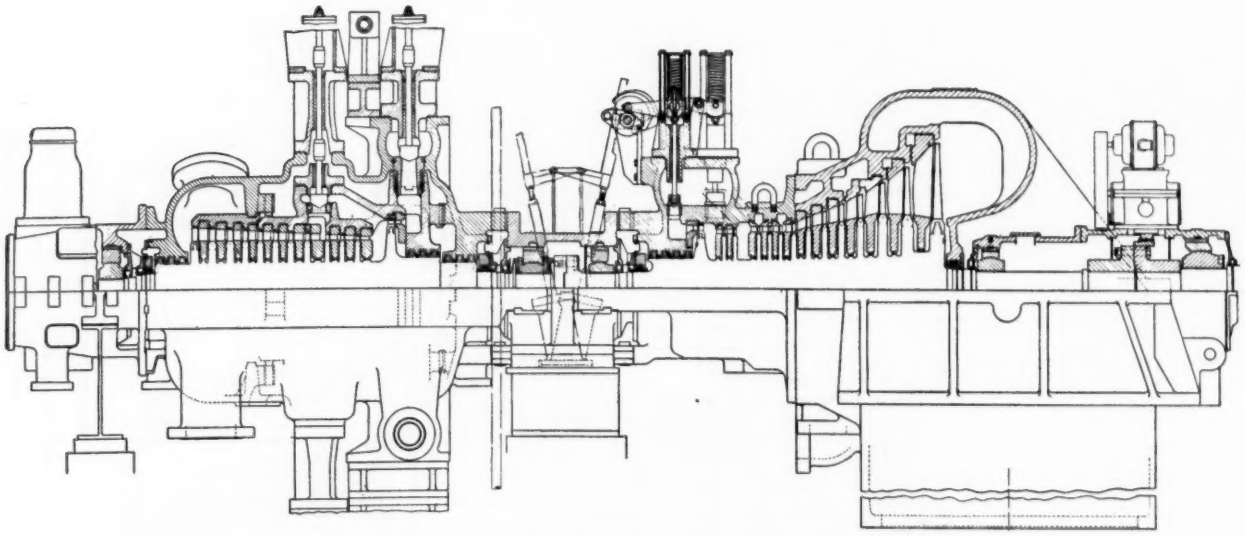

FIG. 3 TANDEM COMPOUND STEAM TURBINE

of pressure and temperature in the hot well for reheating of the condensate.

Under certain conditions, the unit will operate on stand-by service. At such times condensation of 15,000 lb of steam per hr and surrender of 15,000,000 Btu will serve to heat 300,000 lb of evaporator feedwater from 60 to 110 F at a pressure of 3 in. mercury abs. The heating of this water is to be effected in a four-pass heater having 1420 sq ft of surface made up of 242 tubes of same diameter and length as those in the main condenser. This heater will be located in the same shell but above the tubes of the main 18,000-sq-ft condenser. Between the heater and the main tube bank beneath, will be a diaphragm of shutter type at about 45 deg on each side of the condenser consisting of overlapping stainless-steel plates mounted upon shafts extending lengthwise of the shell parallel to but not coinciding with the center line of the plates. This will be counterbalanced to remain in closed position, separating the heater or stand-by section of the shell from the main or load-operation section of the shell during the usual stand-by operation until opened by predetermined pressure difference, thermostatic or load control, or combination of controls.

Air will be vented from the heater section to the main condenser section beneath. Condensate will be drained from the heater section through a conduit sealed deeply in the hot well at a point close to the hot-well pump suctions so that flashing may be avoided and the heat of condensate from the heater section at about 110 F conserved. Upon application of load, momentary rise in steam temperature within the heater to above 115 F will operate an automatic temperature control and cause the butterfly valves between the heater section and the main condenser section to open, thus placing the entire condenser in service. Liberal cutouts will be provided through the intermediate tube-supporting plates to permit free longitudinal distribution of the steam. A deaerating-type hot well of welded steel plate and of 300 cu ft volume is attached directly to the bottom of the condenser shell.

TURBINES

The turbine consists of a combination of high-pressure noncondensing 3600-rpm turbine, coupled to a single-flow 3600-rpm moderate-initial-pressure condensing machine. This turbine is arranged substantially as shown in cross section in Fig. 3. The inlet ends of the two machines are put together on either side of the middle bearing pedestal with the shafts solidly bolted together with forged-on couplings and the thrust bearing in between the two machines. The casings are anchored at the exhaust end of the condensing turbine nearest the generator, the middle pedestal slides guided by a center key, and the forward pedestal on the exhaust end of the high-pressure turbine is supported on a flexible cross member.

The governor is mounted on this forward pedestal and is driven by a worm gear on an extension of the exhaust end of the shaft of the high-pressure unit. The two hydraulic cylinders operating the inlet valves of the high-pressure turbine and the low-pressure turbine are both located and completely enclosed by the middle bearing standard between the two turbines, and the back-pressure governor and control mechanism are mounted on or alongside this pedestal.

The main exhaust of the high-pressure turbine is downward and the two auxiliary pipes leading into the inlet of the low-pressure turbine are from the upper half of the casing and over the top of the high-pressure unit down into either side of the nozzle chest of the low-pressure turbine. This arrangement simplifies the unit and greatly simplifies the foundation, provides ease of expansion in the piping, and results in less exhaust loss in the high-pressure unit, inasmuch as part of the steam is taken away directly from the upper half of the last-stage wheel and part of it from the lower half.

High-Pressure Unit. The high-pressure unit of this machine is of a double-shell internal-by-pass arrangement with the control-valve chests cast integral with the outer casing. This arrangement of the inner shell and outer shell is such that at full load, the pressure between the inner and outer shell is about 45 per cent of the steam pressure on the inside of the inner shell and the temperature about 75 F under the incoming temperature so that the outer shell is, therefore, subjected to quite low steam conditions and the inner shell which carries the high pressure on the inside is not subjected to a high pressure difference.

Primary control valves open until the full quantity of flow which can be passed by the machine in this condition is reached. The pressure drop through the first-stage nozzles is some 10 per cent and the temperature drop some 30 to 40 deg. After this load, additional flow can be passed, up to some 30 per cent, by opening the internal by-pass between the first-stage shell and the fourth-stage shell, lowering the first-stage shell pressure a sufficient amount to pass the additional flow, increasing the

pressure 25 per cent and increasing the temperature drop accordingly. In this way, initial boiler pressure and temperature never penetrate the machine further than the first-stage valve chest and nozzle parts, and the shells, wheels, and diaphragms are protected by the temperature drop incident to the flow through the first stage.

Low-Pressure Turbine. The low-pressure turbine is basically similar to the manufacturer's standard 20,000-kw 3600-rpm turbine. It is arranged with multivalve inlets for maximum economy, has a 20-in-long last-stage bucket shielded with stellite to prevent erosion, and is arranged in the low-pressure stages so as to extract heavier particles of moisture to improve efficiency

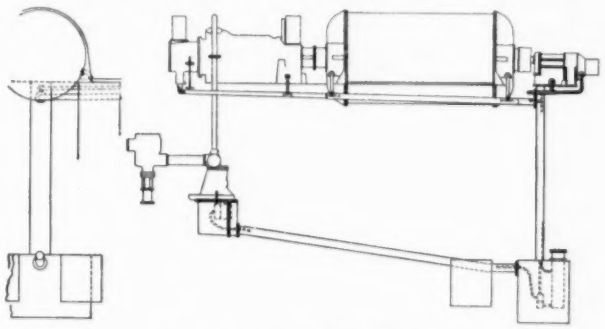

FIG. 4 TURBINE OILING SYSTEM

and reduce bucket and nozzle wear. The turning gear for the entire unit is incorporated on the exhaust-hood pedestal of this machine.

Oiling System. Fig. 4 shows the oiling system in schematic outline. The oil tank is located under the outboard-generator end of the turbine set and contains the coolers and the pumps. The high-pressure oil is conducted to the bearings and to the oil-operated hydraulic system by means of small pipes on the inside of the oil-drain returns from the corresponding bearings and hydraulic cylinders. In this way, no high-pressure piping is exposed and the fire hazard is reduced. The drive for the pumps is by a worm gear from an 1800-rpm shaft connected to the low-speed shaft of the reduction gear which drives an 1800-rpm exciter.

Governing. The governing of these extraction condensing turbines has been worked out, as was suggested by the engineers of the company in such a way as to permit controlling the high- and low-pressure turbines almost as though they were separate machines, i.e., the operation of the main controlling valves on the high-pressure section is controlled largely by the pressure in the exhaust of the high-pressure section with the back-pressure governor automatically reset by the pressure at the exhaust of the evaporators in such a way as to maintain the 180-lb pressure nearly constant. The controlling valves for the low-pressure section, on the other hand, are controlled by the speed governor and hence are responsive to the load requirements. In the event the load requirements are under the output of the high-pressure section when supplying the called-for steam, the high-pressure controlling valves are closed a corresponding amount. The governor of the low-pressure section is also so arranged as to permit holding these controlling valves open just sufficiently to supply cooling steam to the low-pressure turbine, to let no variation in the opening of these valves result from minor changes in frequency in the system, and yet to open the valves automatically to a predetermined limit in the event of a sudden reduction in frequency, i.e., a demand on the system for load from this unit. Various other safety factors are also being put into this governing system in order to insure that the combination will operate safely at all times.

Performance. The high-pressure turbine is designed for a maximum flow of 675,000 lb per hr and any part or all of this flow, with the exception of that required to cool the low-pressure turbine and the gland leakage, may be extracted. The operating back pressure is 240 lb abs. Under these conditions, the ouput is approximately 32,500 kw. The unit will also develop approximately 43,500 kw with zero extraction, i.e., with all of the flow passing to the low-pressure turbine but with this output there is a pressure rise in the exhaust of the high-pressure turbine above 240 lb abs. The unit will carry something in excess of 50,000 kw operating under certain extracting and condensing conditions.

Generator. The 50,000-kva generator will be hydrogen-cooled. There will be four water-cooled hydrogen coolers installed in the stator frame, two on each side. Oil seals will be provided and hydrogen-detraining apparatus will be provided for removal of the hydrogen from the oil. Hydrogen purity will be automatically maintained at 97 per cent.

Supervisory instruments will be installed either to indicate or

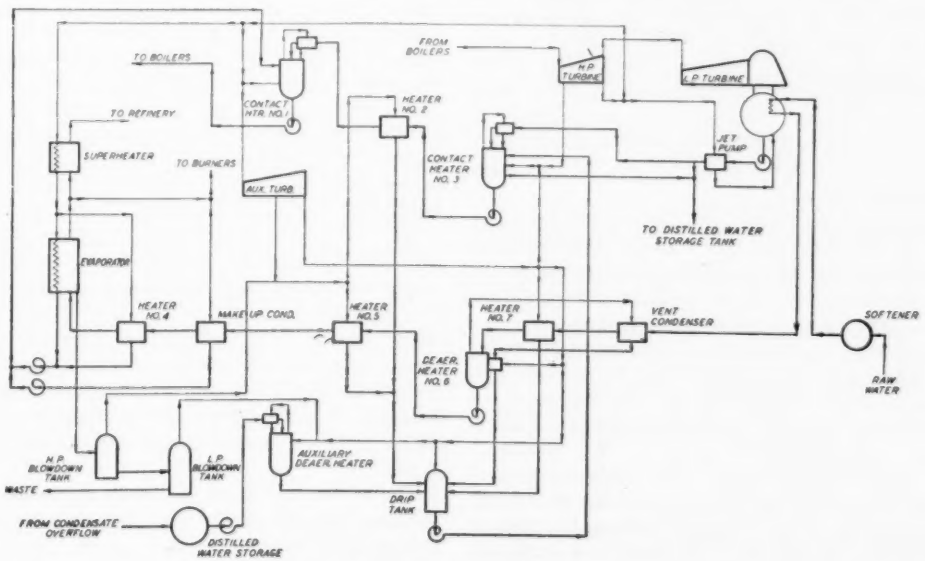

FIG. 5 FLOW DIAGRAM

record eccentricity, vibration, amplitude, expansion, and interference.

Flow Diagram

An examination of the flow diagram, Fig. 5, of the steam station will show that the high- and low-pressure steam cycles are kept separate. This was done in order to insure flexibility of operation and reliability of both the steam supply to the refineries and power output of the plant.

In the high-pressure steam cycle, the condensate after leaving the deaerating hot well of the condenser is pumped through the jet condenser to contact heater No. 3, through closed heater No. 2, and to contact heater No. 1. The pumps indicated at contact heaters Nos. 3 and 1 are the booster pumps and boiler-feed pumps. They are on the same shaft and are driven by an auxiliary turbine. Each auxiliary turbine has a capacity of 1675 kw and drives in addition to the pumps an induction generator of 1000 kw capacity. At light loads, the induction generator may be required to operate as a motor.

The water for the process-steam cycle is first treated by water softeners. At the Avon plant, the feedwater is of such a character that it first requires a lime pretreatment followed by a zeolite-and-acid treatment. At the Martinez and Oleum plants, a zeolite-and-acid treatment is all that will be required. After the water treatment, the process water passes through the feedwater-heating section of the condenser, heater No. 7, and then to deaerating heater No. 6. From heater No. 6, the evaporator-feed pump passes the water to the evaporators. The evaporator-feed pump and the evaporator-condensate pump are on the same shaft and are driven by a single motor.

The make-up condenser, as its name indicates, is used to furnish make-up to the high-pressure steam cycle. This will be regulated by throttling the steam supply to heater No. 5. The condensate from the make-up condenser will be pumped to contact heater No. 1. Provision is made so that, should this be more than the boilers require, condensate will be withdrawn at a point just beyond the jet condenser. An auxiliary deaerating heater No. 8 will be installed to deaerate the distilled water from storage, before it is returned to the high-pressure steam cycle.

Auxiliaries

Boiler-Feed and Evaporator-Feed Pumps. The boiler-feed pumps are divided into two units, a booster pump and the boiler-feed pump. These pumps are on the same shaft and driven by the same driver, as previously mentioned. The capacity of each booster pump is 350,000 lb per hr for a differential of 350 psi and that of the boiler-feed pump is 550,000 lb per hr for a differential head of 1500 psi. The maximum temperature of water to the booster pump will be 225 F and to the boiler-feed pump 400 F. The operating speed of the units is 3570 rpm and the power requirement 1870 hp.

Pumps from two manufacturers have been purchased. At Avon and Martinez, two horizontal split-case high-pressure units will be used. These are similar to those installed at station A, San Francisco. At these stations also will be one solid-case pump. At Oleum there will be three solid-case pumps.

The evaporator-feed pumps are likewise dual pumps driven by a single motor. There are three of these units for each station.

The main-evaporator-feed pumps will each be designed for a capacity of 300,000 lb of water per hr at a temperature of 225 F against a differential pressure of 225 psi gage. The maximum suction pressure will be 50 psi gage. The main-evaporator-condensate pumps will be designed for a capacity of 300,000 lb per hr at a temperature of 375 F against a differential head of 60 psi gage. The pump casings will be designed for a maximum suction pressure of 300 psi gage.

Evaporators. In all, ten horizontal evaporators were purchased for the three stations, four for Martinez and three for each of the other two stations. Each evaporator will have 7500 sq ft of heating surface and will produce 102,000 lb of steam per hr with a heat head of 17 F. The working pressures are 200 psi gage for the shells and 300 psi gage for the tubes. The evaporators are coil-type with welded steel shells, 9 ft diam × 40 ft long and tubes of arsenical copper.

Fans. A single combined forced- and induced-draft fan unit with both impellers mounted on the same shaft will be provided for each boiler. Each unit will be driven by either of two motors mounted on opposite ends, one of 400 hp, 900 rpm, and the other of 1000 hp 1200 rpm. Vane control is provided for each unit on both forced- and induced-draft sides. The forced-draft fan has a maximum capacity of 67,500 cu ft per min of 100 F air at 17.7 in. of water pressure and the induced-draft fan a maximum capacity of 134,000 cu ft per min of 430 F gas at 26.6 in. of water draft. The fans will be out of doors and at ground level.

Circulating Water. The condenser cooling-water supply at Avon will be pumped from a slough connected to upper San Francisco Bay. During the spring season when a large runoff occurs from the Sacramento and San Joaquin Rivers, the water will be fresh but at other times of the year the quality will vary from brackish to salt as the slough is subject to tide flow from the bay.

The Martinez station will be located on a hill some 100 ft above the level of the bay. As it would not be economical to pump bay water for cooling purposes, it has been decided to use a cooling tower, pumping only enough for cooling-tower make-up. This water will vary from brackish to salt.

The Oleum station will be located on the bay and there an ample supply of circulating water will be available. This water will also vary from brackish to salt.

Cooling Tower. A forced-draft cooling tower suitable for salt-water operation will be installed at Martinez. This will consist of 12 cells with a capacity to cool 37,500 gpm from 105 to 90 F with a wet-bulb temperature of 70 F.

Discussion

C. S. Smith.[2] The author describes a notable engineering and economic achievement resulting from the combined efforts of the respective managements of a power company and three oil refineries. His paper gives an interesting account of the advantages accruing on the side of the power and oil companies. From the viewpoint of the boiler manufacturer, the furnishing of nine essentially identical units presented an opportunity to install more efficient, high-pressure, high-temperature units than might have been feasible had the oil companies purchased independently and for their own specific needs. These units reflect the most recent progress in design and at the same time offer the advantages attendant upon a certain degree of standardization.

Of the various types of units available, the radiant boiler most satisfactorily and economically meets the customer's requirements in steam output, steam pressure, total steam temperature, and superheat control. At the same time it is capable of handling efficiently the multiplicity of fuels available. The total steam temperature of 950 F, which is among the highest in commercial use in this country, and superheat control down to one-half load, both of which were prerequisites, immediately eliminated from consideration many of the more conventional boiler types.

The author has briefly described the boiler and has shown a sectional side elevation. Comment on a few of the design details may be pertinent.

[2] The Babcock & Wilcox Company, New York, N. Y.

The various components of the boiler and furnace, such as the side walls, the two large outside downcomers, and inside risers while generally independent, are so integrally connected that the entire unit is suspended from overhead supports. As all pressure parts expand downward, the problem of providing for differential expansion seals and slip joints, is greatly simplified.

The water supply for the furnace walls and boiler is carried through two large vertical pipes leading one from each end of the steam and water drum, down the outside, to the bottom of the furnace waterwalls. Small tubes connect the lowermost portion of these downcomers to the various wall headers. The use of these outside supply tubes insures positive circulation and is simpler mechanically than their equivalent in small tubes.

The furnace wall surfaces and furnace volumes are designed especially for oil and gas fuel and are adequate for pulverized petroleum coke when the unit is operated at full capacity. This latter fuel necessitated a slight increase in the height of the furnaces, to insure proper combustion of the coke, maintain low carbon loss, and minimize the possibility of fouling the heating surfaces. Fully studded tube construction is used in the lower section of the furnace, where maximum protection is required and furnace temperatures must be relatively high to insure efficient combustion at all ratings with gas and oil. In the upper part of the furnace, where the service is relatively lighter and a higher heat-absorption rate is desirable, partly studded tubes are used.

The boilers will be equipped with the latest design of Babcock & Wilcox cyclone separators, a relatively new and important adjunct to modern high-duty boiler practice, and described in a paper by Baker.[3] The use of the cyclone separators, together with the steam scrubber, insures steam of the highest quality and purity known in commercial boiler operation. At the same time it permits wider fluctuations in water level without affecting steam quality, and promotes better circulation in the boiler by insuring that steam-free water enters the downcomers.

The nondrainable pendant superheater is entirely suitable for these units, as there will always be adequate time to bring a cold boiler to line pressure without overheating the pressure parts. Furthermore, there are no banking conditions that would cause condensation in the elements. Consequently, the desirable attributes of pendant superheaters, namely, simplicity of supports, accessibility of headers, and good steam distribution, are obtained.

The air heaters are provided with cold-air by-pass ducts from the forced-draft fan to the third air pass, to reduce the possibility of corrosion caused by condensation at the cooler ends of the tubes at reduced ratings. In other words, if the temperature of the cooler ends of the tubes were to fall below the dew point, moisture would collect, and this would form dilute sulphuric acid when high-sulphur fuels were burned.

Likewise, to prevent corrosion which might occur under these conditions where flue gases come in contact with cold steel, a portion of the casings for these units is made of a nonmetallic millboard that is resistant to such attack. These casings are also weatherproof. In conjunction with the arrangement of pressure parts, flues, and air heater, they render the boilers especially suitable for out-of-door service. By thus taking advantage of prevailing climatic conditions, it was possible to realize a substantial saving in the initial investment.

R. C. Vroom.[4] The author refers to the three combination burners to be used for firing each of the boilers. Each burner is designed for a heat liberation of 118,500,000 Btu per hr. With reference to the liquid fuels, the present method of atomization for sludge or oil will be steam although in the future the atomizers can be converted readily to mechanical atomizers of the wide-range type.

Fig. 6 shows a sectional elevation of the burners as they will be installed initially, without provision for handling pulverized fuels. Fig. 7 is a view taken from the furnace end of the burner as it will appear when assembled as a combined burner for liquid, gaseous, and pulverized fuels.

G. B. Warren.[5] The writer was privileged to work with the author and his associates in designing the turbine equipment to meet the requirements of these outstanding power plants and

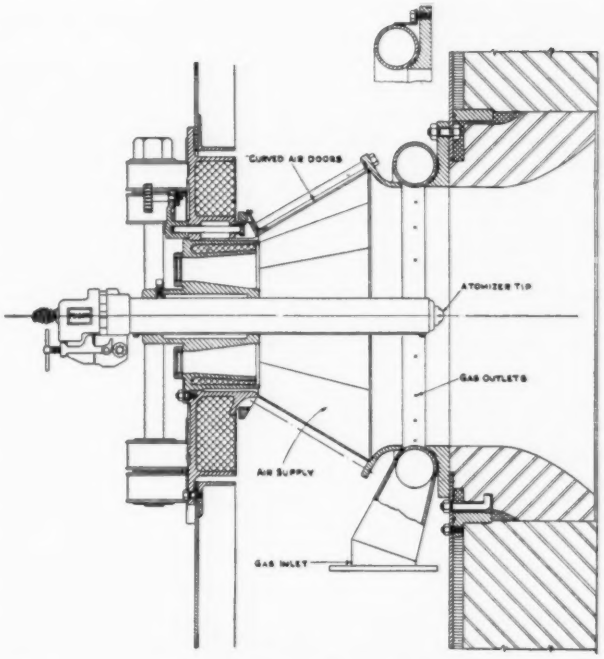

Fig. 6 Sectional Elevation of Burners Without Pulverized-Fuel-Handling Provisions

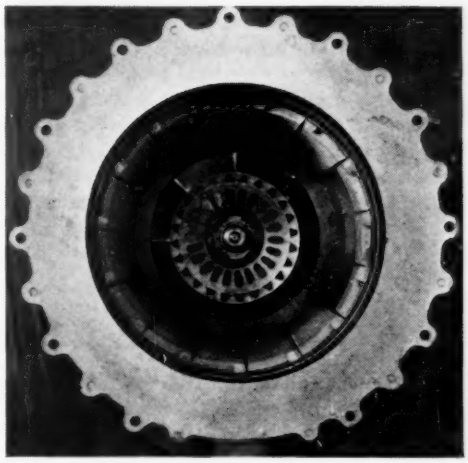

Fig. 7 Combined Burner for Liquid, Gaseous, and Pulverized Fuels

[3] "Mechanical Purification of Steam Within the Boiler Drum," by M. D. Baker, published in this issue of the Transactions, p. 711.

[4] Chief Engineer, Peabody Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

[5] Designing Engineer, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

is, therefore, familiar with the thoroughness and care with which every detail was developed by them.

In the writer's estimation, the success of these newly installed high-pressure, high-temperature power plants, together with the excellent record of the pioneer plants of this type, one of which was installed by the Pacific Gas and Electric Company, has created opportunities not heretofore possible in the construction of power plants for the purpose of furnishing low-grade heat and power as a joint undertaking. Condensing power plants of necessity waste the heat in the exhaust. Where such heat is needed and can be used, it offers the opportunity of obtaining large quantities of power at almost one hundred per cent thermal efficiency.

There is a keen realization of the difficulties which lie in the path of those who seek to apply these principles, because of the many conflicts in the demands of the industry for heat and the demands of the utility for power, together with the risks involved for the utility when its fortunes are tied up with an industry over which it has no control.

This matter was given very careful consideration in the installation under discussion. The risk to the utility was reduced to a minimum by the addition of the condensing element which permits operation of the complete set fully condensing at full power. Although this can be done only at a somewhat lower efficiency, yet, because of the high pressure and high temperature, the efficiency of the condensing set, when so operating, will compare very favorably with many quite modern condensing power plants now in operation.

Methods of Rotor-Unbalance Determination

By J. G. BAKER,[1] EVANSVILLE, WIS.

Rotor-unbalance determinations both in balancing machines and from vibration readings taken on the rotor during normal operation have in some cases been rather complicated and often subject to considerable error. This paper suggests methods intended to improve balancing methods in these cases.

In part I a more or less conventional method of calculating unbalance corrections from vibration readings is reviewed and the limitations and errors pointed out. Next, an extension of the method is developed which is in some cases simpler and inherently more accurate.

In part II a mathematical method is developed for determining unbalance corrections in cases where the locations of the corrections are completely prescribed in contradistinction to the ordinary case in which the axial position of the correction is prescribed but the angular position is to be determined. Also, a balancing machine is described which reads directly the unbalance corrections required at four preselected locations in a rigid rotor. This balancing machine is especially suited for the quick determination of unbalance corrections required in an internal-combustion-engine crankshaft.

In part III center-of-percussion balancing is described which is a method of taking vibration readings which can be interpreted directly in terms of unbalance. This method is applicable only under certain conditions which are noted.

PART I—CONVENTIONAL AND TRIAL-WEIGHT-GROUP METHODS

Introduction

FROM TIME to time methods have been described for determining unbalance corrections from vibration readings made with and without trial unbalance.[2,3,4] All of these methods are fundamentally the same and are based on the assumptions (1) that the system to be balanced is linear or nearly so and (2) that the unbalance remains constant except when deliberately altered by weights added or subtracted. With some systems one or both of these assumptions apply only roughly. The errors in the corrections determined from vibration readings in such cases are especially large if the vibrating system of the machine and the correction locations are selected, as is apt to happen, such that the determination involves the difference between large quantities. If this is the case the computed unbalance correction may be so inaccurate that the vibration of the machine is actually increased by it instead of being decreased.

Derivation of the Usual Formula

In Fig. 1 is shown a rotor supported in three bearings. The object of balancing is to eliminate vibration at each of these bearings. Correction locations are chosen at 1, 2, and 3. The three bearing pedestals on which vibrations are read will be designated as A, B, and C, respectively. The trial weights to be used in 1, 2, and 3 are w_1, w_2, and w_3, respectively. The unbalance component in 1 is W_{I}, that in 2 is W_{II}, and in 3 is W_{III}.[5] The vibration at pedestal A will be represented by the projection of the vector A, the vibration at the B pedestal will likewise correspond to the projection of the vector B, and that at C to the projection of the vector C. A subscript will be used to denote the cause of the vibration or increment in vibration. Thus, A_0 is a vector corresponding to the initial vibration at A; A_1 is a vector corresponding to the vibration at A due to the initial unbalance W_{I} only; and A_{01} is a vector corresponding to the vibration at A after adding the trial weight w_1 to the machine in its initial condition, that is, with W_{I}, W_{II}, W_{III}, and w_1 all present. A_1 is a vector corresponding to the increment in the vibration at A due to adding the trial weight w_1; thus

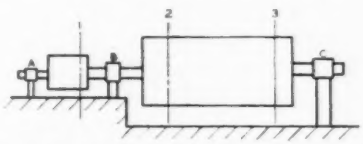

Fig. 1 Three-Bearing Rotor With Correction-Location Planes Indicated

$$A_1 = A_{01} - A_0$$

From the assumed linearity of the system

$$\left.\begin{aligned} A_0 &= A_{\mathrm{I}} + A_{\mathrm{II}} + A_{\mathrm{III}} \\ B_0 &= B_{\mathrm{I}} + B_{\mathrm{II}} + B_{\mathrm{III}} \\ C_0 &= C_{\mathrm{I}} + C_{\mathrm{II}} + C_{\mathrm{III}} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [1]$$

Furthermore, A_{I} and A_1 are related in the same way as W_{I} and w_1 so that

$$A_{\mathrm{I}}/A_1 = W_{\mathrm{I}}/w_1 \quad \text{or} \quad A_{\mathrm{I}} = (W_{\mathrm{I}}/w_1)A_1 \ldots\ldots\ldots [2]$$

In which the product of two vectors is taken to mean a third vector, the angle of which is the sum of the angles of the two factors and the absolute magnitude of which is the product of the absolute magnitudes of the factors. Likewise the quotient of two vectors is taken as the difference between their angles and the quotient of their absolute quantities. Corresponding to Equation [2] A_{II} may be expressed as

$$A_{\mathrm{II}} = (W_{\mathrm{II}}/w_2)A_2 \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

and

$$B_{\mathrm{I}} = (W_{\mathrm{I}}/w_1)B_1 \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

Contributed by the Applied Mechanics Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, New York, N. Y., December 5–9, 1938.

Discussion of this paper was accepted until January 10, 1939, for publication at a later date.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[5] All terms appearing in the equations in this paper are vector quantities.

Using all the relations of the class of Equations [2], [3], and [4], Equation [1] may be rewritten

$$\left.\begin{aligned} A_0 &= \frac{W_{\mathrm{I}}}{w_1}A_1 + \frac{W_{\mathrm{II}}}{w_2}A_2 + \frac{W_{\mathrm{III}}}{w_3}A_3 \\ B_0 &= \frac{W_{\mathrm{I}}}{w_1}B_1 + \frac{W_{\mathrm{II}}}{w_2}B_2 + \frac{W_{\mathrm{III}}}{w_3}B_3 \\ C_0 &= \frac{W_{\mathrm{I}}}{w_1}C_1 + \frac{W_{\mathrm{II}}}{w_2}C_2 + \frac{W_{\mathrm{III}}}{w_3}C_3 \end{aligned}\right\} \quad \ldots\ldots [1a]$$

Since the angle of W_{I}/w_1 is the angle by which W_{I} exceeds w_1 and since its magnitude is the ratio of the absolute magnitude of W_{I} to that w_1 it is the result sought. It is the expression for the unbalance at 1 or the negative of the correction required at 1. Similarly, W_{II}/w_2 and W_{III}/w_3 are the results sought at 2 and 3, respectively. Equation [1a] may be solved for W_{I}/w_1, W_{II}/w_2, and W_{III}/w_3 by means of the rules of determinants thus if

$$\Delta = \begin{vmatrix} A_1 & A_2 & A_3 \\ B_1 & B_2 & B_3 \\ C_1 & C_2 & C_3 \end{vmatrix} \quad \ldots\ldots [5]$$

Then

$$\frac{W_{\mathrm{I}}}{w_1} = \frac{\begin{vmatrix} A_0 & A_2 & A_3 \\ B_0 & B_2 & B_3 \\ C_0 & C_2 & C_3 \end{vmatrix}}{\Delta} \quad \ldots\ldots [6]$$

$$\frac{W_{\mathrm{II}}}{w_2} = \frac{\begin{vmatrix} A_1 & A_0 & A_3 \\ B_1 & B_0 & B_3 \\ C_1 & C_0 & C_3 \end{vmatrix}}{\Delta} \quad \ldots\ldots [7]$$

$$\frac{W_{\mathrm{III}}}{w_3} = \frac{\begin{vmatrix} A_1 & A_2 & A_0 \\ B_1 & B_2 & B_0 \\ C_1 & C_2 & C_0 \end{vmatrix}}{\Delta} \quad \ldots\ldots [8]$$

For a system of n locations at which it is desired to eliminate vibration, n correction locations are required. Corresponding to Equations [1a] there would be a system of n equations each with n right-hand members. Corresponding to the three formulas [6], [7], and [8], there would be n formulas each with the same nth order determinant for a denominator and each with its own nth order determinant for a numerator. Referring to formulas [6], [7], and [8], if the determinants are multiplied out the following equations are obtained

$$\frac{W_{\mathrm{I}}}{w_1} = \frac{A_0(B_2C_3 - B_3C_2) - B_0(A_2C_3 - A_3C_2) + C_0(A_2B_3 - A_3B_2)}{\Delta} \quad \ldots\ldots [9]$$

$$\frac{W_{\mathrm{II}}}{w_2} = \frac{-A_0(B_1C_3 - B_3C_1) + B_0(A_1C_3 - A_3C_1) - C_0(A_1B_3 - A_3B_1)}{\Delta} \quad \ldots\ldots [10]$$

$$\frac{W_{\mathrm{III}}}{w_3} = \frac{A_0(B_1C_2 - B_2C_1) - B_0(A_1C_2 - A_2C_1) + C_0(A_1B_2 - A_2B_1)}{\Delta} \quad \ldots\ldots [11]$$

$$\Delta = A_1(B_2C_3 - B_3C_2) - B_1(A_2C_3 - A_3C_2) + C_1(A_2B_3 - A_3B_2) \quad \ldots\ldots [5a]$$

In a similar way for a two-bearing case or in a case in which it is desired to reduce the vibration at only two bearings, the two equations corresponding to [9], [10], and [11] are
